Foreword

The Intergovernmental Panel on Climate Change (IPCC) was jointly established by the World Meteorological Organization and the United Nations Environment Programme in 1988, in order to (i) assess available scientific information on climate change, (ii) assess the environmental and socioeconomic impacts of climate change, and (iii) formulate response strategies. The IPCC First Assessment Report was completed in August 1990, and served as the basis for negotiating the UN Framework Convention on Climate Change. The IPCC also completed its 1992 Supplement and "Climate Change 1994: Radiative Forcing of Climate Change and an Evaluation of the IPCC IS92 Emission Scenarios" to assist the Convention process further.

In 1992, the Panel reorganized its Working Groups II and III and committed itself to complete a Second Assessment in 1995, not only updating the information on the same range of topics as in the First Assessment, but also including the new subject area of technical issues related to the economic aspects of climate change. We applaud the IPCC for producing its Second Assessment Report (SAR) as scheduled. We are convinced that the SAR, as the earlier IPCC reports, would become a standard work of reference, widely used by policy-makers, scientists, and other experts.

This volume, which forms part of the SAR, has been produced by Working Group II of the IPCC, and focuses on potential impacts of climate change, adaptive responses, and measures that could mitigate future emissions. It consists of 25 chapters covering a wide range of ecological systems and socioeconomic sectors and activities. It also includes brief descriptions of three appendices—two sets of guidelines or methodologies for assessing the potential efficacy of adaptation and mitigation strategies, and an inventory of technology databases and information. The appendices themselves have been or are being published in full as separate stand-alone volumes.

As usual in the IPCC, success in producing this report has depended upon the enthusiasm and cooperation of numerous busy scientists and other experts world-wide. We are exceedingly pleased to note here the very special efforts implemented by the IPCC in ensuring the participation of experts from the developing and transitional economy countries in its activities, in particular in the writing, reviewing, and revising of its reports. The experts have given of their time very generously, and governments have supported them in the enormous intellectual and physical effort required, often going substantially beyond reasonable demands of duty. Without such conscientious and professional involvement, the IPCC would be greatly impoverished. We express to all these experts, and the governments who supported them, our grateful and sincere appreciation for their commitment.

We take this opportunity to express our gratitude for nurturing another IPCC report through to a successful completion to:

- Professor Bolin, Chairman of the IPCC, for his able leadership and skillful guidance of the IPCC
- The Co-Chairs of Working Group II, Dr. R.T. Watson (USA) and Dr. M.C. Zinyowera (Zimbabwe)
- The Vice-Chairs of the Working Group, Dr. M. Beniston (Switzerland), Dr. O. Canziani (Argentina), Dr. J. Friaa (Tunisia), Ing. (Mrs.) M. Perdomo (Venezuela), Dr. M. Petit (France), Dr. S.K. Sharma (India), Mr. H. Tsukamoto (Japan), and Professor P. Vellinga (The Netherlands)
- Dr. R.H. Moss, the Head of the Technical Support Unit of the Working Group, and his staff including Mr. David Jon Dokken, Ms. Flo Ormond, Ms. Sandy MacCracken, and Ms. Laura VanWie, as well as Mr. Shardul Agrawala, Ms. Melissa Taylor, and Ms. Anne Tenney, who served as interns for various periods with the Technical Support Unit
- Dr. N. Sundararaman, Secretary of the IPCC, and his staff including Mr. S. Tewungwa, Mrs. R. Bourgeois, Ms. C. Ettori, and Ms. C. Tanikie.

Preface

In June 1993, Working Group II of the Intergovernmental Panel on Climate Change (IPCC) was asked to review the state of knowledge concerning the impacts of climate change on physical and ecological systems, human health, and socio-economic sectors. Working Group II also was charged with reviewing available information on the technical and economic feasibility of a range of potential adaptation and mitigation strategies.

This volume responds to this charge and represents a tremendous achievement—the coordinated contributions of well over a thousand individuals from over 50 developed and developing countries and a dozen international organizations. It includes introductory "primers" on ecological systems and energy production and use; 25 chapters, covering both vulnerability to climate change and options for reducing emissions or enhancing sinks; and three appendices that inventory mitigation technologies and delineate methodologies for assessing impacts/adaptations and mitigation options.

The chapters provide an overview of developments in our scientific understanding since the first IPCC assessments of impacts and response options in 1990, and the supplemental IPCC assessments of 1992. Uncertainties are described, with an eye for identifying both policy significance and research opportunities. In presenting this information, each team of authors has sought to communicate its findings in way that is useful to decisionmakers, research managers, and peers within their field of research; we hope that these audiences, in addition to educators and the general public, will find this volume useful.

Approach of the Assessment

From the earliest stages of the process, participants in the assessment understood the need to confront the fact that confidence in regional projections of temperature, precipitation, soil moisture, and other climate parameters important to impacts models remains low, that uncertainty increases as scale decreases, that patterns of climate change are interwoven with climate variability, and that regional patterns are likely to be affected by both greenhouse gases and anthropogenic aerosols, the latter of which are only now beginning to be incorporated into transient GCM simulations. To provide useful information to decisionmakers, Working Group II needed to find a way to distinguish between uncertainties arising from remaining questions about the responses of systems to a given level or rate of climate change and uncertainties related to the regional-scale climate projections themselves. Consequently, Working Group II decided to focus on *assessing the sensitivity and vulnerability of systems* to a range of climate changes, and only then, having

identified response functions and/or potential thresholds, on *evaluating the plausible impacts* that would result from a particular regional climate scenario. In essence, the approach first sought to clarify what was known and unknown about three distinct issues before applying regional climate scenarios to estimate potential impacts. These issues were:

- How *sensitive* is a particular system to climate change—that is, in simplified terms, how will a system respond to given changes in climate? Given the wide range of systems reviewed in this assessment, these relationships are described in a variety of forms, ranging from specification of quantitative functional relationships for some systems (e.g., climate-yield models for agriculture, rainfall-runoff models for hydrological systems, models of energy demand for heating or cooling driven by temperature change) to more qualitative relationships for other systems.
- How *adaptable* is a particular system to climate change—that is, to what degree are adjustments possible in practices, processes, or structures of systems in response to projected or actual changes of climate? This issue is important for both ecological and social systems because it is critical to recognize that both types of systems have capacities that will enable them to resist adverse consequences of new conditions or to capitalize on new opportunities. Adaptation can be spontaneous or planned, and can be carried out in response to or in anticipation of changes.
- Finally, how *vulnerable* is a system to climate change—that is, how susceptible is it to damage or harm? Vulnerability defines the extent to which climate change may damage or harm a system. It depends not only on a system's sensitivity but also on its ability to adapt to new climate conditions. Both the magnitude and rate of climate change are important in determining the sensitivity, adaptability, and vulnerability of a system.

Building on this sensitivity/vulnerability approach, the chapters of the assessment distinguish, to the extent possible, uncertainties relating to remaining questions about the sensitivity, adaptability, or vulnerability of systems to climate change from uncertainties related to the particular regional climate scenarios used in their estimation of potential impacts.

Levels of Confidence

In the course of the assessment, Working Group II also developed a common approach to describe the levels of confidence that author teams were asked to assign to the major findings in

the executive summaries of their chapters. Several approaches were considered, and the lead authors finally selected a straight-forward, three-tiered structure:

- *High Confidence*—This category denotes wide agreement, based on multiple findings through multiple lines of investigation. In other words, there was a high degree of consensus among the authors based on the existence of substantial evidence in support of the conclusion.
- *Medium Confidence*—This category indicates that there is a consensus, but not a strong one, in support of the conclusion. This ranking could be applied to a situation in which an hypothesis or conclusion is supported by a fair amount of information, but not a sufficient amount to convince all participating authors, or where other less plausible hypotheses cannot yet be completely ruled out.
- *Low Confidence*—This category is reserved for cases when lead authors were highly uncertain about a particular conclusion. This uncertainty could be a reflection of a lack of consensus or the existence of serious competing hypotheses, each with adherents and evidence to support their positions. Alternatively, this ranking could result from the existence of extremely limited information to support an initial plausible idea or hypothesis.

Readers of the assessment need to keep in mind that while the confidence levels used in the report are an attempt to communicate to decisionmakers a rough sense of the collective judgment by the authors of the degree of certainty or uncertainty that should be associated with a particular finding, they are an imperfect tool. In particular, it should be noted that assigning levels of confidence to research findings is a subjective process; different individuals will assign different levels of confidence to the same findings and the same base of evidence because they demand different standards of proof. Moreover, there are multiple sources of uncertainty, some of which are difficult to identify with precision, leading different individuals to make different judgments. Finally, the amount of evidence that an individual will require to view a finding as "well-established" has been shown to be higher for findings that have high consequence than for findings of lesser consequence or for which less is at stake.

Summary for Policymakers:

Scientific-Technical Analyses of Impacts, Adaptations, and Mitigation of Climate Change

A Report of Working Group II
of the Intergovernmental Panel on Climate Change

CONTENTS

1. Scope of the Assessment

The charge to Working Group II of the Intergovernmental Panel on Climate Change (IPCC) was to review the state of knowledge concerning the impacts of climate change on physical and ecological systems, human health, and socioeconomic sectors. Working Group II also was charged with reviewing available information on the technical and economic feasibility of a range of potential adaptation and mitigation strategies. This assessment provides scientific, technical, and economic information that can be used, *inter alia*, in evaluating whether the projected range of plausible impacts constitutes "dangerous anthropogenic interference with the climate system," as referred to in Article 2 of the United Nations Framework Convention on Climate Change (UNFCCC), and in evaluating adaptation and mitigation options that could be used in progressing towards the ultimate objective of the UNFCCC (see Box 1).

2. Nature of the Issue

Human activities are increasing the atmospheric concentrations of greenhouse gases—which tend to warm the atmosphere—and, in some regions, aerosols—which tend to cool the atmosphere. These changes in greenhouse gases and aerosols, taken together, are projected to lead to regional and global changes in climate and climate-related parameters such as temperature,

---

Box 1. Ultimate Objective of the UNFCCC (Article 2)

"...stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system. Such a level should be achieved within a time frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened, and to enable economic development to proceed in a sustainable manner."

---

precipitation, soil moisture, and sea level. Based on the range of sensitivities of climate to increases in greenhouse gas concentrations reported by IPCC Working Group I and plausible ranges of emissions (IPCC IS92; see Table 1), climate models, taking into account greenhouse gases and aerosols, project an increase in global mean surface temperature of about 1–3.5°C by 2100, and an associated increase in sea level of about 15–95 cm. The reliability of regional-scale predictions is still low, and the degree to which climate variability may change is uncertain. However, potentially serious changes have been identified, including an increase in some regions in the incidence of extreme high-temperature events, floods, and droughts, with resultant consequences for fires, pest outbreaks, and ecosystem composition, structure, and functioning, including primary productivity.

Table 1: *Summary of assumptions in the six IPCC 1992 alternative scenarios.*

Scenario	Population	Economic Growth	Energy Supplies
IS92a,b	World Bank 1991 11.3 billion by 2100	1990–2025: 2.9% 1990–2100: 2.3%	12,000 EJ conventional oil 13,000 EJ natural gas Solar costs fall to $0.075/kWh 191 EJ of biofuels available at $70/barrel[a]
IS92c	UN Medium-Low Case 6.4 billion by 2100	1990–2025: 2.0% 1990–2100: 1.2%	8,000 EJ conventional oil 7,300 EJ natural gas Nuclear costs decline by 0.4% annually
IS92d	UN Medium-Low Case 6.4 billion by 2100	1990–2025: 2.7% 1990–2100: 2.0%	Oil and gas same as IS92c Solar costs fall to $0.065/kWh 272 EJ of biofuels available at $50/barrel
IS92e	World Bank 1991 11.3 billion by 2100	1990–2025: 3.5% 1990–2100: 3.0%	18,400 EJ conventional oil Gas same as IS92a,b Phase out nuclear by 2075
IS92f	UN Medium-High Case 17.6 billion by 2100	1990–2025: 2.9% 1990–2100: 2.3%	Oil and gas same as IS92e Solar costs fall to $0.083/kWh Nuclear costs increase to $0.09/kWh

[a]Approximate conversion factor: 1 barrel = 6 GJ.
Source: IPCC, 1992: Emissions scenarios for IPCC: an update. In: *Climate Change 1992: The Supplementary Report to the IPCC Scientific Assessment* [J.T. Houghton, B.A. Callander, and S.K. Varney (eds.)]. Section A3, prepared by J. Leggett, W.J. Pepper, and R.J. Swart, and WMO/UNEP. Cambridge University Press, Cambridge, UK, 200 pp.

Human health, terrestrial and aquatic ecological systems, and socioeconomic systems (e.g., agriculture, forestry, fisheries, and water resources) are all vital to human development and well-being and are all sensitive to changes in climate. Whereas many regions are likely to experience the adverse effects of climate change—some of which are potentially irreversible—some effects of climate change are likely to be beneficial. Hence, different segments of society can expect to confront a variety of changes and the need to adapt to them.

Policymakers are faced with responding to the risks posed by anthropogenic emissions of greenhouse gases in the face of significant scientific uncertainties. It is appropriate to consider these uncertainties in the context of information indicating that climate-induced environmental changes cannot be reversed quickly, if at all, due to the long time scales associated with the climate system (see Box 2). Decisions taken during the next few years may limit the range of possible policy options in the future because high near-term emissions would require deeper reductions in the future to meet any given target concentration. Delaying action might reduce the overall costs of mitigation because of potential technological advances but could increase both the rate and the eventual magnitude of climate change, hence the adaptation and damage costs.

Policymakers will have to decide to what degree they want to take precautionary measures by mitigating greenhouse gas emissions and enhancing the resilience of vulnerable systems by means of adaptation. Uncertainty does not mean that a nation or the world community cannot position itself better to cope with the broad range of possible climate changes or protect against potentially costly future outcomes. Delaying such measures may leave a nation or the world poorly prepared to deal with adverse changes and may increase the possibility of irreversible or very costly consequences.

**Box 2. Time Scales of Processes
Influencing the Climate System**

- Turnover of the capital stock responsible for emissions of greenhouse gases: *Years to decades* (without premature retirement)
- Stabilization of atmospheric concentrations of long-lived greenhouse gases given a stable level of greenhouse gas emissions: *Decades to millennia*
- Equilibration of the climate system given a stable level of greenhouse gas concentrations: *Decades to centuries*
- Equilibration of sea level given a stable climate: *Centuries*
- Restoration/rehabilitation of damaged or disturbed ecological systems: *Decades to centuries* (some changes, such as species extinction, are irreversible, and it may be impossible to reconstruct and reestablish some disturbed ecosystems)

Options for adapting to change or mitigating change that can be justified for other reasons today (e.g., abatement of air and water pollution) and make society more flexible or resilient to anticipated adverse effects of climate change appear particularly desirable.

3.   Vulnerability to Climate Change

Article 2 of the UNFCCC explicitly acknowledges the importance of natural ecosystems, food production, and sustainable economic development. This report addresses the potential *sensitivity*, *adaptability*, and *vulnerability* of ecological and socioeconomic systems—including hydrology and water resources management, human infrastructure, and human health—to changes in climate (see Box 3).

Human-induced climate change adds an important new stress. Human-induced climate change represents an important additional stress, particularly to the many ecological and socioeconomic systems already affected by pollution, increasing resource demands, and nonsustainable management practices. The most vulnerable systems are those with the greatest sensitivity to climate changes and the least adaptability.

Most systems are sensitive to climate change. Natural ecological systems, socioeconomic systems, and human health are all sensitive to both the magnitude and the rate of climate change.

Impacts are difficult to quantify, and existing studies are limited in scope. Although our knowledge has increased significantly during the last decade, and qualitative estimates can be developed, quantitative projections of the impacts of climate change on any particular system at any particular location are difficult because regional-scale climate change predictions are uncertain; our current understanding of many critical processes is limited; and systems are subject to multiple climatic and non-climatic stresses, the interactions of which are not always linear or additive. Most impact studies have assessed how systems would respond to climate change resulting from an arbitrary doubling of equivalent atmospheric carbon dioxide (CO_2) concentrations. Furthermore, very few studies have considered dynamic responses to steadily increasing concentrations of greenhouse gases; fewer still have examined the consequences of increases beyond a doubling of equivalent atmospheric CO_2 concentrations or assessed the implications of multiple stress factors.

Successful adaptation depends upon technological advances, institutional arrangements, availability of financing, and information exchange. Technological advances generally have increased adaptation options for managed systems such as agriculture and water supply. However, many regions of the world currently have limited access to these technologies and appropriate information. The efficacy and cost-effective use of adaptation strategies will depend upon the availability of financial resources, technology transfer, and cultural, educational,

---

Box 3. Sensitivity, Adaptability, and Vulnerability

Sensitivity is the degree to which a system will respond to a change in climatic conditions (e.g., the extent of change in ecosystem composition, structure, and functioning, including primary productivity, resulting from a given change in temperature or precipitation).

Adaptability refers to the degree to which adjustments are possible in practices, processes, or structures of systems to projected or actual changes of climate. Adaptation can be spontaneous or planned, and can be carried out in response to or in anticipation of changes in conditions.

Vulnerability defines the extent to which climate change may damage or harm a system. It depends not only on a system's sensitivity but also on its ability to adapt to new climatic conditions.

Both the magnitude and the rate of climate change are important in determining the sensitivity, adaptability, and vulnerability of a system.

---

managerial, institutional, legal, and regulatory practices, both domestic and international in scope. Incorporating climate-change concerns into resource-use and development decisions and plans for regularly scheduled investments in infrastructure will facilitate adaptation.

Vulnerability increases as adaptive capacity decreases. The vulnerability of human health and socioeconomic systems—and, to a lesser extent, ecological systems—depends upon economic circumstances and institutional infrastructure. This implies that systems typically are more vulnerable in developing countries where economic and institutional circumstances are less favorable. People who live on arid or semi-arid lands, in low-lying coastal areas, in water-limited or flood-prone areas, or on small islands are particularly vulnerable to climate change. Some regions have become more vulnerable to hazards such as storms, floods, and droughts as a result of increasing population density in sensitive areas such as river basins and coastal plains. Human activities, which fragment many landscapes, have increased the vulnerability of lightly managed and unmanaged ecosystems. Fragmentation limits natural adaptation potential and the potential effectiveness of measures to assist adaptation in these systems, such as the provision of migration corridors. A changing climate's near-term effects on ecological and socioeconomic systems most likely will result from changes in the intensity and seasonal and geographic distribution of common weather hazards such as storms, floods, and droughts. In most of these examples, vulnerability can be reduced by strengthening adaptive capacity.

Detection will be difficult, and unexpected changes cannot be ruled out. Unambiguous detection of climate-induced changes in most ecological and social systems will prove extremely difficult in the coming decades. This is because of the complexity of these systems, their many non-linear feedbacks, and their sensitivity to a large number of climatic and non-climatic factors, all of which are expected to continue to change simultaneously. The development of a baseline projecting future conditions without climate change is crucial, for it is this baseline against which all projected impacts are measured. As future climate extends beyond the boundaries of empirical knowledge (i.e., the documented impacts of climate variation in the past), it becomes more likely that actual outcomes will include surprises and unanticipated rapid changes.

Further research and monitoring are essential. Enhanced support for research and monitoring, including cooperative efforts from national, international, and multi-lateral institutions, is essential in order to improve significantly regional-scale climate projections; understand the responses of human health, ecological, and socioeconomic systems to changes in climate and other stress factors; and improve our understanding of the efficacy and cost-effectiveness of adaptation strategies.

3.1. *Terrestrial and Aquatic Ecosystems*

Ecosystems contain the Earth's entire reservoir of genetic and species diversity and provide many goods and services critical to individuals and societies. These goods and services include (i) providing food, fiber, medicines, and energy; (ii) processing and storing carbon and other nutrients; (iii) assimilating wastes, purifying water, regulating water runoff, and controlling floods, soil degradation, and beach erosion; and (iv) providing opportunities for recreation and tourism. These systems and the functions they provide are sensitive to the rate and extent of changes in climate. Figure 1 illustrates that mean annual temperature and mean annual precipitation can be correlated with the distribution of the world's major biomes.

The composition and geographic distribution of many ecosystems will shift as individual species respond to changes in climate; there will likely be reductions in biological diversity and in the goods and services that ecosystems provide society. Some ecological systems may not reach a new equilibrium for several centuries after the climate achieves a new balance.

Forests. Models project that a sustained increase of 1°C in global mean temperature is sufficient to cause changes in regional climates that will affect the growth and regeneration capacity of forests in many regions. In several instances this will alter the function and composition of forests significantly. As a consequence of possible changes in temperature and water availability under doubled equivalent-CO_2 equilibrium conditions, a substantial fraction (a global average of one-third, varying by region from one-seventh to two-thirds) of the existing forested area of the world will undergo major changes in broad vegetation types—with the greatest changes occurring in high latitudes and the least in the tropics. Climate change is expected to occur at a rapid rate relative to the speed at which forest species grow,
Figure 1: This figure illustrates that mean annual temperature and mean annual precipitation can be correlated with the distribution of the world's major biomes. While the role of these annual means in affecting this distribution is important, it should be noted that the distribution of biomes may also strongly depend on seasonal factors such as the length of the dry season or the lowest absolute minimum temperature, on soil properties such as water-holding capacity, on land-use history such as agriculture or grazing, and on disturbance regimes such as the frequency of fire.

reproduce, and reestablish themselves. For mid-latitude regions, a global average warming of 1–3.5°C over the next 100 years would be equivalent to a poleward shift of the present isotherms by approximately 150–550 km or an altitude shift of about 150–550 m; in low latitudes, temperatures would generally be increased to higher levels than now exist. This compares to past tree species migration rates that are believed to be on the order of 4–200 km per century. Therefore, the species composition of forests is likely to change; entire forest types may disappear, while new assemblages of species, hence new ecosystems, may be established. Figure 2 depicts potential distribution of biomes under current and a doubled equivalent-CO_2 climate. Although net primary productivity could increase, the standing biomass of forests may not because of more frequent outbreaks and extended ranges of pests and pathogens, and increasing frequency and intensity of fires. Large amounts of carbon could be released into the atmosphere during transitions from one forest type to another because the rate at which carbon can be lost during times of high forest mortality is greater than the rate at which it can be gained through growth to maturity.

Rangelands. In tropical rangelands, mean temperature increases should not lead to major alterations in productivity and

species composition, but altered rainfall amount and seasonality and increased evapotranspiration will. Increases in atmospheric CO_2 concentration may raise the carbon-to-nitrogen ratio of forage for herbivores, thus reducing its food value. Shifts in temperature and precipitation in temperate rangelands may result in altered growing seasons and boundary shifts between grasslands, forests, and shrublands.

Deserts and Desertification. Deserts are likely to become more extreme—in that, with few exceptions, they are projected to become hotter but not significantly wetter. Temperature increases could be a threat to organisms that exist near their heat-tolerance limits. The impacts on water balance, hydrology, and vegetation are uncertain. Desertification, as defined by the UN Convention to Combat Desertification, is land degradation in arid, semi-arid, and dry sub-humid areas resulting from various factors, including climatic variations and human activities. Desertification is more likely to become irreversible if the environment becomes drier and the soil becomes further degraded through erosion and compaction. Adaptation to drought and desertification may rely on the development of diversified production systems.

Cryosphere. Models project that between one-third and one-half of existing mountain glacier mass could disappear over the next 100 years. The reduced extent of glaciers and depth of snow cover also would affect the seasonal distribution of river flow and water supply for hydroelectric generation and agriculture. Anticipated hydrological changes and reductions in the areal extent and depth of permafrost could lead to large-scale damage to infrastructure, an additional flux of CO_2 into the atmosphere, and changes in processes that contribute to the flux of methane (CH_4) into the atmosphere. Reduced sea-ice extent and thickness would increase the seasonal duration of navigation on rivers and in coastal areas that are presently affected by seasonal ice cover, and may increase navigability in the Arctic Ocean. Little change in the extent of the Greenland and Antarctic ice sheets is expected over the next 50–100 years.

Mountain Regions. The projected decrease in the extent of mountain glaciers, permafrost, and snow cover caused by a warmer climate will affect hydrologic systems, soil stability, and related socioeconomic systems. The altitudinal distribution of vegetation is projected to shift to higher elevation; some species with climatic ranges limited to mountain tops could become extinct because of disappearance of habitat or reduced migration potential. Mountain resources such as food and fuel for indigenous populations may be disrupted in many developing countries. Recreational industries—of increasing economic importance to many regions—also are likely to be disrupted.

Lakes, Streams, and Wetlands. Inland aquatic ecosystems will be influenced by climate change through altered water temperatures, flow regimes, and water levels. In lakes and streams, warming would have the greatest biological effects at high latitudes, where biological productivity would increase, and at the low-latitude boundaries of cold- and cool-water species ranges, where extinctions would be greatest. Warming

FIGURE SPM-2 GOES HERE!!

of larger and deeper temperate zone lakes would increase their productivity; although in some shallow lakes and in streams, warming could increase the likelihood of anoxic conditions. Increases in flow variability, particularly the frequency and duration of large floods and droughts, would tend to reduce water quality and biological productivity and habitat in streams. Water-level declines will be most severe in lakes and streams in dry evaporative drainages and in basins with small catchments. The geographical distribution of wetlands is likely to shift with changes in temperature and precipitation. There will be an impact of climate change on greenhouse gas release from non-tidal wetlands, but there is uncertainty regarding the exact effects from site to site.

Coastal Systems. Coastal systems are economically and ecologically important and are expected to vary widely in their response to changes in climate and sea level. Climate change and a rise in sea level or changes in storms or storm surges could result in the erosion of shores and associated habitat, increased salinity of estuaries and freshwater aquifers, altered tidal ranges in rivers and bays, changes in sediment and nutrient transport, a change in the pattern of chemical and microbiological contamination in coastal areas, and increased coastal flooding. Some coastal ecosystems are particularly at risk, including saltwater marshes, mangrove ecosystems, coastal wetlands, coral reefs, coral atolls, and river deltas. Changes in these ecosystems would have major negative effects on tourism, freshwater supplies, fisheries, and biodiversity. Such impacts would add to modifications in the functioning of coastal oceans and inland waters that already have resulted from pollution, physical modification, and material inputs due to human activities.

Oceans. Climate change will lead to changes in sea level, increasing it on average, and also could lead to altered ocean circulation, vertical mixing, wave climate, and reductions in sea-ice cover. As a result, nutrient availability, biological productivity, the structure and functions of marine ecosystems, and heat and carbon storage capacity may be affected, with important feedbacks to the climate system. These changes would have implications for coastal regions, fisheries, tourism and recreation, transport, off-shore structures, and communication. Paleoclimatic data and model experiments suggest that abrupt climatic changes can occur if freshwater influx from the movement and melting of sea ice or ice sheets significantly weakens global thermohaline circulation.

3.2.   *Hydrology and Water Resources Management*

Climate change will lead to an intensification of the global hydrological cycle and can have major impacts on regional water resources. A change in the volume and distribution of water will affect both ground and surface water supply for domestic and industrial uses, irrigation, hydropower generation, navigation, instream ecosystems, and water-based recreation.

Changes in the total amount of precipitation and in its frequency and intensity directly affect the magnitude and timing of runoff and the intensity of floods and droughts; however, at present, specific regional effects are uncertain. Relatively small changes in temperature and precipitation, together with the non-linear effects on evapotranspiration and soil moisture, can result in relatively large changes in runoff, especially in arid and semi-arid regions. High-latitude regions may experience increased runoff due to increased precipitation, whereas runoff may decrease at lower latitudes due to the combined effects of increased evapotranspiration and decreased precipitation. More intense rainfall would tend to increase runoff and the risk of flooding, although this would depend not only on the change in rainfall but also on catchment physical and biological characteristics. A warmer climate could decrease the proportion of precipitation falling as snow, leading to reductions in spring runoff and increases in winter runoff.

The quantity and quality of water supplies already are serious problems today in many regions, including some low-lying coastal areas, deltas, and small islands, making countries in these regions particularly vulnerable to any additional reduction in indigenous water supplies. Water availability currently falls below 1,000 m³ per person per year—a common benchmark for water scarcity—in a number of countries (e.g., Kuwait, Jordan, Israel, Rwanda, Somalia, Algeria, Kenya) or is expected to fall below this benchmark in the next 2 to 3 decades (e.g., Libya, Egypt, South Africa, Iran, Ethiopia). In addition, a number of countries in conflict-prone areas are highly dependent on water originating outside their borders (e.g., Cambodia, Syria, Sudan, Egypt, Iraq).

The impacts of climate change will depend on the baseline condition of the water supply system and the ability of water resource managers to respond not only to climate change but also to population growth and changes in demands, technology, and economic, social, and legislative conditions. In some cases—particularly in wealthier countries with integrated water-management systems—improved management may protect water users from climate change at minimal cost; in many others, however, there could be substantial economic, social, and environmental costs, particularly in regions that already are water-limited and where there is a considerable competition among users. Experts disagree over whether water supply systems will evolve substantially enough in the future to compensate for the anticipated negative impacts of climate change on water resources and for potential increases in demand.

Options for dealing with the possible impacts of a changed climate and increased uncertainty about future supply and demand for freshwater include more efficient management of existing supplies and infrastructure; institutional arrangements to limit future demands/promote conservation; improved monitoring and forecasting systems for floods/droughts; rehabilitation of watersheds, especially in the tropics; and construction of new reservoir capacity to capture and store excess flows produced by altered patterns of snowmelt and storms.

3.3.   *Food and Fiber*

Agriculture. Crop yields and changes in productivity due to climate change will vary considerably across regions and among localities, thus changing the patterns of production. Productivity is projected to increase in some areas and decrease in others, especially the tropics and subtropics (Table 2). However, existing studies show that on the whole global agricultural production could be maintained relative to baseline production in the face of climate change modeled by general circulation models (GCMs) at doubled equivalent-CO_2 equilibrium conditions, but that regional effects would vary widely. This conclusion takes into account the beneficial effects of CO_2 fertilization, but does not allow for changes in agricultural pests and the possible effects of changing climatic variability.

Focusing on global agricultural production does not address the potentially serious consequences of large differences at local and regional scales, even at mid-latitudes. There may be increased risk of hunger and famine in some locations; many of the world's poorest people—particularly those living in subtropical and tropical areas, and dependent on isolated agricultural systems in semi-arid and arid regions—are most at risk of increased hunger. Many of these at-risk populations are found in sub-Saharan Africa; south, east, and southeast Asia; and tropical areas of Latin America, as well as some Pacific island nations.

Adaptation—such as changes in crops and crop varieties, improved water-management and irrigation systems, and changes in planting schedules and tillage practices—will be important in limiting negative effects and taking advantage of beneficial changes in climate. The extent of adaptation depends on the affordability of such measures, particularly in developing countries; access to know-how and technology; the rate of climate change; and biophysical constraints such as water availability, soil characteristics, and crop genetics. The incremental costs of adaptation strategies could create a serious burden for developing countries; some adaptation strategies may result in cost savings for some countries. There are significant uncertainties about the capacity of different regions to adapt successfully to projected climate change.

Livestock production may be affected by changes in grain prices and rangeland and pasture productivity. In general, analyses indicate that intensively managed livestock systems have more potential for adaptation than crop systems. This may not be the case in pastoral systems, where the rate of technology adoption is slow and changes in technology are viewed as risky.

Forest Products. Global wood supplies during the next century may become increasingly inadequate to meet projected consumption due to both climatic and non-climatic factors. Boreal forests are likely to undergo irregular and large-scale losses of living trees because of the impacts of projected climate change. Such losses could initially generate additional wood supply from salvage harvests, but could severely reduce standing stocks and wood-product availability over the long term. The exact timing and extent of this pattern is uncertain. Climate and land-use impacts on the production of temperate forest products are expected to be relatively small. In tropical regions, the availability of forest products is projected to decline by about half for non-climatic reasons related to human activities.

Fisheries. Climate-change effects interact with those of pervasive overfishing, diminishing nursery areas, and extensive inshore and coastal pollution. Globally, marine fisheries production is expected to remain about the same; high-latitude freshwater and aquaculture production are likely to increase, assuming that natural climate variability and the structure and strength of ocean currents remain about the same. The principal impacts will be felt at the national and local levels as species mix and centers of production shift. The positive effects of climate change—such as longer growing seasons, lower natural winter mortality, and faster growth rates in higher latitudes—may be offset by negative factors such as changes in established reproductive patterns, migration routes, and ecosystem relationships.

3.4.   *Human Infrastructure*

Climate change and resulting sea-level rise can have a number of negative impacts on energy, industry, and transportation infrastructure; human settlements; the property insurance industry; tourism; and cultural systems and values.

In general, the sensitivity of the energy, industry, and transportation sectors is relatively low compared to that of agricultural or natural ecosystems, and the capacity for adaptation through management and normal replacement of capital is expected to be high. However, infrastructure and activities in these sectors would be susceptible to sudden changes, surprises, and increased frequency or intensity of extreme events. The subsectors and activities most sensitive to climate change include agroindustry, energy demand, production of renewable energy such as hydroelectricity and biomass, construction, some transportation activities, existing flood mitigation structures, and transportation infrastructure located in many areas, including vulnerable coastal zones and permafrost regions.

Climate change clearly will increase the vulnerability of some coastal populations to flooding and erosional land loss. Estimates put about 46 million people per year currently at risk of flooding due to storm surges. This estimate results from multiplying the total number of people currently living in areas potentially affected by ocean flooding by the probability of flooding at these locations in any year, given the present protection levels and population density. In the absence of adaptation measures, a 50-cm sea-level rise would increase this number to about 92 million; a 1-m sea-level rise would raise it to 118 million. If one incorporates anticipated population growth, the estimates increase substantially. Some small island nations and other countries will confront greater vulnerability because their existing sea and

Table 2: *Selected crop study results for 2 x CO_2-equivalent equilibrium GCM scenarios.*

Region	Crop	Yield Impact (%)	Comments
Latin America	Maize	-61 to increase	Data are from Argentina, Brazil, Chile, and Mexico; range is across GCM scenarios, with and without CO_2 effect.
	Wheat	-50 to -5	Data are from Argentina, Uruguay, and Brazil; range is across GCM scenarios, with and without CO_2 effect.
	Soybean	-10 to +40	Data are from Brazil; range is across GCM scenarios, with CO_2 effect.
Former Soviet Union	Wheat	-19 to +41	Range is across GCM scenarios and region, with CO_2 effect.
	Grain	-14 to +13	
Europe	Maize	-30 to increase	Data are from France, Spain, and northern Europe; with adaptation and CO_2 effect; assumes longer season, irrigation efficiency loss, and northward shift.
	Wheat	increase or decrease	Data are from France, UK, and northern Europe; with adaptation and CO_2 effect; assumes longer season, northward shift, increased pest damage, and lower risk of crop failure.
	Vegetables	increase	Data are from UK and northern Europe; assumes pest damage increased and lower risk of crop failure.
North America	Maize	-55 to +62	Data are from USA and Canada; range is across GCM scenarios and sites, with/without adaptation and with/without CO_2 effect.
	Wheat	-100 to +234	
	Soybean	-96 to +58	Data are from USA; less severe or increase with CO_2 and adaptation.
Africa	Maize	-65 to +6	Data are from Egypt, Kenya, South Africa, and Zimbabwe; range is over studies and climate scenarios, with CO_2 effect.
	Millet	-79 to -63	Data are from Senegal; carrying capacity fell 11–38%.
	Biomass	decrease	Data are from South Africa; agrozone shifts.
South Asia	Rice	-22 to +28	Data are from Bangladesh, India, Philippines, Thailand, Indonesia, Malaysia, and Myanmar; range is over GCM scenarios, with CO_2 effect; some studies also consider adaptation.
	Maize	-65 to -10	
	Wheat	-61 to +67	
China	Rice	-78 to +28	Includes rainfed and irrigated rice; range is across sites and GCM scenarios; genetic variation provides scope for adaptation.
Other Asia and Pacific Rim	Rice	-45 to +30	Data are from Japan and South Korea; range is across GCM scenarios; generally positive in north Japan, and negative in south.
	Pasture	-1 to +35	Data are from Australia and New Zealand; regional variation.
	Wheat	-41 to +65	Data are from Australia and Japan; wide variation, depending on cultivar.

Note: For most regions, studies have focused on one or two principal grains. These studies strongly demonstrate the variability in estimated yield impacts among countries, scenarios, methods of analysis, and crops, making it difficult to generalize results across areas or for different climate scenarios.

coastal defense systems are less well-established. Countries with higher population densities would be more vulnerable. For these countries, sea-level rise could force internal or international migration of populations.

A number of studies have evaluated sensitivity to a 1-m sea-level rise. This increase is at the top of the range of IPCC Working Group I estimates for 2100; it should be noted, however, that sea level is actually projected to continue to rise beyond 2100. Studies using this 1-m projection show a particular risk for small islands and deltas. Estimated land losses range from 0.05% for Uruguay, 1% for Egypt, 6% for the Netherlands, and 17.5% for Bangladesh to about 80% for the Majuro Atoll in the Marshall Islands, given the present state of protection systems. Large numbers of people also are affected—for example, about 70 million each in China and Bangladesh. Many nations face lost capital value in excess of 10% of their gross domestic product (GDP). Although annual protection costs for many nations are relatively modest (about 0.1% of GDP), the average annual costs to many small island states total several percent of GDP. For some island nations, the high cost of providing storm-surge protection would make it essentially infeasible, especially given the limited availability of capital for investment.

The most vulnerable human settlements are located in damage-prone areas of the developing world that do not have the resources to cope with impacts. Effective coastal-zone management and land-use regulation can help direct population shifts away from vulnerable locations such as flood plains, steep hillsides, and low-lying coastlines. One of the potentially unique and destructive effects on human settlements is forced internal or international migration of populations. Programs of disaster assistance can offset some of the more serious negative consequences of climate change and reduce the number of ecological refugees.

Property insurance is vulnerable to extreme climate events. A higher risk of extreme events due to climate change could lead to higher insurance premiums or the withdrawal of coverage for property in some vulnerable areas. Changes in climate variability and the risk for extreme events may be difficult to detect or predict, thus making it difficult for insurance companies to adjust premiums appropriately. If such difficulty leads to insolvency, companies may not be able to honor insurance contracts, which

could economically weaken other sectors, such as banking. The insurance industry currently is under stress from a series of "billion dollar" storms since 1987, resulting in dramatic increases in losses, reduced availability of insurance, and higher costs. Some in the insurance industry perceive a current trend toward increased frequency and severity of extreme climate events. Examination of the meteorological data fails to support this perception in the context of a long-term change, although a shift within the limits of natural variability may have occurred. Higher losses strongly reflect increases in infrastructure and economic worth in vulnerable areas as well as a possible shift in the intensity and frequency of extreme weather events.

3.5.   *Human Health*

Climate change is likely to have wide-ranging and mostly adverse impacts on human health, with significant loss of life. These impacts would arise by both direct and indirect pathways (Figure 3), and it is likely that the indirect impacts would, in the longer term, predominate.

Direct health effects include increases in (predominantly cardiorespiratory) mortality and illness due to an anticipated increase

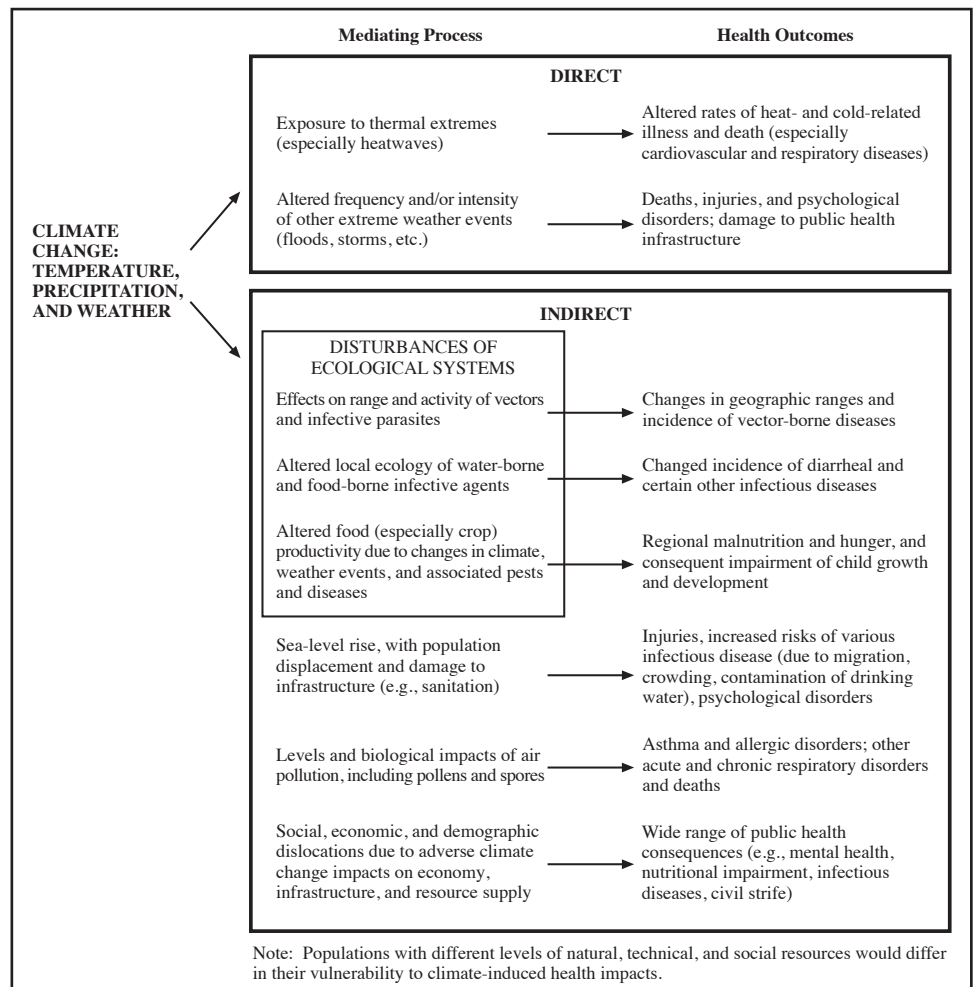

Figure 3: Ways in which climate change can affect human health.

in the intensity and duration of heat waves. Temperature increases in colder regions should result in fewer cold-related deaths. An increase in extreme weather would cause a higher incidence of death, injury, psychological disorders, and exposure to contaminated water supplies.

Indirect effects of climate change include increases in the potential transmission of vector-borne infectious diseases (e.g., malaria, dengue, yellow fever, and some viral encephalitis) resulting from extensions of the geographical range and season for vector organisms. Projections by models (that entail necessary simplifying assumptions) indicate that the geographical zone of potential malaria transmission in response to world temperature increases at the upper part of the IPCC-projected range (3–5°C by 2100) would increase from approximately 45% of the world population to approximately 60% by the latter half of the next century. This could lead to potential increases in malaria incidence (on the order of 50–80 million additional annual cases, relative to an assumed global background total of 500 million cases), primarily in tropical, subtropical, and less well-protected temperate-zone populations. Some increases in non-vector-borne infectious diseases—such as salmonellosis, cholera, and giardiasis—also could occur as a result of elevated temperatures and increased flooding.

Additional indirect effects include respiratory and allergic disorders due to climate-enhanced increases in some air pollutants, pollens, and mold spores. Exposure to air pollution and stressful weather events combine to increase the likelihood of morbidity and mortality. Some regions could experience a decline in nutritional status as a result of adverse impacts on food and fisheries productivity. Limitations on freshwater supplies also will have human health consequences.

Quantifying the projected impacts is difficult because the extent of climate-induced health disorders depends on numerous coexistent and interacting factors that characterize the vulnerability of the particular population, including environmental and socioeconomic circumstances, nutritional and immune status, population density, and access to quality health care services. Adaptive options to reduce health impacts include protective technology (e.g., housing, air conditioning, water purification, and vaccination), disaster preparedness, and appropriate health care.

4.   Options to Reduce Emissions and Enhance Sinks of Greenhouse Gases

Human activities are directly increasing the atmospheric concentrations of several greenhouse gases, especially CO_2, CH_4, halocarbons, sulfur hexafluoride (SF_6), and nitrous oxide (N_2O). CO_2 is the most important of these gases, followed by CH_4. Human activities also indirectly affect concentrations of water vapor and ozone. Significant reductions in net greenhouse gas emissions are technically possible and can be economically feasible. These reductions can be achieved by utilizing an extensive array of technologies, and policy measures

that accelerate technology development, diffusion, and transfer in all sectors including the energy, industry, transportation, residential/commercial, and agricultural/forestry sectors. By the year 2100, the world's commercial energy system in effect will be replaced at least twice, offering opportunities to change the energy system without premature retirement of capital stock; significant amounts of capital stock in the industrial, commercial, residential, and agricultural/forestry sectors will also be replaced. These cycles of capital replacement provide opportunities to use new, better performing technologies. It should be noted that the analyses of Working Group II do not attempt to quantify potential macroeconomic consequences that may be associated with mitigation measures. Discussion of macroeconomic analyses is found in the IPCC Working Group III contribution to the Second Assessment Report. The degree to which technical potential and cost-effectiveness are realized is dependent on initiatives to counter lack of information and overcome cultural, institutional, legal, financial and economic barriers that can hinder diffusion of technology or behavioral changes. The pursuit of mitigation options can be carried out within the limits of sustainable development criteria. Social and environmental criteria not related to greenhouse gas emissions abatement could, however, restrict the ultimate potential of each of the options.

4.1.   Energy, Industrial Process, and Human Settlement Emissions

Global energy demand has grown at an average annual rate of approximately 2% for almost 2 centuries, although energy demand growth varies considerably over time and between different regions. In the published literature, different methods and conventions are used to characterize energy consumption. These conventions differ, for example, according to their definition of sectors and their treatment of energy forms. Based on aggregated national energy balances, 385 EJ of primary energy was consumed in the world in 1990, resulting in the release of 6 Gt C as CO_2. Of this, 279 EJ was delivered to end users, accounting for 3.7 Gt C emissions as CO_2 at the point of consumption. The remaining 106 EJ was used in energy conversion and distribution, accounting for 2.3 Gt C emissions as CO_2. In 1990, the three largest sectors of energy consumption were industry (45% of total CO_2 releases), residential/commercial sector (29%), and transport (21%). Of these, transport sector energy use and related CO_2 emissions have been the most rapidly growing over the past 2 decades. For the detailed sectoral mitigation option assessment in this report, 1990 energy consumption estimates are based on a range of literature sources; a variety of conventions are used to define these sectors and their energy use, which is estimated to amount to a total of 259–282 EJ.

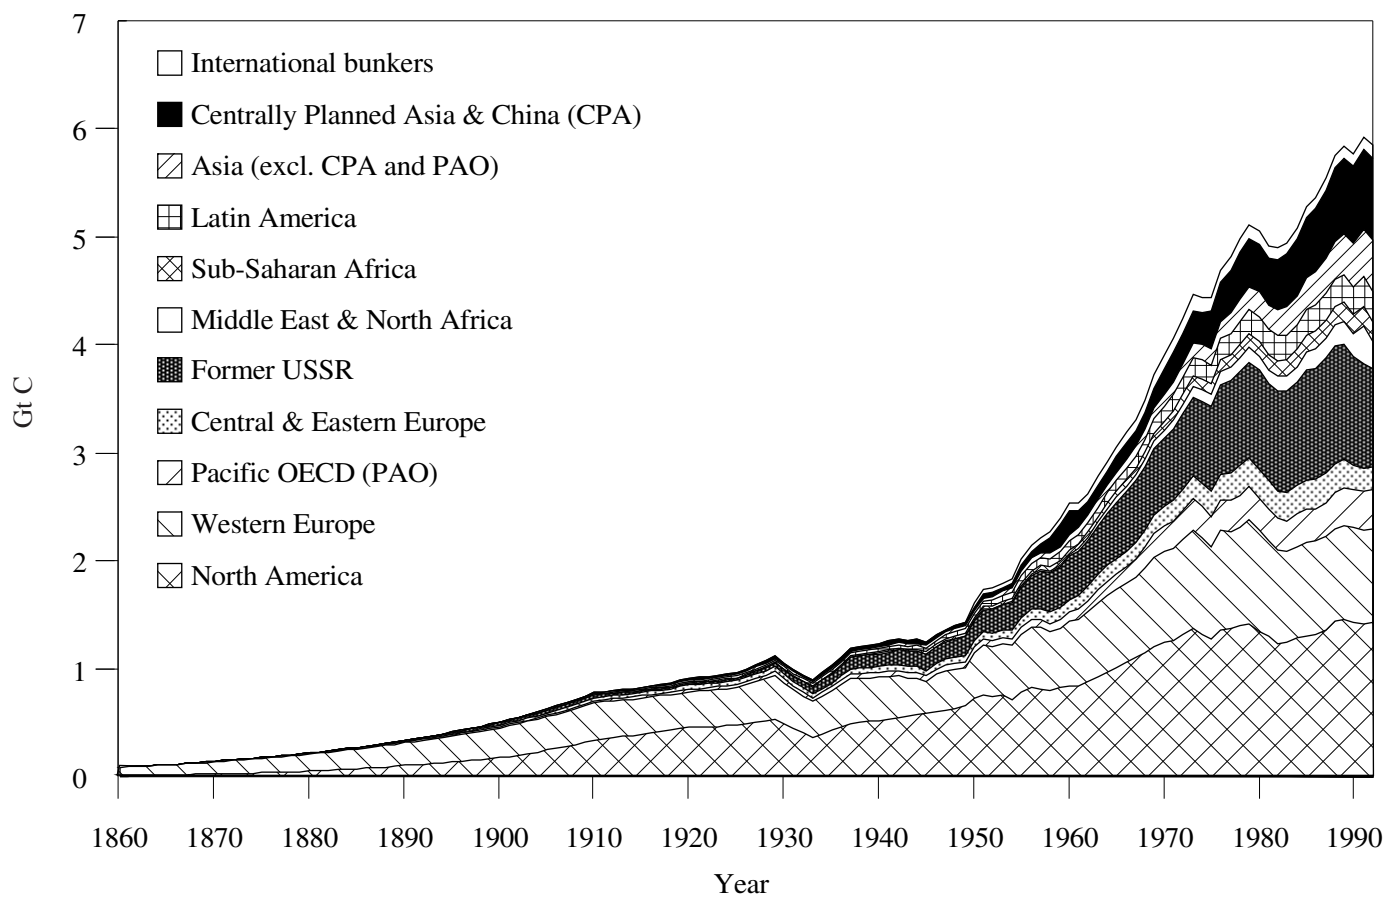
Figure 4 depicts total energy-related emissions by major world region. Organisation for Economic Cooperation and Development (OECD) nations have been and remain major energy users and fossil fuel CO_2 emitters, although their share of global fossil fuel carbon emissions has been declining.


Figure 4: Global energy-related CO_2 emissions by major world region in Gt C/yr. Sources: Keeling, 1994; Marland *et al.*, 1994; Grübler and Nakicenovic, 1992; Etemad and Luciani, 1991; Fujii, 1990; UN, 1952 (see the Energy Primer for reference information).

Developing nations, taken as a group, still account for a smaller portion of total global CO_2 emissions than industrialized nations—OECD and former Soviet Union/Eastern Europe (FSU/EE)—but most projections indicate that with forecast rates of economic and population growth, the future share of developing countries will increase. Future energy demand is anticipated to continue to grow, at least through the first half of the next century. The IPCC (1992, 1994) projects that without policy intervention, there could be significant growth in emissions from the industrial, transportation, and commercial/residential buildings sectors.

4.1.1. Energy Demand

Numerous studies have indicated that 10–30% energy-efficiency gains above present levels are feasible at little or no net cost in many parts of the world through technical conservation measures and improved management practices over the next 2 to 3 decades. Using technologies that presently yield the highest output of energy services for a given input of energy, efficiency gains of 50–60% would be technically feasible in many countries over the same time period. Achieving these potentials will depend on future cost reductions, financing, and technology transfer, as well as measures to overcome a variety of non-technical barriers. The potential for greenhouse gas emission reductions exceeds the potential for energy use efficiency because of the possibility of switching fuels and energy sources. Because energy use is growing world-wide, even replacing current technology with more efficient technology could still lead to an absolute increase in CO_2 emissions in the future.

In 1992, the IPCC produced six scenarios (IS92a-f) of future energy use and associated greenhouse gas emissions (IPCC, 1992, 1995). These scenarios provide a wide range of possible future greenhouse gas emission levels, without mitigation measures.

In the Second Assessment Report, future energy use has been reexamined on a more detailed sectoral basis, both with and without new mitigation measures, based on existing studies. Despite different assessment approaches, the resulting ranges of energy consumption increases to 2025 without new measures are broadly consistent with those of IS92. If past trends continue, greenhouse gas emissions will grow more slowly than energy use, except in the transport sector.

The following paragraphs summarize energy-efficiency improvement potentials estimated in the IPCC Second

Assessment Report. Strong policy measures would be required to achieve these potentials. Energy-related greenhouse gas emission reductions depend on the source of the energy, but reductions in energy use will in general lead to reduced greenhouse gas emissions.

Industry. Energy use in 1990 was estimated to be 98–117 EJ, and is projected to grow to 140–242 EJ in 2025 without new measures. Countries differ widely in their current industrial energy use and energy-related greenhouse gas emission trends. Industrial sector energy-related greenhouse gas emissions in most industrialized countries are expected to be stable or decreasing as a result of industrial restructuring and technological innovation, whereas industrial emissions in developing countries are projected to increase mainly as a result of industrial growth. The short-term potential for energy-efficiency improvements in the manufacturing sector of major industrial countries is estimated to be 25%. The potential for greenhouse gas emission reductions is larger. Technologies and measures for reducing energy-related emissions from this sector include improving efficiency (e.g., energy and materials savings, cogeneration, energy cascading, steam recovery, and use of more efficient motors and other electrical devices); recycling materials and switching to those with lower greenhouse gas emissions; and developing processes that use less energy and materials.

Transportation. Energy use in 1990 was estimated to be 61–65 EJ, and is projected to grow to 90–140 EJ in 2025 without new measures. Projected energy use in 2025 could be reduced by about a third to 60–100 EJ through vehicles using very efficient drive-trains, lightweight construction, and low air-resistance design, without compromising comfort and performance. Further energy-use reductions are possible through the use of smaller vehicles; altered land-use patterns, transport systems, mobility patterns, and lifestyles; and shifting to less energy-intensive transport modes. Greenhouse gas emissions per unit of energy used could be reduced through the use of alternative fuels and electricity from renewable sources. These measures, taken together, provide the opportunity for reducing global transport energy-related greenhouse gas emissions by as much as 40% of projected emissions by 2025. Actions to reduce energy-related greenhouse gas emissions from transport can simultaneously address other problems such as local air pollution.

Commercial/Residential Sector. Energy use in 1990 was estimated to be about 100 EJ, and is projected to grow to 165–205 EJ in 2025 without new measures. Projected energy use could be reduced by about a quarter to 126–170 EJ by 2025 without diminishing services through the use of energy efficient technology. The potential for greenhouse gas emission reductions is larger. Technical changes might include reduced heat transfers through building structures and more efficient space-conditioning and water supply systems, lighting, and appliances. Ambient temperatures in urban areas can be reduced through increased vegetation and greater reflectivity of building surfaces, reducing the energy required for space conditioning. Energy-related greenhouse gas emission reductions beyond

those obtained through reduced energy use could be achieved through changes in energy sources.

4.1.2. Mitigating Industrial Process and Human Settlement Emissions

Process-related greenhouse gases including CO_2, CH_4, N_2O, halocarbons, and SF_6 are released during manufacturing and industrial processes, such as the production of iron, steel, aluminum, ammonia, cement, and other materials. Large reductions are possible in some cases. Measures include modifying production processes, eliminating solvents, replacing feedstocks, materials substitution, increased recycling, and reduced consumption of greenhouse gas-intensive materials. Capturing and utilizing CH_4 from landfills and sewage treatment facilities and lowering the leakage rate of halocarbon refrigerants from mobile and stationary sources also can lead to significant greenhouse gas emission reductions.

4.1.3. Energy Supply

This assessment focuses on new technologies for capital investment and not on potential retrofitting of existing capital stock to use less carbon-intensive forms of primary energy. It is technically possible to realize deep emissions reductions in the energy supply sector in step with the normal timing of investments to replace infrastructure and equipment as it wears out or becomes obsolete. Many options for achieving these deep reductions will also decrease the emissions of sulfur dioxide, nitrogen oxides, and volatile organic compounds. Promising approaches, not ordered according to priority, are described below.

4.1.3.1. Greenhouse gas reductions in the use of fossil fuels

More Efficient Conversion of Fossil Fuels. New technology offers considerably increased conversion efficiencies. For example, the efficiency of power production can be increased from the present world average of about 30% to more than 60% in the longer term. Also, the use of combined heat and power production replacing separate production of power and heat—whether for process heat or space heating—offers a significant rise in fuel conversion efficiency.

Switching to Low-Carbon Fossil Fuels and Suppressing Emissions. Switching from coal to oil or natural gas, and from oil to natural gas, can reduce emissions. Natural gas has the lowest CO_2 emissions per unit of energy of all fossil fuels at about 14 kg C/GJ, compared to oil with about 20 kg C/GJ and coal with about 25 kg C/GJ. The lower carbon-containing fuels can, in general, be converted with higher efficiency than coal. Large resources of natural gas exist in many areas. New, low capital cost, highly efficient combined-cycle technology has reduced electricity costs considerably in some areas. Natural gas could potentially replace oil in the transportation sector.

Approaches exist to reduce emissions of CH_4 from natural gas pipelines and emissions of CH_4 and/or CO_2 from oil and gas wells and coal mines.

Decarbonization of Flue Gases and Fuels, and CO_2 Storage. The removal and storage of CO_2 from fossil fuel power-station stack gases is feasible, but reduces the conversion efficiency and significantly increases the production cost of electricity. Another approach to decarbonization uses fossil fuel feedstocks to make hydrogen-rich fuels. Both approaches generate a byproduct stream of CO_2 that could be stored, for example, in depleted natural gas fields. The future availability of conversion technologies such as fuel cells that can efficiently use hydrogen would increase the relative attractiveness of the latter approach. For some longer term CO_2 storage options, the costs, environmental effects, and efficacy of such options remain largely unknown.

4.1.3.2.   Switching to non-fossil fuel sources of energy

Switching to Nuclear Energy. Nuclear energy could replace baseload fossil fuel electricity generation in many parts of the world if generally acceptable responses can be found to concerns such as reactor safety, radioactive-waste transport and disposal, and nuclear proliferation.

Switching to Renewable Sources of Energy. Solar, biomass, wind, hydro, and geothermal technologies already are widely used. In 1990, renewable sources of energy contributed about 20% of the world's primary energy consumption, most of it fuelwood and hydropower. Technological advances offer new opportunities and declining costs for energy from these sources. In the longer term, renewable sources of energy could meet a major part of the world's demand for energy. Power systems can easily accommodate limited fractions of intermittent generation, and with the addition of fast-responding backup and storage units, also higher fractions. Where biomass is sustainably regrown and used to displace fossil fuels in energy production, net carbon emissions are avoided as the CO_2 released in converting the biomass to energy is again fixed in biomass through photosynthesis. If the development of biomass energy can be carried out in ways that effectively address concerns about other environmental issues and competition with other land uses, biomass could make major contributions in both the electricity and fuels markets, as well as offering prospects of increasing rural employment and income.

4.1.4.   Integration of Energy System Mitigation Options

To assess the potential impact of combinations of individual measures at the energy system level, in contrast to the level of individual technologies, variants of a Low CO_2-Emitting Energy Supply System (LESS) are described. The LESS constructions are "thought experiments" exploring possible global energy systems.

The following assumptions were made: World population grows from 5.3 billion in 1990 to 9.5 billion by 2050 and 10.5

billion by 2100. GDP grows 7-fold by 2050 (5-fold and 14-fold in industrialized and developing countries, respectively) and 25-fold by 2100 (13-fold and 70-fold in industrialized and developing countries, respectively), relative to 1990. Because of emphasis on energy efficiency, primary energy consumption rises much more slowly than GDP. The energy supply constructions were made to meet energy demand in (i) projections developed for the IPCC's First Assessment Report (1990) in a low energy demand variant, where global primary commercial energy use approximately doubles, with no net change for industrialized countries but a 4.4-fold increase for developing countries from 1990 to 2100; and (ii) a higher energy demand variant, developed in the IPCC IS92a scenario where energy demand quadruples from 1990 to 2100. The energy demand levels of the LESS constructions are consistent with the energy demand mitigation chapters of this Second Assessment Report.

Figure 5 shows combinations of different energy sources to meet changing levels of demand over the next century. The analysis of these variants leads to the following conclusions:

- Deep reductions of CO_2 emissions from energy supply systems are technically possible within 50 to 100 years, using alternative strategies.
- Many combinations of the options identified in this assessment could reduce global CO_2 emissions from fossil fuels from about 6 Gt C in 1990 to about 4 Gt C/yr by 2050, and to about 2 Gt C/yr by 2100 (see Figure 6). Cumulative CO_2 emissions, from 1990 to 2100, would range from about 450 to about 470 Gt C in the alternative LESS constructions.
- Higher energy efficiency is underscored for achieving deep reductions in CO_2 emissions, for increasing the flexibility of supply side combinations, and for reducing overall energy system costs.
- Interregional trade in energy grows in the LESS constructions compared to today's levels, expanding sustainable development options for Africa, Latin America, and the Middle East during the next century.

Costs for energy services in each LESS variant relative to costs for conventional energy depend on relative future energy prices, which are uncertain within a wide range, and on the performance and cost characteristics assumed for alternative technologies. However, within the wide range of future energy prices, one or more of the variants would plausibly be capable of providing the demanded energy services at estimated costs that are approximately the same as estimated future costs for current conventional energy. It is not possible to identify a least-cost future energy system for the longer term, as the relative costs of options depend on resource constraints and technological opportunities that are imperfectly known, and on actions by governments and the private sector.

The literature provides strong support for the feasibility of achieving the performance and cost characteristics assumed for energy technologies in the LESS constructions, within the next 2 decades, though it is impossible to be certain until the research

Figure 5: Global primary energy use for alternative Low CO_2-Emitting Energy Supply System (LESS) constructions: Alternatives for meeting different energy demand levels over time, using various fuel mixes.

and development is complete and the technologies have been tested in the market. Moreover, these performance and cost characteristics cannot be achieved without a strong and sustained investment in research, development, and demonstration (RD&D). Many of the technologies being developed would need initial support to enter the market, and to reach sufficient volume to lower costs to become competitive.

Market penetration and continued acceptability of different energy technologies ultimately depends on their relative cost, performance (including environmental performance), institutional arrangements, and regulations and policies. Because costs vary by location and application, the wide variety of circumstances creates initial opportunities for new technologies to enter the market. Deeper understanding of the opportunities

for emissions reductions would require more detailed analysis of options, taking into account local conditions.

Because of the large number of options, there is flexibility as to how the energy supply system could evolve, and paths of energy system development could be influenced by considerations other than climate change, including political, environmental (especially indoor and urban air pollution, acidification, and land restoration), and socioeconomic circumstances.

4.2.   *Agriculture, Rangelands, and Forestry*

Beyond the use of biomass fuels to displace fossil fuels, the management of forests, agricultural lands, and rangelands can play an
Figure 6: Annual CO_2 emissions from fossil fuels for alternative LESS constructions, with comparison to the IPCC IS92a-f scenarios (see Figure 5 for acronym definitions).

important role in reducing current emissions of CO_2, CH_4, and N_2O and in enhancing carbon sinks. A number of measures could conserve and sequester substantial amounts of carbon (approximately 60–90 Gt C in the forestry sector alone) over the next 50 years. In the forestry sector, costs for conserving and sequestering carbon in biomass and soil are estimated to range widely but can be competitive with other mitigation options. Factors affecting costs include opportunity costs of land; initial costs of planting and establishment; costs of nurseries; the cost of annual maintenance and monitoring; and transaction costs. Direct and indirect benefits will vary with national circumstances and could offset the costs. Other practices in the agriculture sector could reduce emissions of other greenhouse gases such as CH_4 and N_2O. Land-use and management measures include:

- Sustaining existing forest cover
- Slowing deforestation
- Regenerating natural forests
- Establishing tree plantations
- Promoting agroforestry
- Altering management of agricultural soils and rangelands
- Improving efficiency of fertilizer use

- Restoring degraded agricultural lands and rangelands
- Recovering CH_4 from stored manure
- Improving the diet quality of ruminants.

The net amount of carbon per unit area conserved or sequestered in living biomass under a particular forest management practice and present climate is relatively well understood. The most important uncertainties associated with estimating a global value are (i) the amount of land suitable and available for forestation, regeneration, and/or restoration programs; (ii) the rate at which tropical deforestation can actually be reduced; (iii) the long-term use (security) of these lands; and (iv) the continued suitability of some practices for particular locations given the possibility of changes in temperature, water availability, and so forth under climate change.

4.3. Cross-Sectoral Issues

Cross-sectoral assessment of different combinations of mitigation options focuses on the interactions of the full range of technologies and practices that are potentially capable of reducing

emissions of greenhouse gases or sequestering carbon. Current analysis suggests the following:

- **Competing Uses of Land, Water, and Other Natural Resources**. A growing population and expanding economy will increase the demand for land and other natural resources needed to provide, *inter alia*, food, fiber, forest products, and recreation services. Climate change will interact with the resulting intensified patterns of resource use. Land and other resources could also be required for mitigation of greenhouse gas emissions. Agricultural productivity improvements throughout the world and especially in developing countries would increase availability of land for production of biomass energy.
- **Geoengineering Options**. Some geoengineering approaches to counterbalance greenhouse gas-induced climate change have been suggested (e.g., putting solar radiation reflectors in space or injecting sulfate aerosols into the atmosphere to mimic the cooling influence of volcanic eruptions). Such approaches generally are likely to be ineffective, expensive to sustain, and/or to have serious environmental and other effects that are in many cases poorly understood.

4.4. Policy Instruments

Mitigation depends on reducing barriers to the diffusion and transfer of technology, mobilizing financial resources, supporting capacity building in developing countries, and other approaches to assist in the implementation of behavioral changes and technological opportunities in all regions of the globe. The optimum mix of policies will vary from country to country, depending upon political structure and societal receptiveness. The leadership of national governments in applying these policies will contribute to responding to adverse consequences of climate change. Governments can choose policies that facilitate the penetration of less greenhouse gas-intensive technologies and modified consumption patterns. Indeed, many countries have extensive experience with a variety of policies that can accelerate the adoption of such technologies. This experience comes from efforts over the past 20 to 30 years to achieve improved energy efficiency, reduce the environmental impacts of agricultural policies, and meet conservation and environmental goals unrelated to climate change. Policies to reduce net greenhouse gas emissions appear more easily implemented when they are designed to address other concerns that impede sustainable development (e.g., air pollution and soil erosion). A number of policies, some of which may need regional or international agreement, can facilitate the penetration of less greenhouse gas-intensive technologies and modified consumption patterns, including:

- Putting in place appropriate institutional and structural frameworks
- Energy pricing strategies (e.g., carbon or energy taxes, and reduced energy subsidies)
- Reducing or removing other subsidies (e.g., agricultural and transport subsidies) that increase greenhouse gas emissions
- Tradable emissions permits
- Voluntary programs and negotiated agreements with industry
- Utility demand-side management programs
- Regulatory programs, including minimum energy efficiency standards (e.g., for appliances and fuel economy)
- Stimulating RD&D to make new technologies available
- Market pull and demonstration programs that stimulate the development and application of advanced technologies
- Renewable energy incentives during market build-up
- Incentives such as provisions for accelerated depreciation and reduced costs for consumers
- Education and training; information and advisory measures
- Options that also support other economic and environmental goals.

Accelerated development of technologies that will reduce greenhouse gas emissions and enhance greenhouse gas sinks—as well as understanding the barriers that inhibit their diffusion into the marketplace—requires intensified research and development by governments and the private sector.

CONTENTS

1.   Scope of the Assessment

The Intergovernmental Panel on Climate Change (IPCC) charged Working Group II with reviewing current knowledge about the impacts of climate change on physical and ecological systems, human health, and socioeconomic sectors. IPCC also asked Working Group II to review available data on the technical and economic feasibility of a range of potential adaptation and mitigation strategies. In producing this report, Working Group II has coordinated its activities with those of Working Groups I and III, and built on the 1990 and 1992 IPCC assessments.

This assessment provides scientific, technical, and economic information that can be used, *inter alia*, in evaluating whether the projected range of plausible impacts constitutes "dangerous anthropogenic interference with the climate system" at the local, regional, or global scales as referred to in Article 2 of the United Nations Framework Convention on Climate Change (UNFCCC), and in evaluating adaptation and mitigation options that could be used in progressing toward the ultimate objective of the UNFCCC (see Box 1). However, the assessment makes no attempt to quantify "dangerous anthropogenic interference with the climate system." Interpreting what is "dangerous" involves political judgment—a role reserved to governments and the Conference of Parties to the UNFCCC.

The UNFCCC's Article 2 explicitly acknowledges the importance of natural ecosystems, food security, and sustainable economic development. This report directly addresses these and other issues important to society, including water resources and human health. It assesses what is known about the impact of climate change on terrestrial and aquatic ecosystems, human health, and socioeconomic systems at varying time and geographic scales, as well as what is known about their vulnerability to climate change. A system's vulnerability to climate change depends on its sensitivity to changes in climate and its ability to adapt. The vulnerability assessment takes into account the different economic and institutional circumstances among developed and developing countries. It also recognizes the strong influence on most of these systems of other human-induced stresses (e.g., population demographics, land-use practices, industrialization, consumption patterns, air and water pollution, and soil degradation). Where possible, this assessment attempts to evaluate the sensitivity of systems and their potential for adaptation to: (i) changes in mean climate; (ii) changes in extreme weather events; (iii) changes in variability; (iv) the rate of climate change; and (v) the effects of elevated CO_2 concentrations on vegetation (via enhanced photosynthesis and water-use efficiency). The report also describes technical guidelines for assessing climate change impacts and adaptations.

This assessment also reviews and analyzes practices and technologies that (i) reduce anthropogenic emissions of greenhouse gases arising from the production and use of energy (industry, transportation, human settlements) and (ii) increase carbon storage (in what are generally called sinks) and reduce greenhouse gas emissions from agricultural, forestry, and rangeland

---

Box 1. Ultimate Objective of the UNFCCC (Article 2)

"...stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system. Such a level should be achieved within a time frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened, and to enable economic development to proceed in a sustainable manner."

---

systems. It also describes methodologies for assessing mitigation options and an inventory of technology characterizations.

2.   The Nature of the Issue: Projected Changes in Climate

Earth's climate has remained relatively stable (global temperature changes of less than 1°C over a century) during the last 10,000 years (the present interglacial period). Over this period, modern society has evolved and, in many cases, successfully adapted to the prevailing local climate and its natural variability. Now, however, society faces potentially rapid changes in future climate because of human activities that alter the atmosphere's composition and change the Earth's radiation balance.

Atmospheric concentrations of greenhouse gases (which tend to warm the atmosphere) and aerosols (which in some regions partially offset the greenhouse effect) have increased since the industrial era began around 1750. Carbon dioxide (CO_2) has risen by about 30%, methane (CH_4) by more than 100%, and nitrous oxide (N_2O) by about 15%. These gases now are at greater concentrations than at any time in the past 160,000 years (the period for which scientists can reconstruct historical climates and atmospheric compositions by analyzing ice-core data). The combustion of fossil fuels and, to a lesser extent, changes in land use account for anthropogenic CO_2 emissions. Agriculture is responsible for nearly 50% of human-generated CH_4 emissions and about 70% of anthropogenic N_2O emissions. Although CO_2 emissions far exceed those of CH_4 and N_2O, the global warming potentials of these latter two gases are relatively high. Hence, they represent significant contributors to the anthropogenic greenhouse effect. CO_2 has contributed about 65% of the combined radiative effects of the long-lived gases over the past 100 years; CH_4 and N_2O have contributed about 20 and 5%, respectively.

Most projections suggest that without policies specifically designed to address climate change greenhouse gas concentrations will increase significantly during the next century. Emissions of greenhouse gases and the sulfate aerosol precursor sulfur dioxide (SO_2) are sensitive to growth in population and gross domestic product (GDP), the rate of diffusion of new technologies into the market place, production and consumption patterns, land-use practices, energy intensity, the price and availability of energy, and other policy and institutional developments

Table 1: *Summary of assumptions in the six IPCC 1992 alternative scenarios.*

Scenario	Population	Economic Growth	Energy Supplies
IS92a,b	World Bank 1991 11.3 billion by 2100	1990–2025: 2.9% 1990–2100: 2.3%	12,000 EJ conventional oil 13,000 EJ natural gas Solar costs fall to $0.075/kWh 191 EJ of biofuels available at $70/barrel[a]
IS92c	UN Medium-Low Case 6.4 billion by 2100	1990–2025: 2.0% 1990–2100: 1.2%	8,000 EJ conventional oil 7,300 EJ natural gas Nuclear costs decline by 0.4% annually
IS92d	UN Medium-Low Case 6.4 billion by 2100	1990–2025: 2.7% 1990–2100: 2.0%	Oil and gas same as IS92c Solar costs fall to $0.065/kWh 272 EJ of biofuels available at $50/barrel
IS92e	World Bank 1991 11.3 billion by 2100	1990–2025: 3.5% 1990–2100: 3.0%	18,400 EJ conventional oil Gas same as IS92a,b Phase out nuclear by 2075
IS92f	UN Medium-High Case 17.6 billion by 2100	1990–2025: 2.9% 1990–2100: 2.3%	Oil and gas same as IS92e Solar costs fall to $0.083/kWh Nuclear costs increase to $0.09/kWh

[a]Approximate conversion factor: 1 barrel = 6 GJ.

Varney (eds.)]. Section A3, prepared by J. Leggett, W.J. Pepper, and R.J. Swart, and WMO/UNEP. Cambridge University Press, Cambridge, UK, 200 pp.

(see Table 1 for a summary of assumptions used in the six IPCC 1992 emissions scenarios). Figure 1 shows plausible ranges of CO_2 emissions, in the absence of emissions abatement policies, projected over the next 100 years in the IPCC IS92 emissions scenarios, which are reevaluated in the Working Group III volume of this 1995 assessment.

Climate models, taking into account greenhouse gases and aerosols, calculate that the global mean surface temperature could rise by about 1 to 3.5°C by 2100. This range of projections is based on the range of sensitivities of climate[1] to increases in greenhouse gas concentrations reported by IPCC Working Group I and plausible ranges of greenhouse gas emissions projected by IPCC in 1992. These projected global-average temperature changes would be greater than recent natural fluctuations and would occur at a rate significantly faster than any since the last ice age more than 10,000 years ago. High latitudes are projected to warm more than the global average. The reliability of regional projections remains low.

Model calculations, however, suggest the following:

- Climate warming will enhance evaporation, and global mean precipitation will increase, as will the frequency of intense rainfall. However, some land regions will not experience an increase in precipitation, and even those that do may experience decreases in soil moisture because of enhanced evaporation. Climate models also project seasonal shifts in precipitation. In general, models project that precipitation will increase at high latitudes in winter, and soil moisture will decrease in some mid-latitude continental regions during the summer.

- Variability associated with the enhanced hydrological cycle translates into prospects for more severe droughts and floods in some places, and less severe droughts and/or floods in other places. As a consequence, the incidence of fires and pest outbreaks may increase in some regions. It remains unclear whether the frequency and intensity of extreme weather events such as tropical storms, cyclones, and tornadoes will change.

- Regional and global climate changes are expected to have wide-ranging and potentially adverse effects on physical and ecological systems, human health, and socioeconomic sectors. These will affect the economy and the quality of life for this and future generations.

- Models project that sea level will increase by about 15 to 95 cm by 2100, allowing for average ice melt, but could be either higher or lower than this range.

_____

[1] Climate sensitivity is the equilibrium change in global annual mean surface temperature due to a doubling of atmospheric concentration of CO_2 (or equivalent doubling of other greenhouse gases).
Figure 1: Projected anthropogenic CO_2 emissions from fossil fuel use, deforestation, and cement production for the six IPCC 1992 scenarios (IS92a-f)—from *Climate Change 1994: Radiative Forcing of Climate Change and An Evaluation of the IPCC IS92 Emission Scenarios* (IPCC, 1995).

Policymakers are faced with responding to the risks posed by anthropogenic emissions of greenhouse gases in the face of significant scientific uncertainties. It is appropriate to consider these uncertainties in the context of information indicating that climate-induced environmental changes cannot be reversed quickly, if at all, due to the long time scales associated with the climate system (see Box 2). Decisions taken during the next few years may limit the range of possible policy options in the future, because high near-term emissions would require deeper reductions in the future to meet any given target concentrations. Delaying action might reduce the overall costs of mitigation because of potential technological advances but could increase both the rate and eventual magnitude of climate change, hence the adaptation and damage costs.

Policymakers will have to decide to what degree they want to take precautionary measures by mitigating greenhouse gas emissions and enhancing the resilience of vulnerable systems by means of adaptation. Uncertainty does not mean that a nation or the world community cannot position itself better to cope with the broad range of possible climate changes or protect against potentially costly future outcomes. Delaying such measures may leave a nation or the world poorly prepared to deal with adverse changes and may increase the possibility of irreversible or very costly consequences. Options for adapting to change or mitigating change that can be justified for other reasons today (e.g., abatement of air and water pollution) and make society more flexible or resilient to anticipated adverse effects of climate change appear particularly desirable.

3. Vulnerability to Climate Change: Impacts and Adaptation

This section discusses the sensitivity, adaptability, and vulnerability (see Box 3) of physical and ecological systems, human health, and socioeconomic sectors to changes in climate. It begins with a number of common conclusions, then describes to the extent possible (i) the functions and current status of each system; (ii) the sensitivity of each system to climate change and to other environmental and human-induced factors; and (iii) the vulnerability of each system to climate change, taking into account adaptation options and impediments to adaptation.

Although we have made much progress in understanding the climate system and the consequences of climate change, large uncertainties cloud our view of the 21st century. In particular,

---

Box 2. Time Scales of Processes Influencing the Climate System

- Turnover of the capital stock responsible for emissions of greenhouse gases: ***Years to decades*** (without premature retirement)
- Stabilization of atmospheric concentrations of long-lived greenhouse gases given a stable level of greenhouse gas emissions: ***Decades to millennia***
- Equilibration of the climate system given a stable level of greenhouse gas concentrations: ***Decades to centuries***
- Equilibration of sea level given a stable climate: ***Centuries***
- Restoration/rehabilitation of damaged or disturbed ecological systems: ***Decades to centuries*** (some changes, such as species extinction, are irreversible, and it may be impossible to reconstruct and reestablish some disturbed ecosystems)

Box 3. Sensitivity, Adaptability, and Vulnerability

Sensitivity is the degree to which a system will respond to a change in climatic conditions (e.g., the extent of change in ecosystem composition, structure, and functioning, including primary productivity, resulting from a given change in temperature or precipitation).

Adaptability refers to the degree to which adjustments are possible in practices, processes, or structures of systems to projected or actual changes of climate. Adaptation can be spontaneous or planned, and can be carried out in response to or in anticipation of changes in conditions.

Vulnerability defines the extent to which climate change may damage or harm a system. It depends not only on a system's sensitivity but also on its ability to adapt to new climatic conditions.

Both the magnitude and the rate of climate change are important in determining the sensitivity, adaptability, and vulnerability of a system.

our understanding of some key ecological processes remains limited. So does our current ability to predict regional climate changes, future conditions in the absence of climate change, or to what degree climate will become more variable. Changes in average conditions, climate variability, and the frequency and intensity of extreme weather events all would have important implications for both ecological and social systems.

3.1.   Common Themes and Conclusions

Human health, terrestrial and aquatic ecological systems, and socioeconomic systems (e.g., agriculture, forestry, fisheries, and water resources) are all vital to human development and well-being, and are all sensitive to changes in climate. Whereas many regions are likely to experience the adverse effects of climate change—some of which are potentially irreversible—some effects of climate change are likely to be beneficial. Hence, different segments of society can expect to confront a variety of changes and the need to adapt to them. The following conclusions apply to many ecological and socioeconomic systems:

- **Human-induced climate change adds an important new stress**. Human-induced climate change represents an important additional stress, particularly to the many ecological and socioeconomic systems already affected by pollution, increasing resource demands, and nonsustainable management practices. The most vulnerable systems are those with the greatest sensitivity to climate changes and the least adaptability.
- **Most systems are sensitive to climate change**. Natural ecological systems, socioeconomic systems, and human health are all sensitive to both the magnitude and the rate of climate change.
  - *Natural ecosystems*. The composition and geographic distribution of many ecosystems will shift as individual species respond to changes in climate; there will likely be reductions in biological diversity and in the goods and services that ecosystems provide society—for example, sources of food, fiber, medicines, recreation and tourism, and ecological services such as nutrient cycling, waste assimilation, and controlling water runoff and soil erosion. Large amounts of carbon could be released into the atmosphere during periods of high forest mortality in the transition from one forest type to another.
  - *Food security*. Some regions, especially in the tropics and subtropics, may suffer significant adverse consequences for food security, even though the effect of climate change on global food production may prove small to moderate.
  - *Sustainable economic development*. Some countries will face threats to sustainable development from losses of human habitat due to sea-level rise, reductions in water quality and quantity, disruptions from extreme events, and an increase in human diseases (particularly vector-borne diseases such as malaria).

- **Impacts are difficult to quantify, and existing studies are limited in scope**. While our knowledge has increased significantly during the last decade and qualitative estimates can be developed, quantitative projections of the impacts of climate change on any particular system at any particular location are difficult because regional scale climate change projections are uncertain; our current understanding of many critical processes is limited; and systems are subject to multiple climatic and non-climatic stresses, the interactions of which are not always linear or additive. Most impact studies have assessed how systems would respond to climate change resulting from an arbitrary doubling of equivalent atmospheric CO_2 concentrations. Furthermore, very few studies have considered dynamic responses to steadily increasing greenhouse gas concentrations; fewer still have examined the consequences of increases beyond a doubling of equivalent atmospheric CO_2 concentrations or assessed the implications of multiple stress factors.
- **Successful adaptation depends upon technological advances, institutional arrangements, availability of financing, and information exchange**. Technological advances generally have increased adaptation options for managed systems such as agriculture and water supply. However, many regions of the world currently have limited access to these technologies and appropriate information. The efficacy and cost-effective use of adaptation strategies will depend upon the availability of financial resources, technology transfer, and cultural, educational, managerial, institutional, legal, and regulatory practices, both domestic and international in scope. Incorporating climate-change concerns into resource-use and development decisions and plans for regularly scheduled investments in infrastructure will facilitate adaptation.
- **Vulnerability increases as adaptive capacity decreases**. The vulnerability of human health and socioeconomic systems—and to a lesser extent ecological systems—depends upon economic circumstances and institutional infrastructure. This implies that systems typically are more vulnerable in developing countries where economic and institutional circumstances are less favorable. People who live on arid or semi-arid lands, in low-lying coastal areas, in water-limited or flood-prone areas, or on small islands are particularly vulnerable to climate change. Some regions have become more vulnerable to hazards such as storms, floods, and droughts as a result of increasing population density in sensitive areas such as river basins and coastal plains. Human activities, which fragment many landscapes, have increased the vulnerability of lightly managed and unmanaged ecosystems. Fragmentation limits natural adaptation potential and the potential effectiveness of measures to assist adaptation in these systems, such as the provision of migration corridors. A changing climate's near-term effects on ecological and socioeconomic

systems most likely will result from changes in the intensity and seasonal and geographic distribution of common weather hazards such as storms, floods, and droughts. In most of these examples, vulnerability can be reduced by strengthening adaptive capacity.

- **Detection will be difficult and unexpected changes cannot be ruled out**. Unambiguous detection of climate-induced changes in most ecological and social systems will prove extremely difficult in the coming decades. This is because of the complexity of these systems, their many non-linear feedbacks, and their sensitivity to a large number of climatic and non-climatic factors, all of which are expected to continue to change simultaneously. The development of a baseline projecting future conditions without climate change is crucial, for it is this baseline against which all projected impacts are measured. The more that future climate extends beyond the boundaries of empirical knowledge (i.e., the documented impacts of climate variation in the past), the more likely that actual outcomes will include surprises and unanticipated rapid changes.

- **Further research and monitoring are essential**. Enhanced support for research and monitoring, including cooperative efforts from national, international, and multilateral institutions, is essential in order to improve significantly regional-scale climate projections; to understand the responses of human health, ecological, and socioeconomic systems to changes in climate and other stress factors; and to improve our understanding of the efficacy and cost-effectiveness of adaptation strategies.

Figure 2: This figure illustrates that mean annual temperature and mean annual precipitation can be correlated with the distribution of the world's major biomes. While the role of these annual means in affecting this distribution is important, it should be noted that the distribution of biomes may also strongly depend on seasonal factors such as the length of the dry season or the lowest absolute minimum temperature, on soil properties such as water-holding capacity, on land-use history such as agriculture or grazing, and on disturbance regimes such as the frequency of fire.

3.2. Terrestrial Ecosystems

Ecosystems contain the Earth's entire reservoir of genetic and species diversity, and provide goods and services critical to individuals and societies. These services include (i) providing food, fiber, medicines, and energy; (ii) processing and storing carbon and other nutrients, which affect the atmospheric concentrations of greenhouse gases; (iii) regulating water runoff, thus controlling floods and soil erosion; (iv) assimilating wastes and purifying water; and (v) providing opportunities for recreation and tourism. These systems and the functions they provide are sensitive to the rate and extent of changes in climate. Figure 2 illustrates that mean annual temperature and mean annual precipitation can be correlated with the distribution of the world's major biomes. While the role of these annual means in affecting this distribution appears to be important, it should be noted that the distribution of biomes also strongly depends on seasonal factors and other non-climate conditions, such as soil properties and disturbance regimes.

Changes in climate and associated changes in the frequency of fires and the prevalence of pests could alter various properties of terrestrial ecosystems. These include structure (physical arrangement, density of populations, species composition),

function (movement of energy and material within ecosystems), and productivity (rates and magnitudes of carbon fixation and respiration).

Most terrestrial ecosystems are under major pressures from population increases and human decisions about land use, which probably will continue to cause the largest adverse effects for the foreseeable future. However, continuing climate change would induce a disassembly of existing ecosystems and an ongoing assembly of plants and animals into new ecosystems—a process that may not reach a new equilibrium for several centuries after the climate achieves a new balance.

In analyzing the potential impacts of climate change, researchers must consider how species and ecosystems respond to elevated concentrations of atmospheric CO_2. Higher CO_2 concentrations may increase the net primary productivity (NPP) of plants, which would alter species composition by changing the competitive balance among different plants. Although biologists have quantified these effects at the leaf to plant level in controlled settings, such effects are only now being quantified at the ecosystem level. This is because of the complex interactions among plants in their natural environments, which depend

---

Box 4. Regional Implications of Climate Change for Forests

Tropical forests. It is likely that temperature increases will have a smaller impact on tropical forests than on temperate or boreal forests, because models project that temperatures will increase less in the tropics than at other latitudes. However, tropical forests are very sensitive to the amount and seasonality of rainfall. In general, human activities causing conversion to other land-cover types will likely affect tropical forests more than climate change. If CO_2 fertilization is important, it may lead to a gain in net carbon storage because of the slow rate at which the associated soil respiration increases in this zone.

Temperate forests. In some temperate forests, NPP may increase due to warming and increased atmospheric CO_2. However, in other regions warming-induced water shortages, pest activity, and fires may cause decreased NPP and possible changes in temperate forest distribution. Most temperate forests are located primarily in developed countries that have the resources to reduce the impacts of climate change on their forests through integrated fire, pest, and disease management, and/or encouraging reforestation.

Boreal forests. As warming is expected to be particularly large at high latitudes, and as boreal forests are more strongly affected by temperature than forests in other latitudinal zones, climatic change is likely to have its greatest impact on boreal forests. Increased fire frequency and pest outbreaks are likely to decrease the average age, biomass and carbon store, with greatest impact at the southern boundary, where the boreal coniferous forest is likely to give way to temperate zone pioneer species or grasslands. Northern treelines are likely to advance slowly into regions currently occupied by tundra. The NPP of forests that are not limited by water availability is likely to increase in response to warming, partly mediated by increased nitrogen mineralization. However, there may be a net loss of carbon from the ecosystem because of associated increases in soil organic matter decomposition.

---

upon changes in factors such as temperature, soil moisture, and the availability of nutrients. To date, the magnitude and persistence of the CO_2 fertilization effect remains unquantified. Despite increases in plant growth anticipated from CO_2 fertilization, the total amount of carbon stored in an ecosystem may still decrease because increased temperature also stimulates the decomposition of dead leaves and soil organic matter.

In addition to the changes within ecosystems, temperature changes and increased CO_2 could result in significant alterations in the overall distribution of the world's biomes. Figure 3 shows the potential distribution of the major world biomes under current climate conditions and a doubled CO_2-equivalent climate-change scenario. The possible effects of climate change on the boundaries of forests and rangelands are discussed further in Boxes 4 and 5. The consequences for some terrestrial ecosystems depend critically on how fast climate zones shift. The rates of these shifts are important in part because different plant species migrate at different rates, depending on their growth and reproductive cycles.

3.2.1.   Forests

Forests contain a wide range of species with complex life cycles. These ecosystems contain 80% of all aboveground carbon in vegetation and about 40% of all soil carbon. Forests and forest soils also play a major role in the carbon cycle as sources (e.g., forest degradation and deforestation) and sinks (reforestation, afforestation, and possibly enhanced growth resulting from carbon dioxide fertilization). Forests, particularly in the tropics, harbor as much as two-thirds of the world's biodiversity. They

directly affect climate up to the continental scale by influencing ground temperatures, evapotranspiration, surface roughness, albedo, cloud formation, and precipitation.

A variety of biological, chemical, and physical factors affect forest ecosystems. Forest productivity and the number of species generally increase with increasing temperature, precipitation, and nutrient availability. Forests are particularly vulnerable to and may decline rapidly under extreme changes in water availability (either drought or waterlogging). Models project that a sustained increase of 1°C in global mean temperature is sufficient to cause changes in regional climates that will affect the growth and regeneration capacity of forests in many regions. In several instances, this will alter the function and composition of forests significantly. As a consequence of possible changes in temperature and water availability under doubled equivalent-CO_2 equilibrium conditions, a substantial fraction (a global average of one-third, varying by region from one-seventh to two-thirds) of the existing forested area of the world will undergo major changes in broad vegetation types—with the greatest changes occurring in high latitudes.

Climate change is expected to occur rapidly relative to the speed at which forest species grow, reproduce, and reestablish themselves. For mid-latitude regions, an average global warming of 1–3.5°C over the next 100 years would be equivalent to shifting isotherms poleward approximately 150–550 km or an altitude shift of 150–550 m; in low latitudes, temperatures would generally be increased to higher levels than now exist. This compares to past tree species migration rates on the order of 4–200 km per century. Entire forest types may disappear, and new ecosystems may take their places.

FIGURE TS-3 GOES HERE!!

Box 5. Regional Implications of Climate Change for Rangelands

Tropical rangelands. Temperature increases *per se* should not lead to major alterations in tropical rangelands, except where infrequent frosts currently limit some species. The most severe consequences could result from altered rainfall (seasonality and amount). Increasing carbon-to-nitrogen ratios could also result in reduced forage quality and palatability. The influence of increasing concentrations of CO_2 on photosynthesis and greater growth would have a major impact on the productivity of these rangelands.

Temperate rangelands. Climate change clearly will alter temperate rangelands and associated savannas and shrublands. Because of the high correlation between rangeland types and climate belts, any shifts in temperature and precipitation will bring corresponding shifts in rangeland boundaries. Continental areas that experience drier conditions during the growing season may see a shift from grasslands to shrublands.

Tundra. Tundra systems should exhibit high sensitivity to climatic warming. Indirect temperature effects, especially those associated with decreases in the amount of frozen soil and with changes in nutrient availability, will result in shifts in species composition. Changes in precipitation and temperature could decrease soil moisture in high-latitude tundra systems, changing some tundra systems from net sinks to net sources of carbon dioxide to the atmosphere while also increasing surface oxidation and decreasing methane flux.

Mature forests are a large terrestrial store of carbon. In general, temperate and tropical forests contain as much carbon aboveground as belowground, but boreal forests contain most of their carbon belowground. It remains unclear whether forests will continue to sequester carbon through growth under less suitable conditions than exist today. Although NPP could increase, the standing biomass of forests may not because of more frequent outbreaks and extended ranges of pests and pathogens, and increasing frequency and intensity of fires. Large amounts of carbon could be released into the atmosphere during transitions from one forest type to another, because the rate at which carbon can be lost during times of high forest mortality is greater than the rate at which it can be gained through growth to maturity.

3.2.2.   *Rangelands*

Rangelands (i.e., unimproved grasslands, shrublands, savannas, deserts, and tundra) occupy 51% of the Earth's land surface. They contain about 36% of its total carbon in living and dead biomass, include a large number of economically important species and ecotypes, and sustain millions of people. Rangelands support 50% of the world's livestock and provide forage for domesticated animals and wildlife.

The amounts and seasonal distribution of precipitation are the primary controls on rangeland carbon cycling and productivity. Water availability and balance play vital roles in controlling the productivity and geographic distribution of rangeland ecosystems; thus, small changes in extreme temperatures and precipitation may have disproportionate effects.

Increases in CO_2 likely will result in reductions of forage quality and palatability because of increasing carbon-to-nitrogen ratios and shrub encroachment. These effects will become more evident in low-latitude rangelands, where the low nutritional value of forage already creates a chronic problem.

Boundaries between rangelands and other ecosystems appear likely to change as a result of direct climate effects on species composition as well as indirect factors such as changes in wildfire frequency and land use. Temperate rangelands will experience these effects the most. Migration rates of rangeland vegetation appear to be faster than for forests.

Precipitation and temperature variations associated with climate change may alter the role of high-latitude tundra systems in the carbon cycle. During the past decade, some tundra systems have shifted from a net sink to a net source of atmospheric CO_2, perhaps due to decreased soil moisture associated with warmer summers (a positive climate feedback). The tundra and taiga (subarctic evergreen forests) also provide 10% of the global atmospheric input of CH_4. Warming-related changes may dry soils and increase surface oxidation, thus decreasing CH_4 releases (a negative climate feedback).

Devising adaptation strategies for rangeland systems may prove difficult in marginal food-producing areas where production is very sensitive to climate change, changing of technology is risky, and the rate of adoption of new techniques and practices is slow. Decreases in rangeland productivity would result in a decline in the overall contribution of the livestock industries to national economies, with serious implications for food production in many developing areas with pastoral economies. Adaptation options in more highly managed pastures include management of forage, animal breeding, pasture renewal, and irrigation.

3.2.3.   *Deserts and Land Degradation*

If the Earth's climate does change as projected in current scenarios, conditions in most deserts are likely to become more extreme—in that, with few exceptions, they are projected to become hotter but not significantly wetter. Temperature

increases, in particular, could be a threat to organisms that now exist near their heat-tolerance limits. The impacts of climate change on water balance, hydrology, and vegetation remain uncertain and would probably vary significantly among regions.

Land degradation—which reduces the physical, chemical, or biological quality of land and lowers its productive capacity—already poses a major problem in many countries. Current general circulation models (GCMs) project that in some regions, climate change will increase drought and result in rainfall of higher intensity and more irregular distribution. This could increase the potential for land degradation, including loss of organic matter and nutrients, weakening of soil structure, decline in soil stability, and an increase in soil erosion and salinization. Areas that experience increased rainfall and soil moisture will benefit from the opportunities for more flexible use. However, they may experience stronger leaching, leading to increased acidification and loss of nutrients. In appropriate situations, additions of lime and fertilizers or conservation management policies could correct these deficiencies.

Desertification, as defined by the United Nations Convention to Combat Desertification, is land degradation in arid, semi-arid, and dry sub-humid areas resulting from various factors, including climatic variations and human activities. Droughts may trigger or accelerate desertification by reducing the growth of important plant species. Grazing can strip the land of its cover under these conditions. However, the amount of precipitation needed to sustain growth varies with the temperature, soil moisture capacity, and species. Desertification is more likely to become irreversible if the environment becomes drier and the soil becomes further degraded through erosion and compaction. Adaptation to drought and desertification may rely on the development of diversified production systems, such as agroforestry techniques and ranching of animals better adapted to local conditions. However, adaptation also needs political, social, extension service, and educational inputs.

3.2.4.   Cryosphere

Many components of the cryosphere (i.e., snow, ice, and permafrost) are particularly sensitive to changes in atmospheric temperature. The last century has witnessed a massive loss and retreat of mountain glaciers, a reduction in the areal distribution of permafrost, and evidence of later freeze-up and earlier break-up of river and lake ice in many northern countries. These observations are consistent with a 0.5°C increase in the annual global mean temperature during the last century.

Projected changes in climate will substantially reduce the extent and volume of the cryosphere over the next century, causing pronounced reductions in mountain glaciers, permafrost, and seasonal snow cover. By the year 2100, between one-third and one-half of all mountain glaciers could disappear. The reduced extent of glaciers and depth of snow cover would affect the seasonal distribution of river flow, with potential implications for water resources (e.g., hydroelectric generation, agriculture). Data on

iceberg calving from ice sheets and expected changes in calving as a result of projected temperature increases are inconclusive, although some scientists suggest that certain ice shelves currently are breaking up systematically. Little change in the extent of the Greenland and Antarctic ice sheets is expected over the next 50–100 years. An increase in temperature would extend the duration of the navigation season on rivers and lakes affected by seasonal ice cover. Projected reductions in the extent and thickness of the sea-ice cover in the Arctic Ocean and its peripheral seas could substantially benefit shipping, perhaps opening the Arctic Ocean as a major trade route. A reduction in the areal extent and depth of permafrost would have serious consequences for a number of human activities. Thawing of permafrost releases CH_4 hydrates.

3.2.5.   Mountain Regions

Mountains cover about 20% of continental surfaces and serve as an important water source for most of the world's major river systems. Mountain ecosystems are under considerable stress from humans, and climate change will exacerbate existing conflicts between environmental and socioeconomic concerns.

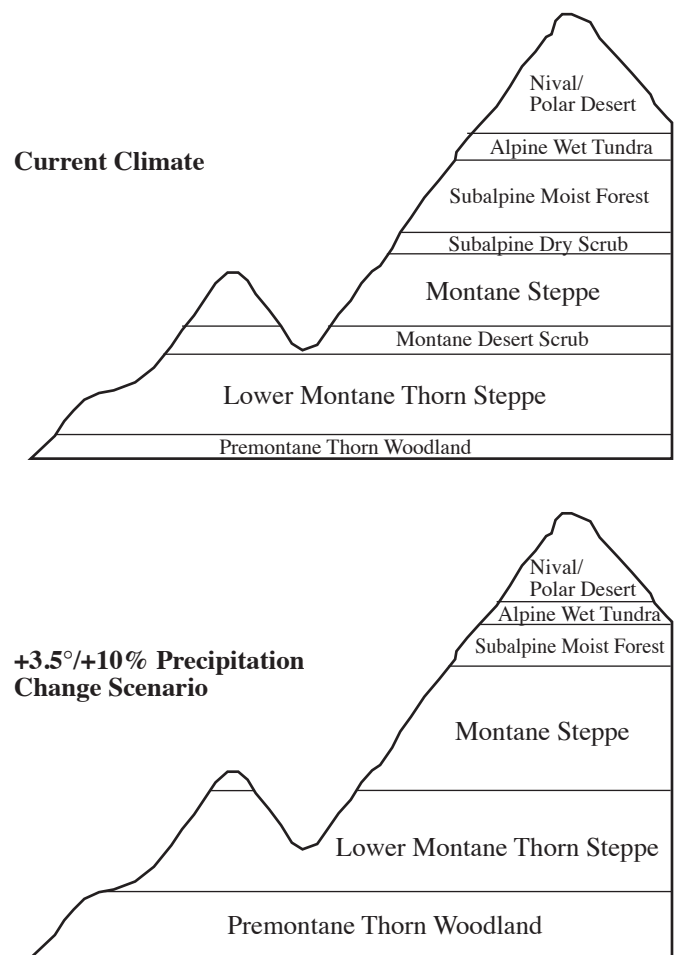

Figure 4: Comparison of current vegetation zones at a hypothetical dry temperate mountain site with simulated vegetation zones under a climate-warming scenario. Source: Beniston, 1994 (see Chapter 5 for complete citation).

Paleologic records indicate that past warming of the climate has caused the distribution of vegetation to shift to higher elevations, resulting in the loss of some species and ecosystems. Simulated scenarios for temperate-climate mountain sites suggest that continued warming could have similar consequences (see Figure 4), thus species and ecosystems with limited climatic ranges could disappear because of disappearance of habitat or reduced migration potential.

In most mountain regions, a warmer climate will reduce the extent and volume of glaciers and the extent of permafrost and seasonal snow cover. Along with possible precipitation changes, this would affect soil stability and a range of socioeconomic activities (e.g., agriculture, tourism, hydropower, and logging). Climate change may disrupt mountain resources for indigenous populations (e.g., fuel and subsistence and cash crops) in many developing countries. Recreational activities, which are increasingly important economically to many regions, also face likely disruptions. People living outside mountain regions who use water originating in them also would experience significant consequences.

Because of their climatic and habitat diversity, mountains provide excellent locations for maintaining biological diversity. In particular, large north-south mountain chains such as the Andes can facilitate migration under changing climate if appropriately managed.

3.3. *Aquatic Ecosystems*

Aquatic ecosystems encompass lakes and streams, non-tidal wetlands, coastal environs, and oceans. These systems are sensitive to changes in temperature, precipitation, and sea level and in turn exert important feedbacks on climate by influencing carbon fluxes. They provide a range of socioeconomic values and benefits—including food, energy, transportation, timber, flood mitigation, erosion control, water supply, and recreation.

3.3.1. *Lakes and Streams*

Climate change will influence lakes and streams through altered water temperatures, flow regimes, and water levels. These will directly affect the survival, reproduction, and growth of organisms; the productivity of ecosystems; the persistence and diversity of species; and the regional distribution of biota. Climatic warming would tend to shift geographic ranges of many species poleward by approximately 150 km for every 1°C increase in air temperature. Changes in the heat balance of lakes would alter their mixing properties, which would have large effects on their primary productivity. Changes in runoff and groundwater flows to lakes and streams would alter the input of nutrients and dissolved organic carbon, which in turn would alter the productivity and clarity of the waters. Changes in hydrologic variability are expected to have greater ecological effects than changes in mean values. For example, increased frequency or duration of flash floods and droughts

would reduce the biological diversity and productivity of stream ecosystems.

Although the effects on lake and stream ecosystems will vary with the distribution of climate changes, some general conclusions emerge. Warming would have the greatest biological effects at high latitudes, where biological productivity would increase, and at the low-latitude boundaries of cold- and cool-water species ranges, where appropriate thermal habitat would become more fragmented and extinctions would be greatest. The rate of climatic warming may exceed the rate of shifts in species ranges. Warming of the larger and deeper temperate lakes will increase their productivity and thermal habitat favorable for native fishes, whereas warming of shallow lakes and streams could lead to increased anoxia and reduction in suitable habitat. Deep tropical lakes may become less productive as thermal stratification intensifies and nutrients become trapped below the mixed layer. Lakes and streams in dry, evaporative drainages and in basins with small catchments are most sensitive to changes in precipitation and would experience the most severe water-level declines if precipitation were to decrease. For many lakes and streams, the most severe effects of climate change may be the exacerbation of current stresses resulting from human activities, including increasing demands for consumptive uses, increasing waste effluent loadings and runoff of agricultural and urban pollutants, and altered water balance and chemical input rates from landscape disturbance and atmospheric deposition.

3.3.2. *Non-Tidal Wetlands*

Wetlands are areas of low-lying land where the water table lies at or near the surface for some defined period of time, producing extensive shallow, open water and waterlogged areas. Wetlands exist on every continent (except Antarctica), in both inland and coastal areas, and cover approximately 4–6% of the Earth's land surface. Human activities such as agricultural development, construction of dams and embankments, and peat mining already threaten these ecosystems and have contributed to the disappearance of more than half of the world's wetlands during the last century. Non-tidal (primarily inland) wetlands provide refuge and breeding grounds for many species, including a large number with commercial value; are an important repository of biodiversity; control floods and droughts; and improve water quality. They also serve as a carbon sink. Boreal and subarctic peatlands store an estimated 412 Gt C, or about 20% of the global organic carbon stored in soils.

Climate change will most greatly influence wetlands by altering their hydrologic regimes (increasing or decreasing water availability; changing the depth, duration, frequency, and season of flooding). These changes will affect the biological, biogeochemical, and hydrological functions of wetlands and alter their value to societies for such functions as aquifer recharge, sediment retention, waste processing, and carbon storage. There will be an impact of climate change on greenhouse gas release from non-tidal wetlands, but there is uncertainty

regarding the exact effects from site to site; some arctic areas already have shifted from weak carbon sinks to weak CO_2 sources due to drying.

The geographical distribution of wetlands is likely to shift with changes in temperature and precipitation. Warming would severely affect wetlands in arctic and subarctic regions by thawing permafrost, which is key to maintaining high water tables in these ecosystems.

Possibilities for adaptation, conservation, and restoration in response to climate change vary among wetland types and their various functions. For regional and global functions (e.g., trace-gas fluxes and carbon storage), no responses exist that humans can apply at the necessary scale. For wetland functions at the local scale (habitat value, pollution trapping, and, to some degree, flood control), possibilities do exist. However, interest in wetland creation and restoration has outpaced the science and technology needed to successfully create wetlands for many specific purposes.

3.3.3. Coastal Ecosystems

Many commercially important marine species depend on coastal ecosystems for some part of their life cycle, and some coastal ecosystems (e.g., coral reefs, mangrove communities, and beaches) provide an important buffer against storms and surges. Sea-level rise, altered rainfall patterns, and changes in ocean temperature likely will result in additional adverse impacts on coastal ecosystems, particularly where human activities already affect environmental conditions.

Coastal systems are ecologically and economically important, and are expected to vary widely in their response to changes in climate and sea level. Climate change and a rise in sea level or changes in storms or storm surges could result in the displacement of wetlands and lowlands, erosion of shores and associated habitat, increased salinity of estuaries and freshwater aquifers, altered tidal ranges in rivers and bays, changes in sediment and nutrient transport, a change in the pattern of chemical and microbiological contamination in coastal areas, and increased coastal flooding. In many areas, intensive human alteration and use of coastal environments already have reduced the capacity of natural systems to respond dynamically. Other regions, however, may prove far less sensitive and may keep pace with climate and sea-level change. This suggests that future impact analyses must be carried out region by region.

Nonetheless, research findings strongly indicate that some coastal ecosystems face particular risks from changes in climate and sea level. A number of regional studies show the disappearance of saltwater marshes, mangrove ecosystems, and coastal wetlands at a rate of 0.5–1.5% per year over the last few decades. The interaction of climate change, sea-level rise, and human development will further threaten these particularly sensitive ecosystems. Climate-change impacts on coastal ecosystems will vary widely. The sea level may rise faster than sediment accretion rates in many coastal areas; thus, existing wetlands will disappear faster than new ones appear. Ecosystems on coral atolls and in river deltas show special sensitivity to climate and sea-level change. Changes in these ecosystems almost certainly would have major negative effects on tourism, freshwater supplies, fisheries, and biodiversity. Such impacts would further modify the functioning of coastal oceans and inland waters already stressed by pollution, physical modification, and material inputs due to human activities.

Coral reefs are the most biologically diverse marine ecosystems; they also are very sensitive to climate change. Short-term increases in water temperatures on the order of only 1–2°C can cause "bleaching," leading to reef destruction. Sustained increases of 3–4°C above long-term average seasonal maxima over a 6-month period can cause significant coral mortality. Biologists suggest that fully restoring these coral communities could require several centuries. A rising sea level also may harm coral reefs. Although available studies indicate that even slow-growing corals can keep pace with the "central estimate" of sea-level rise (approximately 0.5 cm per year), these studies do not take account of other pressures on coral populations, such as pollution or enhanced sedimentation.

3.3.4. Oceans

Oceans occupy 71% of the Earth's surface. They provide an important component of the climate system, due to their role in controlling the distribution and transfer of heat and CO_2 (internally and with the atmosphere) and in the transfer of water back to the continents as precipitation. They provide vital mineral resources, an environment for living resources ranging from phytoplankton to whales, and support for socioeconomic activities such as transportation, fishing, and recreation.

Oceans are sensitive to changes in temperature, freshwater inputs from continents and atmospheric circulation, and the interaction of these factors with other environmental factors such as ultraviolet-B (UV-B) radiation and pollution (which is especially important in inland seas, bays, and other coastal areas). Climate change may alter sea level, increasing it on average, and could also lead to altered ocean circulation, vertical mixing, wave climate, and reductions in sea-ice cover. As a result, nutrient availability, biological productivity, the structure and functions of marine ecosystems, the ocean's heat- and carbon-storage capacity, and important feedbacks to the climate system will change as well. These changes would have implications for coastal regions, fisheries, tourism and recreation, transport, off-shore structures, and communication. Paleoclimatic data and model experiments suggest that abrupt climatic changes can occur if freshwater influx from the movement and melting of sea ice or ice sheets significantly weakens global thermohaline circulation (the sinking of dense surface waters in polar seas that moves bottom water toward the equator).

3.4.   *Water*

Water availability is essential to national welfare and productivity. The world's agriculture, hydropower production, municipal and industrial water supply, instream ecosystems, water-based recreation, and inland navigation depend on surface and groundwater resources. The quantity and quality of water supplies pose a serious problem today in many regions, including some low-lying coastal areas, deltas, and small islands. Water availability already falls below 1,000 m^3 per person per year—a common benchmark for water scarcity—in a number of countries (e.g., Kuwait, Jordan, Israel, Rwanda, Somalia, Algeria, Kenya). Other nations likely to fall below this benchmark in the next 2 to 3 decades include Libya, Egypt, South Africa, Iran, and Ethiopia. In addition, a number of countries in conflict-prone areas depend on water originating outside their borders (e.g., Cambodia, Syria, Sudan, Egypt, Iraq). This makes them quite vulnerable to any additional reduction in indigenous water supplies. The depletion of aquifers, urbanization, land-cover changes, and contamination exacerbate the problem of water availability.

A changing climate will lead to an intensification of the global hydrological cycle, which determines how precipitation is partitioned between ground and surface water storage (including snow cover), fluxes to the atmosphere, and flows to the oceans. Changes in the total amount of precipitation and in its frequency and intensity directly affect the magnitude and timing of runoff and the intensity of floods and droughts; however, at present, specific regional effects are uncertain. In addition, changes in the hydrological cycle affect land cover and the surface energy balance, thus altering important feedbacks on the climate system.

Relatively small changes in temperature and precipitation, together with the non-linear effects on evapotranspiration and soil moisture, can result in relatively large changes in runoff, especially in arid and semi-arid lands. High-latitude regions may experience increased runoff due to increased precipitation, whereas runoff may decrease at lower latitudes due to the combined effects of increased evapotranspiration and decreased precipitation. Even in areas where models project a precipitation increase, higher evaporation rates may lead to reduced runoff. More intense rainfall would tend to increase runoff and the risk of flooding, although the magnitude of the effect would depend on both an area's rainfall change and its catchment characteristics. This effect could be exacerbated in regions where extensive reductions occur in vegetation (e.g., deforestation, overgrazing, logging). Winter snowfall and spring snowmelt determine the flow rates of rivers and streams in many continental and mountain areas. Should the climate change and the proportion of precipitation falling as snow decrease, widespread reductions in spring runoff and increases in winter runoff seem likely. These changes would have consequences for water storage and delivery systems, irrigation, and hydroelectricity production.

Many factors, including changes in vegetation, population growth, and industrial and agricultural demands complicate an assessment of the potential effects of climate change on water resources. Current understanding suggests that climate change can have major impacts on regional water supplies. At present, general circulation models only provide projections on a large geographic scale. They do not agree on a likely range of changes in average annual precipitation for any given basin or watershed, hence fail to provide sufficient information to assist water managers in making decisions.

A change in the volume and distribution of water would affect all of a region's water uses. The impacts, however, will depend also on the actions of water users and managers, who will respond not only to climate change but also to population growth and changes in demands, technology, and economic, social, and legislative conditions. In some cases—particularly in wealthier countries with integrated water-management systems—these actions may protect water users from climate change at minimal cost. In many others however—particularly those regions that already are water-limited—substantial economic, social, and environmental costs could occur. Water resources in arid and semi-arid zones are particularly sensitive to climate variations because of low-volume total runoff and infiltration and because relatively small changes in temperature and precipitation can have large effects on runoff. Irrigation—the largest use of water in many countries—will be the first activity affected in regions where precipitation decreases. This is because in some regions water used for agriculture costs less than water for domestic and industrial activities. During water shortages, allocations to agriculture will most likely decline before allocations to those other uses.

The increased uncertainty in the future supply and demand of water resources raises a key issue for water management. Countries with high population growth rates are likely to experience significant decreases in per capita water availability even without climate change. The issue is complicated further when projected climate change is taken into account. Based on outputs from transient climate models, hydrological models indicate that per capita water availability would vary widely, from slight increases in percentage of water available per capita to large percentage decreases, for the countries considered. Significant differences in the regional distribution of water deficits and surpluses also may occur within each country.

Options for dealing with the possible impacts of a changed climate and increased uncertainty about future supply and demand for freshwater include:

- More efficient management of existing supplies and infrastructure
- Institutional arrangements (e.g., market and regulatory measures) to limit future demands on scarce water supplies
- Improved hydrological monitoring and forecasting systems and establishment of early warning systems for floods/drought
- Rehabilitation of presently denuded tracts of upland watersheds, especially in the tropics

- Construction of new reservoir capacity to capture and store excess flows produced by altered patterns of snowmelt and storms (although this often would be difficult to plan in the absence of improved watershed climate information).

Water managers, in a continuously adaptive enterprise, respond to changing demographic and economic demands, information, and technologies. Experts disagree about whether water supply systems will evolve substantially enough in the future to compensate for the anticipated negative impacts of climate change and the anticipated increases in demand.

3.5. Food and Fiber

Two broad classes of climate-induced effects influence the quality and quantity of agricultural and forestry yields: (i) direct effects from changes in temperature, water balance, atmospheric composition, and extreme events; and (ii) indirect effects through changes in the distribution, frequency, and severity of pest and disease outbreaks, incidence of fire, weed infestations, or through changes in soil properties. Fisheries respond to direct climate-change effects such as increases in water temperature and sea level and changes in precipitation, freshwater flows, climate variability, and currents. They respond also to indirect effects such as shifts in food supply and the expansion in ranges of red tides and other biotoxins, which could lead to increased contamination of fisheries. The vulnerability of food and fiber production to climate change depends not only on the physiological response of plants and animals but also on the ability of the affected production and distribution systems to cope with fluctuations in yield.

3.5.1. Agriculture

Recent studies support evidence in the 1990 assessment that, on the whole, global agricultural production could be maintained relative to baseline production in the face of climate change modeled by GCMs at doubled-equivalent CO_2 equilibrium conditions. However, more important than global food production—in terms of the potential for hunger, malnutrition, and famine—is the access to and availability of food for specific local and regional populations. Many new crop studies conducted since the 1990 assessment report results that vary widely by crop, climate scenario, study methodology, and site (results are aggregated and summarized in Table 2). Limited ranges for some countries reflect the small number of studies available. At broader regional scales, subtropical and tropical areas—home to many of the world's poorest people—show negative consequences more often than temperate areas. People dependent on isolated agricultural systems in semi-arid and arid regions face the greatest risk of increased hunger due to climate change. Many of these at-risk populations live in sub-Saharan Africa; South, East, and Southeast Asia; and tropical areas of Latin America, as well as some Pacific island nations.

These conclusions emerge from studies that model the effects on agricultural yields induced by climate change and elevated CO_2. These studies presently do not include changes in insects, weeds, and diseases; direct effects of climate change on livestock; changes in soils and soil-management practices; and changes in water supply caused by alterations in river flows and irrigation. Moreover, the studies have considered only a limited set of adaptation measures and are based on yield analyses at a limited number of sites. Failure to integrate many key factors into agronomic and economic models limits their ability to consider transient climate scenarios and to fully address the costs and potential of adaptation. However, increased productivity of crops due to elevated concentrations of CO_2 is an important assumption in most crop modeling studies. Although the mean value response under experimental conditions is a 30% increase in productivity for C_3 crops (e.g., rice and wheat) under doubled-CO_2 conditions, the range is -10 to +80%. The response depends on the availability of plant nutrients, plant species, temperature, precipitation, and other factors, as well as variations in experimental technique.

A wide range of views exists on the potential of agricultural systems to adapt to climate change. Historically, farming systems have adapted to changing economic conditions, technology and resource availability, and population pressures. Uncertainty remains regarding whether the rate of climate change and required adaptation would add significantly to the disruptions resulting from other socioeconomic or environmental changes. Adaptation to climate change via new crops and crop varieties, improved water-management and irrigation systems, and information (e.g., optimal planting times) will prove important in limiting negative effects and taking advantage of beneficial changes in climate. The extent of adaptation depends in part on the cost of the measures used, particularly in developing countries; access to technology and skills; the rate of climate change; and constraints such as water availability, soil characteristics, topography, and the genetic diversity bred into crops. The incremental costs of these adaptation strategies could create a serious burden for some developing countries; some adaptation strategies may result in cost savings for some countries. There are significant uncertainties about the capacity of different regions to adapt successfully to projected climate change. Many current agricultural and resource policies—already a source of land degradation and resource misuse—likely will discourage effective adaptation measures.

Changes in grain prices, in the prevalence and distribution of livestock pests, and in grazing land and pasture productivity all will affect livestock production and quality. In general, analyses indicate that intensively managed livestock systems have more potential for adaptation than crop systems. In contrast, adaptation presents greater problems in pastoral systems where production is very sensitive to climate change, technology changes incur risks, and the rate of technology adoption is slow.

3.5.2. Forestry

Global wood supplies during the next century may become increasingly inadequate to meet projected consumption due to

Table 2: *Selected crop study results for 2 x CO$_2$-equivalent equilibrium GCM scenarios.*

Region	Crop	Yield Impact (%)	Comments
Latin America	Maize	-61 to increase	Data are from Argentina, Brazil, Chile, and Mexico; range is across GCM scenarios, with and without CO$_2$ effect.
	Wheat	-50 to -5	Data are from Argentina, Uruguay, and Brazil; range is across GCM scenarios, with and without CO$_2$ effect.
	Soybean	-10 to +40	Data are from Brazil; range is across GCM scenarios, with CO$_2$ effect.
Former Soviet Union	Wheat Grain	-19 to +41 -14 to +13	Range is across GCM scenarios and region, with CO$_2$ effect.
Europe	Maize	-30 to increase	Data are from France, Spain, and northern Europe; with adaptation and CO$_2$ effect; assumes longer season, irrigation efficiency loss, and northward shift.
	Wheat	increase or decrease	Data are from France, UK, and northern Europe; with adaptation and CO$_2$ effect; assumes longer season, northward shift, increased pest damage, and lower risk of crop failure.
	Vegetables	increase	Data are from UK and northern Europe; assumes pest damage increased and lower risk of crop failure.
North America	Maize Wheat	-55 to +62 -100 to +234	Data are from USA and Canada; range is across GCM scenarios and sites, with/without adaptation and with/without CO$_2$ effect.
	Soybean	-96 to +58	Data are from USA; less severe or increase with CO$_2$ and adaptation.
Africa	Maize	-65 to +6	Data are from Egypt, Kenya, South Africa, and Zimbabwe; range is over studies and climate scenarios, with CO$_2$ effect.
	Millet	-79 to -63	Data are from Senegal; carrying capacity fell 11–38%.
	Biomass	decrease	Data are from South Africa; agrozone shifts.
South Asia	Rice Maize Wheat	-22 to +28 -65 to -10 -61 to +67	Data are from Bangladesh, India, Philippines, Thailand, Indonesia, Malaysia, and Myanmar; range is over GCM scenarios, with CO$_2$ effect; some studies also consider adaptation.
China	Rice	-78 to +28	Includes rainfed and irrigated rice; range is across sites and GCM scenarios; genetic variation provides scope for adaptation.
Other Asia and Pacific Rim	Rice	-45 to +30	Data are from Japan and South Korea; range is across GCM scenarios; generally positive in north Japan, and negative in south.
	Pasture	-1 to +35	Data are from Australia and New Zealand; regional variation.
	Wheat	-41 to +65	Data are from Australia and Japan; wide variation, depending on cultivar.

Note: For most regions, studies have focused on one or two principal grains. These studies strongly demonstrate the variability in estimated yield impacts among countries, scenarios, methods of analysis, and crops, making it difficult to generalize results across areas or for different climate scenarios.

both climatic and non-climatic factors. Assuming constant per capita wood use, analysis of changing human populations suggests that the annual need for timber will exceed the current annual growth increment of 2% by the year 2050. However, growth could increase slightly from warming and enhanced atmospheric CO_2 concentrations, or decrease greatly from declines and mortality of forest ecosystems brought on by climate change.

Tropical forest product availability appears limited more by changes in land use than by climate change, at least through the middle of the next century. By then, projections indicate that growing stock will have declined by about half due to non-climatic reasons related to human activities. This projected decline holds up even after calculating changes in climate and atmospheric composition during this period, which could increase forest productivity and the areas where tropical forests can potentially grow. Communities that depend on tropical forests for fuelwood, nutrition, medicines, and livelihood will most feel the effects of declines in forested area, standing stock, and biodiversity.

Temperate-zone requirements for forest products should be met for at least the next century. This conclusion emerges from projected climate and land-use changes that leave temperate forest covering about as much land in 2050 as today. It further assumes that current harvests increase only slightly, that the annual growth increment remains constant, and that imports from outside increasingly meet the temperate zone's need for forest products—although it is not clear if this assumption can be met given production projections in other zones.

Boreal forests are likely to undergo irregular and large-scale losses of living trees because of the impacts of projected rapid climate change. Such losses could initially generate additional wood supply from salvage harvests, but could severely reduce standing stocks and wood-product availability over the long term. The exact timing and extent of this pattern is uncertain. Current and future needs for boreal forest products are largely determined outside the zone by importers; future requirements for forest products may exceed the availability of boreal industrial roundwood during the 21st century, given the projections for temperate- and tropical-zone forest standing stocks and requirements.

Effective options for adapting to and ameliorating potential global wood supply shortages include the following:

- In the tropics, the greatest progress may result from developing practices and policies that reduce social pressures driving land conversion (e.g., by increasing crop and livestock productivity) and by developing large plantations.
- In temperate areas, application of modern forestry practices to reduce harvest damage to ecosystems, combined with the substitution of nontimber products, could reduce significantly the effect of climate on wood availability.
- In boreal regions, adaptation to potential climate-induced, large-scale disturbances—such as by rapid reforestation with warmth-adapted seeds—appears to

be most useful. Increased prices for forestry products seem certain to lead to adaptation measures that will reduce demand, increase harvest intensity, and make tree plantations more economically feasible.

3.5.3.   *Fisheries*

Climate-change effects will interact with other stresses on fisheries, including pervasive overfishing, diminishing nursery areas, and extensive inshore and coastal pollution. Overfishing stresses fisheries more than climate change today, but if fisheries management improves and climate changes develop according to IPCC scenarios, climate change may become the dominant factor by the last half of the next century.

Although marine fisheries production will remain about the same globally, projections indicate that higher latitude freshwater and aquaculture production will increase. This assumes, however, that natural climate variability and the structure and strength of ocean currents remains unchanged. Alterations in either would have significant impacts on the distribution of major fish stocks, rather than on global production. Positive effects (e.g., longer growing seasons, lower natural winter mortality, and faster growth rates in higher latitudes) may be offset by negative factors such as changes in established reproductive patterns, migration routes, and ecosystem relationships. Climate change can be expected to have the greatest impact on the following (in decreasing order): (i) freshwater fisheries in small rivers and lakes in regions with larger temperature and precipitation change; (ii) fisheries within exclusive economic zones, particularly where access regulations artificially reduce the mobility of fisher groups and fishing fleets, thus their capacity to adjust to fluctuations in stock distribution and abundance; (iii) fisheries in large rivers and lakes; (iv) fisheries in estuaries, particularly where there are species without migration or spawn dispersal paths, or estuaries affected by sea-level rise or decreased river flow; and (v) high-seas fisheries. Where rapid change occurs due to physical forcing (e.g., changes in currents and natural variability), production will usually favor smaller, low-priced, opportunistic species that discharge large numbers of eggs over long periods. Loss of coastal wetlands could cause a loss of nurseries and have significant adverse effects on fisheries.

If institutional mechanisms do not enable fishers to move across national boundaries, some national fish industries may suffer negative effects. Subsistence and other small-scale fishers, often the most dependent on specific fisheries, will suffer disproportionately from changes. Several adaptation options exist. These include improved management systems, ecological and institutional research, and expansion of aquaculture.

3.6.   *Human Infrastructure*

Human infrastructure, a key determinant of a region's productivity and development, includes all varieties of human-made

capital and assets—residential and commercial properties, transportation facilities, industries and manufactured goods, coastal embankments, and equipment for energy production and distribution. Human infrastructure and socioeconomic systems—including industry, energy, and transportation—may be affected *directly* through changes in temperature, precipitation, sea level, or increased frequency or intensity of extreme events that can damage exposed infrastructure or affect outputs. Due to the interconnectedness of economic activity, many of the influences of climate change on industry, energy, and transportation are expected to be *indirect* and transmitted by changes in markets sensitive to climate (e.g., energy demand for space heating and cooling) or changes in resources sensitive to climate (e.g., agroindustries and biomass production). Human migration in response to chronic crop failures, regional flooding, or drought may create additional pressure on human infrastructures. These indirect impacts are difficult to quantify or value in monetary terms.

In many sectors, the effects of climate change will amount to less than those resulting from changes in demography, technology, and markets. Yet unexpected changes in climate could occur and much capital is invested in locations that could be affected by such changes. Relocating or defending this infrastructure could require costly actions and a high degree of foresight and coordination.

3.6.1.   *Industry, Energy, and Transportation*

In general, the climate sensitivity of most activities in these sectors is relatively low compared to that of agriculture or natural ecosystems. Certain activities, however, display a greater degree of climate sensitivity than do industry, energy, and transportation as a whole. Subsectors and activities most sensitive to climate change include agroindustry, production of renewable energy such as hydroelectricity and biomass, energy demand, construction, some transportation activities, existing flood mitigation structures, and transportation infrastructure located in many areas, including vulnerable coastal zones and permafrost regions.

In the energy sector, the consequences for hydroelectric power generation will depend upon changes in the balance between the amount and timing of precipitation and evaporation. Increased scarcity of fuelwood in dry and densely populated regions could exacerbate problems caused by deforestation. Peak winter demand for primary energy is projected to decrease due to a reduction in space-heating needs; peak summer demand for electricity may increase with greater cooling requirements in some regions. 'The net effects of these changes in energy demand will be regionally dependent. There is low confidence in estimates of these net effects.

In contrast to research on mitigation options, relatively few studies exist on climate change impacts on and adaptation options for the industry, energy, and transportation sectors. This situation reflects a perception of low vulnerability to climate change for these sectors.

3.6.2.   *Coastal Zones/Small Islands*

Many coastal zones and small islands are particularly vulnerable to direct effects of climate change and sea-level rise. Present estimates of global sea-level rise represent a rate two to five times that experienced during the last 100 years. Recent scientific findings indicate that sea-level rise may deviate from the global average by a factor of two or more due to regional differences in ocean salinity and temperature change.

Sea-level rise can have negative impacts on tourism, freshwater supplies, fisheries, exposed infrastructure, agricultural and dry lands, and wetlands. Impacts may vary across regions; societal costs will greatly depend upon the vulnerability of the coastal system and a country's economic situation.

Climate change clearly will increase the vulnerability of some coastal populations to flooding and erosional land loss. Estimates put about 46 million people per year currently at risk of flooding due to storm surges. This estimate results from multiplying the total number of people currently living in areas potentially affected by ocean flooding by the probability of flooding at these locations in any year, given the present protection levels and population density. In the absence of adaptation measures, a 50-cm sea-level rise would increase this number to about 92 million; a 1-m sea-level rise would raise it to 118 million. If one incorporates anticipated population growth, the estimates increase substantially. Some small island nations and other countries will confront greater vulnerability because their existing sea and coastal defense systems are less well-established. Countries with higher population densities would be more vulnerable. For these countries, sea-level rise could force internal or international migration of populations.

A number of studies have evaluated sensitivity to a 1-m sea-level rise. This increase is at the top of the range of IPCC Working Group I estimates for 2100; it should be noted, however, that sea level is actually projected to continue to rise in future centuries beyond 2100. Studies using this 1-m projection show a particular risk for small islands and deltas. Given the present state of protection systems, estimated land losses range from 0.05% for Uruguay, 1% for Egypt, 6% for the Netherlands, and 17.5% for Bangladesh up to about 80% for the Majuro Atoll in the Marshall Islands. Large numbers of people are also affected—for example, about 70 million each in China and Bangladesh. Many nations face lost capital value in excess of 10% of GDP. Although annual adaptation/protection costs for many nations are relatively modest (about 0.1% of GDP), the average annual costs to many small island states total several percent of GDP. For some island nations, the high cost of providing storm-surge protection would make it essentially infeasible, especially given the limited availability of capital for investment.

3.6.3.   *Human Settlements*

Projected climate change will affect human settlements in the context of changes such as population growth, migration, and

industrialization. Settlements where these forces already stress the infrastructure are most vulnerable. Besides coastal communities and those dependent on subsistence, rain-fed agriculture, or commercial fishing, vulnerable settlements include large primary coastal cities and squatter settlements located in flood plains and steep hillsides. Many of the expected impacts in the developing world could occur because climate change may reduce natural resource productivity in rural areas, thus may generally accelerate rural-to-urban migration. Direct impacts on infrastructure would most likely occur as a result of changes in the frequency and intensity of extreme events. These include coastal storm surges, floods and landslides induced by local downpours, windstorms, rapid snowmelt, tropical cyclones and hurricanes, and forest and brush fires made possible in part by more intense or lengthier droughts.

3.6.4. Insurance and Financial Services

Within the financial services sector, property insurance stands most vulnerable to direct climatic influence. A higher risk of extreme events due to climate change could lead to higher insurance premiums or the withdrawal of coverage for property in some vulnerable areas. Changes in climate variability and the risk for extreme events may be difficult to detect or predict, thus making it difficult for insurance companies to adjust premiums appropriately. If such difficulty leads to insolvency, companies may not be able to honor insurance contracts, which could economically weaken other sectors such as banking. The insurance industry currently is under stress from a series of "billion dollar" storms since 1987 (see Table 3), resulting in dramatic increases in losses, reduced availability of insurance, and higher premiums. Some in the insurance industry perceive a current trend toward increased frequency and severity of extreme climate events. Examination of the meteorological data fails to support this perception in the context of a long-term change, although a shift within the limits of natural variability may have occurred. Higher losses strongly reflect increases in infrastructure and economic worth in vulnerable

Table 3: *"Billion dollar" storms.*

Year	Event	Insured Cost ($B)
1987	"Hurricane" in SE England/NW France	2.5
1988	Hurricane Gilbert in Jamaica/Mexico	0.8
1989	Hurricane Hugo in Puerto Rico/S. Carolina	5.8
1990	European Storms—Four	10.4
1991	Typhoon Mireille in Japan	4.8
1992	Hurricane Andrew in Florida	16.5
1993	"Storm of the Century" in Eastern USA	1.7
1995	Hailstorms in Texas	1.1
1995	Hurricane Opal in Southern USA	2.1

areas, as well as a possible shift in the intensity and frequency of extreme weather events.

Withdrawal of insurance would increase direct financial losses to property owners and businesses unable to obtain insurance, with serious long-term implications for societies and governments. The implications of climate change for financial services outside of property insurance appear less clear; these sectors generally have not acknowledged the potential for such impacts. Adaptation may prove difficult, given the long-term nature of many investors' financial commitments.

3.6.5. Adaptation Options for Human Infrastructure

Because the life cycles of planning and investment for much human infrastructure are shorter than those associated with climate change, adaptation could occur through management and the normal replacement of capital in many sectors, as long as climate change happens gradually. This, however, depends on people and organizations becoming adequately informed about potential impacts and having the financial, technical, and institutional capacity to respond. In the more sensitive sectors, adaptation may need the support of policy measures. Incorporating potential climate and sea-level changes in planning would reduce future risks to human infrastructure. Climate changes, however, could occur suddenly. Uncertainty about the rate and effects of climate change makes some investment decisions difficult. This holds particularly true for planning and investments for infrastructure such as channels, water supply systems, and coastal or river-flooding defenses, which can have lifetimes as long as 100 years.

Many developing countries currently depend on a limited number of crops or on fishing—hence are economically vulnerable to climate change that harms agroindustry. For these countries in particular, diversifying economic activity—coupled with improved management practices such as integrated coastal-zone management and land-use regulation—could constitute an important precautionary response and facilitate successful adaptation to climate change (e.g., by directing populations away from vulnerable locations).

Implementing adaptation measures and integrated management practices requires overcoming constraints that include (but are not limited to) technology and human resource capability; financial limitations; cultural and social acceptability; and political, legal, and other institutional bottlenecks. The literature remains scarce on adaptation; dealing effectively with the issue requires additional research and new methods of risk and probability assessment.

3.7. Human Health

Climate changes and their effects on food security, water supply and quality, and the distribution of ecological systems may have wide-ranging and potentially adverse effects on

human health, via both direct and indirect pathways (see Figure 5); it is likely that the indirect impacts would, in the longer term, predominate. Quantifying the potential health impacts of climate change remains difficult. For many effects, forecasting techniques—especially modeling—are just being developed. Furthermore, the extent of climate-induced health disorders depends on numerous coexistent and interacting factors that characterize the vulnerability of the particular population. These include environmental circumstances (such as water purity) and socioeconomic factors (such as nutritional and immune status, population density, and access to health care).

Direct health effects include increases in heat-related (predominantly cardiorespiratory) mortality and illness resulting from an anticipated increase in the intensity and duration of heat waves. Studies in selected cities in North America, North Africa, and East Asia indicate that the annual numbers of heat-related deaths would increase several-fold in response to climate-change projections. Temperature increases in colder regions should result in fewer cold-related deaths.

The incidence of deaths, injuries, psychological disorders, and exposure to chemical pollutants in water supplies would increase if extreme weather events (e.g., droughts and floods) were to become more frequent.

Indirect effects include increases in the potential transmission of vector-borne infectious diseases (e.g., malaria, dengue, Chagas' disease, yellow fever, and some viral encephalitis) caused by extensions of the ranges and seasons of vector organisms. Climate change also would accelerate the maturation of certain infectious parasites (e.g., the malaria organism). Currently, approximately 350 million cases of malaria occur annually, resulting in 2 million deaths. Using first-generation mathematical models, scientists recently forecast the impact of changes in basic climate variables on the global/regional pattern of potential malaria transmission. Approximately 45% of the world's population presently lives in the climate zone where mosquitoes transmit malaria. Projections by models (that entail necessary simplifying assumptions) indicate that the geographical zone of potential malaria transmission in response to world temperature increases at the upper part of the IPCC-projected range (3–5°C by 2100) would increase to approximately 60% by the latter half of the next century. This possible extension in potential transmission area would encroach most on temperate regions. However, actual climate-related increases in malaria incidence (50 to 80 million additional annual cases) would occur primarily in tropical, subtropical, and less well-protected temperate-zone populations currently at the margins of endemically infected areas.

Some increases in non-vector-borne infectious diseases—such as salmonellosis, cholera, and other food- and water-related infections could occur—particularly in tropical and subtropical regions because of climatic impacts on water distribution, temperature, and microorganism proliferation.

Other likely indirect effects include increases in asthma, allergic disorders, cardiorespiratory diseases, and associated deaths. These might result from climate-induced changes in pollens and spores, and from temperature increases that enhance the formation, persistence, and respiratory impact of certain air pollutants. Exposure to air pollution and stressful weather events combine to increase the likelihood of morbidity and mortality.

Though still uncertain, the regional effects of climate change upon agricultural, animal, and fisheries productivity could increase the local prevalence of hunger, malnutrition,

Figure 5: Ways in which climate change can affect human health.

and their long-term health impairments, especially in children. Limitations on freshwater supplies also will have human health consequences. A range of adverse public health effects would result from physical and demographic disruptions due to sea-level rise.

Various technological, organizational, and behavioral adaptations would lessen these adverse effects. These include protective technology (e.g., housing, air conditioning, water purification, and vaccination), disaster preparedness, and appropriate health care. However, the tropical and subtropical countries at highest risk from many of these impacts may still lack adequate resources for adaptation.

4. Options to Reduce Emissions and Enhance Sinks of Greenhouse Gases: Mitigation

4.1. Common Themes and Conclusions

Significant reductions in net greenhouse gas emissions are technically possible and can be economically feasible. These reductions can be achieved by employing an extensive array of technologies and policy measures that accelerate technology development, diffusion, and transfer in all sectors, including the energy, industry, transportation, residential/commercial, and agricultural/forestry sectors. By the year 2100, the world's commercial energy system in effect will be replaced at least twice, offering opportunities to change the energy system without premature retirement of capital stock; significant amounts of capital stock in the industrial, commercial, residential, and agricultural/forestry sectors also will be replaced. These cycles of capital replacement provide opportunities to use new, better performing technologies. It should be noted that the analyses of Working Group II do not attempt to quantify potential macroeconomic consequences that may be associated with mitigation measures. Discussion of macroeconomic analyses is found in the contribution of IPCC Working Group III to the Second Assessment Report. The degree to which technical potential and cost-effectiveness are realized is dependent on initiatives to counter lack of information and overcome cultural, institutional, legal, financial, and economic barriers that can hinder diffusion of technology or behavioral changes. The pursuit of mitigation options can be carried out within the limits of sustainable development criteria. Social and environmental criteria not related to greenhouse gas emissions abatement could, however, restrict the ultimate potential of each of the options.

- **Numerous technology options are available for reducing emissions and enhancing sinks**. Promising technologies and measures follow:
  - *Energy demand*. The technical potential for best practice energy technologies to improve energy efficiency relative to present average practice is large; 10–30% efficiency gains at little or no cost in many parts of the world, through conservation measures and improved management practices, and 50–60% is possible, provided that relevant technologies and financing are available.

  - *Industry*. Short-term emissions reductions of about 25% can be obtained in industrialized nations by improving efficiency, recycling materials, and implementing "industrial ecology" practices that use less energy and fewer materials.
  - *Transportation*. Emissions reductions of up to 40% by 2025 could be achieved by changing vehicle engineering to use more efficient drive trains and materials; reducing the size of vehicles; switching to alternative fuels; reducing the level of passenger and freight transport activity by altering land-use patterns, transport systems, mobility patterns, and lifestyles; and shifting to less energy-intensive transportation modes.
  - *Commercial/residential sector*. Cuts of 50% in the projected growth in emissions over the next 35 years—and deeper cuts in the longer term—could be achieved by more efficient lighting, appliances, and space-conditioning systems; reduced heat transfers through walls, ceilings, and windows; and modern control systems such as automatic sensors.
  - *Energy supply*. Options include more efficient conversion of fossil fuels (from the present world average for electric power generation of about 30% to more than 60% in the longer term); switching from high- to low-carbon fossil fuels (coal to oil to gas); decarbonization of flue gases and fuels, coupled with CO_2 storage; increasing the use of nuclear energy; and increased use of modern renewable sources of energy (e.g., biomass for production of electricity and liquid/gaseous fuels, wind, and solar). In the longer term, renewable sources of energy could meet the major part of the world's demand for energy as technological advances offer new opportunities and declining costs.
  - *Land management*. A number of measures could conserve and sequester substantial amounts of carbon (approximately 60–90 Gt C in the forestry sector alone) over the next 50 years, including slowing deforestation, enhancing natural forest generation, establishing tree plantations, and promoting agroforestry. Significant additional amounts could be sequestered by altering management of agricultural soils and rangelands, and by restoring degraded agricultural lands and rangelands. Other practices, such as improving efficiency of fertilizer use or the diet of domesticated ruminants, could reduce emissions of other greenhouse gases such as CH_4 and N_2O.
- **Policies can accelerate reductions in greenhouse gas emissions**. Governments can choose policies that facilitate the penetration of less carbon-intensive technologies and modified consumption patterns. Indeed, many countries have extensive experience with a variety of policies that can accelerate the adoption of such technologies. This experience comes from efforts over the past 20 to 30 years to achieve improved energy

efficiency, reduce the environmental impacts of agricultural policies, and meet conservation and environmental goals unrelated to climate change. Many of these policies appear potentially useful for reducing greenhouse gas emissions. They include energy pricing strategies; changes in agricultural subsidies; provisions for accelerated depreciation and reduced costs for the consumer; tradable emissions permits; negotiated agreements with industry; utility demand-side management programs; regulatory programs, including minimum energy-efficiency standards; market pull and demonstration programs that stimulate the development and application of advanced technologies; and product labeling. The optimum mix of policies will vary from country to country; each nation needs to tailor its policies for local situations and develop them through consultation with those affected. Analysis of the historical experience of different countries with various policy instruments can provide guidance on their strengths and weaknesses.

- **Success is most likely if there are multiple benefits**. Actions to reduce greenhouse gas emissions appear more easily implemented when they are designed to address other concerns that impede sustainable development (e.g., air pollution, traffic congestion, soil erosion).

- **Commitment to further research is essential**. Developing technologies that will reduce greenhouse gas emissions and enhance greenhouse gas sinks—as well as understanding the barriers that inhibit their diffusion into the marketplace—requires a continuing commitment to research.

4.2. Energy, Industrial Process, and Human Settlement Emissions

The production, conversion, and end-use of fossil fuel energy results in significant atmospheric releases of greenhouse gases— in particular, CO_2 and CH_4. In the published literature, different methods and conventions are used to characterize energy consumption. These conventions differ, for example, according to their definition of sectors and their treatment of energy forms. Based on aggregated national energy balances, 385 EJ of primary energy was consumed in the world in 1990, resulting in the release of 6 Gt C as CO_2. Of this, 279 EJ was delivered to end users, accounting for 3.7 Gt of carbon emissions as CO_2 at the point of consumption. The remaining 106 EJ was used in energy conversion and distribution, accounting for 2.3 Gt C emissions as CO_2. In 1990, the three largest sectors of energy consumption were industry (45% of total CO_2 releases), residential/commercial (29%), and transport (21%). Of these, transport sector energy use and related CO_2 emissions have been the most rapidly growing over the past 2 decades. The combustion of fossil fuels ranks as the primary human-generated source of SO_2 (the sulfate aerosol precursor), as well as other air pollutants.

Global energy demand has grown at an average annual rate of approximately 2% for almost 2 centuries, although energy demand growth varies considerably over time and between different regions. During that time, the mix of fuels has changed dramatically (see Figure 6). Figure 7 depicts total energy-related emissions by major world region. The Organisation for Economic Cooperation and Development (OECD) nations have been and remain major energy users and fossil fuel CO_2 emitters, although their share of global fossil fuel carbon emissions has been declining. The contribution to global fossil fuel carbon emissions by the former Soviet Union and Eastern Europe (FSU/EE) has grown, although recent economic restructuring has reduced emissions. The diverse developing nations, taken as a group, still account for a smaller fraction of total global CO_2 emissions than industrialized nations (OECD and FSU/EE) due to their lower per capita emission rates (see Figure 8). Most projections indicate that with forecast rates of population and economic growth, the developing world will increase its share of CO_2 emissions as its standard of living increases and as population grows.

Oil and gas reserves worldwide contain approximately 200 Gt C and coal reserves about 600 Gt C. Estimates place remaining, ultimately recoverable, fossil fuel resources at some 4,000 Gt C, roughly three-quarters of it in coal and the rest in conventional and unconventional oil and gas. Atmospheric content totaled about 750 Gt C in 1990. Exhaustion of fossil resources therefore offers no near-term physical-barrier solution to the emissions of energy-related CO_2. The carbon-to-energy intensity ratio of different fossil fuels varies by a factor of almost two: Coal contains 25 Mt C/EJ; oil, 20 Mt C/EJ; and natural gas, 15 Mt C/EJ.Renewable energy sources are sufficiently abundant that they potentially could provide all of the world's energy needs foreseen over the next century. However, economics, technology development, and other practical constraints limit the rate at which the use of renewable energy can expand.

The prices of fuels and electricity influence energy use and fuel choice in all sectors. In many instances, prices do not reflect the full social costs of providing energy; subsidies and other

Figure 7: Global energy-related CO_2 emissions by major world region in Gt C/yr. Sources: Keeling, 1994; Marland *et al.*, 1994; Grübler and Nakicenovic, 1992; Etemad and Luciani, 1991; Fujii, 1990; UN, 1952 (see the Energy Primer for complete citations).

interventions restrict the choices made by energy suppliers and users. Price rationalization, voluntary agreements, regulations, and information programs have successfully helped to accelerate the use of more energy-efficient technologies and practices in various areas of end-use, especially in the residential and transport sectors. These measures—when implemented as part of the normal replacement cycles of the world's energy supply infrastructure and energy-use equipment—offer the greatest potential to change the technology and systems now used.

4.2.1.   Energy Demand

Numerous studies have indicated that 10–30% energy efficiency gains above present levels are feasible at little or no net cost in many parts of the world through technical conservation measures and improved management practices over the next 2 to 3 decades. Using technologies that presently yield the highest output of energy services for a given input of energy, efficiency gains of 50–60% would be technically feasible in many countries over the same time period. Achieving these potentials will depend on future cost reductions, financing, and technology transfer, as well as measures to overcome a variety of non-technical barriers. The potential for greenhouse gas emission

reductions exceeds the potential for energy use efficiency because of the possibility of switching fuels and energy sources. Because energy use is growing world-wide, even replacing current technology with more-efficient technology could still lead to an absolute increase in CO_2 emissions in the future.

In 1992, the IPCC produced six scenarios (IS92a-f) of future energy use and associated greenhouse gas emissions. These scenarios provide a wide range of possible future greenhouse gas emission levels, without mitigation measures. In the Second Assessment Report, future energy use has been reexamined on a more detailed sectoral basis, both with and without new mitigation measures, based on existing studies. Despite different assessment approaches, the resulting ranges of energy consumption increases to 2025 without new measures are broadly consistent with those of IS92. If past trends continue, greenhouse gas emissions will grow more slowly than energy use, except in the transport sector.

The following paragraphs summarize energy efficiency improvement potentials estimated in the IPCC Second Assessment Report. Strong policy measures would be required to achieve these potentials. Energy-related greenhouse gas emission reductions depend on the source of the energy, but

Figure 8: 1990 per capita CO_2 emissions by region and source, fossil fuels, and range for biota sources (includes sustainable use of biomass that does not contribute to atmospheric concentration increase). Sources: IEA, 1993; Marland *et al*., 1994; Nakicenovic *et al*., 1993; Subak *et al*., 1993; IPCC, 1990, 1992; Bos *et al*., 1992; Houghton *et al*., 1987 (see the Energy Primer for complete citations).

reductions in energy use will, in general, lead to reduced greenhouse gas emissions.

4.2.1.1.   Emissions mitigation in industry

Energy use in 1990 is estimated to be 98–117 EJ, and is projected to grow to 140–242 EJ in 2025 without new measures. Developing countries now account for only about one-quarter of global industrial final energy use, but projections put their share of industrial energy demand growth over the next century at more than 90%.

A few basic processes, including the production of iron and steel, chemicals, building materials, and food, account for more than half of all energy use in the industrial sector. Industry has reduced energy intensity impressively over the past 2 decades. In some countries, improvements in energy efficiency have permitted major increases in production with little or no increase in energy use. In contrast to the industrial emissions of developing countries, which continue to increase as their economies grow, developed countries' industrial-sector emissions have stabilized or declined during the past 2 decades. Even the former Soviet Union's industrial emissions have remained stable for a decade. These changes have

occurred without any climate policies in place and essentially have arisen from a combination of economic restructuring, shedding of some energy-intensive industries, and gains in the energy efficiency of industrial processes. These developments have combined to decrease overall primary energy intensity (see Figure 9), resulting in stabilized or decreased CO_2 emissions in many industrialized countries (see Figure 10). Because each nation has a unique set of resources, labor, and capital that will influence its development path, this historical perspective does not suggest a particular outcome for developing countries. It does imply that the relationship between CO_2 emissions and GDP is unlikely to retain its present course, given the technological opportunities currently available.

Opportunities now exist to use advanced technologies to reduce emissions significantly in each of the major energy-consuming industries. The short-term potential for energy-efficiency improvements in the manufacturing sector of major industrial nations is around 25%. The potential for greenhouse gas emission reductions is larger. The application of available, highly efficient technologies and practices could significantly reduce industrial energy demand growth.

Efficient use of materials can lower industrial greenhouse gas emissions, and recycling materials can reduce energy
Figure 9: Primary energy intensity (including wood and biomass) of value added in MJ per constant GDP in 1980 dollars [at market exchange rates (mexr) and purchasing power parities (ppp)]. The countries shown account for approximately 80% of energy-related CO_2 emissions. Source: Grübler, 1991 (see the Energy Primer for a complete citation).

requirements and energy-related emissions substantially (see Figure 11). Recycling iron and steel scrap, for example, could cut the energy required per ton of steel produced to half the current level even in Japan, the world's most efficient steel-producing nation. Not all steel scrap is recyclable, however, so recycling provides no panacea. Using less energy-intensive materials offers another option—for example, substituting wood for concrete and other materials as possible.

Some technologies—such as electric motor drives, heating, and evaporation—are used across many industries, thus offering large opportunities for energy savings. Electric motor drives, for example, use more than half of all electricity in the industrial sector in many developing countries, including China and Brazil. Investments in motor-speed controls and more efficient motor components can reduce electricity use in

industrial motor applications, with an internal rate of return on investment of 30 to 50%.

Integrating industrial and residential-commercial energy use by establishing energy-management systems that utilize an "energy cascade" presents promising opportunities for increased efficiency—especially in newly industrialized nations, where a systematic approach to efficiency improvements is particularly important. An energy cascade uses successively lower temperature industrial waste heat in a variety of other industrial, residential, and commercial district heating and cooling applications.

Limiting industrial emissions of CO_2 and other greenhouse gases, such as halocarbons, CH_4, and N_2O associated with industrial processes, can also play an important role.

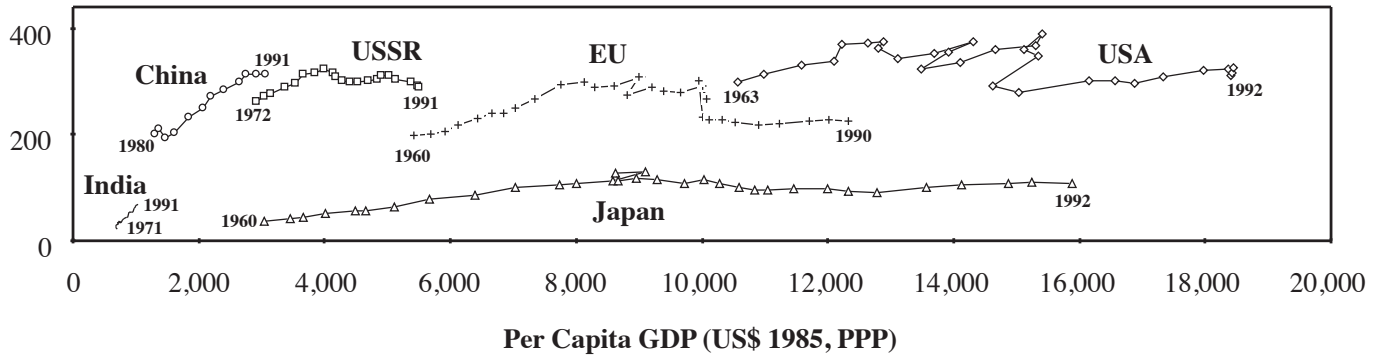
Industrial CO$_2$ Emissions (in Million Metric Tons of Carbon)


Figure 10: Fossil fuel CO$_2$ development path for the industrial sectors of the United States, the 15 nations that now comprise the European Union (less the former East Germany), Japan, China, India, and the former Soviet Union. The industrial sector is as defined by OECD, plus CO$_2$ associated with refineries and the fraction of electricity that is used by industry. The CO$_2$ values are from OECD (1994), and the ppp values are from Sommers and Heston (1991, 1994); see Chapter 20 for complete citations.

Identifying all the benefits, costs, and potentials for reducing both process and energy greenhouse gases in the industrial sector requires an examination of all aspects of resource use. Developing the capability to carry out full "industrial ecology" analyses represents a major research need.

Implementing more energy-efficient industrial technologies will depend on many factors. Chief among them are financing, energy and materials pricing, market imperfections, research and development, and the extent to which technology transfer occurs from developed countries to developing nations and those with economies in transition.

Figure 11: Tons of carbon avoided by OECD countries by increasing recycling by 10%—from *Long-Term Strategies for Mitigating Global Warming* (IIASA, 1993).

4.2.1.2.   *Emissions mitigation in transportation*

Transport energy use in 1990 is estimated to be 61–65 EJ, and is projected to grow to 90–140 EJ in 2025 without new measures (see Figure 12). Energy use by cars, aircraft, and heavy trucks is growing particularly rapidly. Although industrialized countries account for about 75% of current energy use and greenhouse gas emissions from this sector, the greatest growth is expected in developing countries and transition economies. By 2025, these countries could generate the majority of transport-related emissions.

Transportation energy demand historically has been linked closely to GDP growth, although there is also a strong negative correlation with fuel prices (see Figures 13 and 14). However, projected energy use in 2025 could be reduced by about a third to 60–100 EJ through vehicles using very efficient drive-trains, light-weight construction and low-air-resistance design, without compromising comfort and performance. Further energy-use reductions are possible through the use of smaller vehicles; altered land-use patterns, transport systems, mobility patterns, and lifestyles; and shifting to less energy-intensive transport modes. Greenhouse gas emissions per unit of energy used could be reduced through the use of alternative fuels and electricity from renewable sources. These measures, taken together, provide the opportunity for reducing global transport emissions by as much as 40% of projected emissions by 2025. Actions to reduce greenhouse gas emissions from transport can simultaneously address other problems, such as local air pollution.

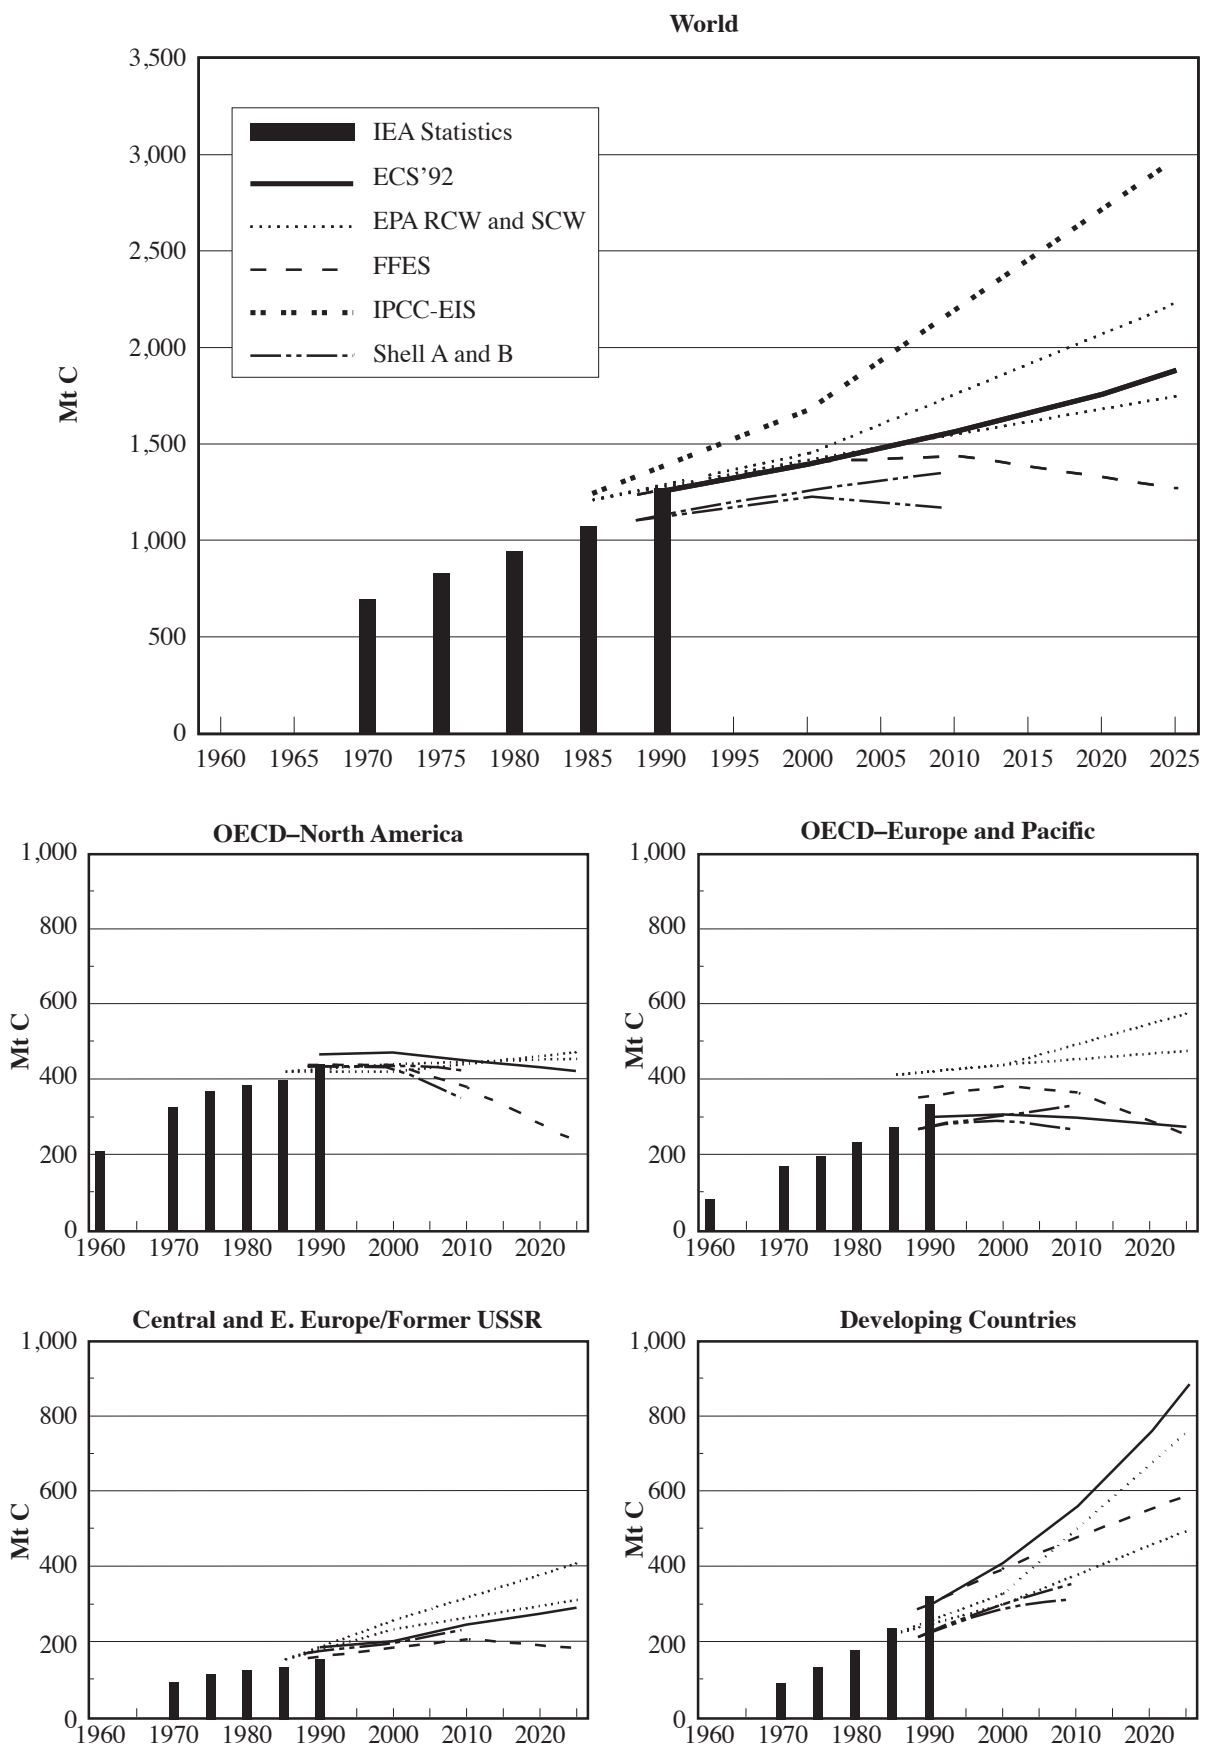
Realizing these opportunities seems unlikely, however, without new policies and measures in many countries. We have learned much already about the effective use of policies, such as fuel and vehicle taxes and fuel-economy standards, to encourage energy-efficiency improvements. Yet developing cheap, light-weight, recyclable materials and advanced propulsion and vehicle-control systems will require continued research. Policies that affect traffic volume also play an important role. These include road tolls, restriction of car access and parking


Figure 12: Comparison of transport CO$_2$ emission scenarios to 2025 (Grübler, 1993). Note: IEA = International Energy Agency; ECS = Environmentally Compatible Energy Strategies; RCW = Rapidly Changing World and SCW = Slowly Changing World; FFES = Fossil-Free Energy System; and EIS = Energy Industry System.
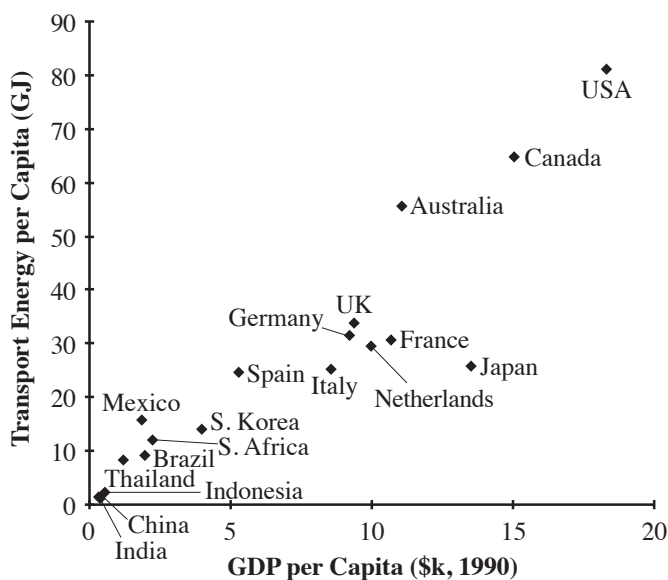

Figure 13: Total transport energy use vs. gross domestic product in 1990, for 18 of the world's largest transport energy users. Excludes Russia, Ukraine, Iran, Saudi Arabia, and Kazakhstan; former West and East Germany data have been combined. Sources: IEA, 1993c, 1993d (see Chapter 21 for complete citations).

in town centers, and the provision of infrastructure for nonmotorized transport in town centers. Several cities in Latin America, Southeast Asia, and Europe have succeeded in stemming growth in car use by employing combined strategies.

Transport plays an increasingly important social and economic role, and measures to reduce emissions may fail if people perceive them as compromising this role. Success in reducing carbon emissions will require integrated approaches and probably will depend on simultaneously addressing other problems such as congestion and air pollution [including emissions of particulates, and of nitrogen oxides (NO_x) and volatile organic compounds (VOCs) that are precursors to tropospheric ozone].

4.2.1.3.   *Emissions mitigation in the commercial/residential sector*

Activities in this sector currently account for just over 40% of energy use. Figure 15 shows historical carbon emissions from the developing world, industrialized countries, and the FSU/EE resulting from energy use in the residential and commercial sectors in 1973, 1983, and 1990. Energy use in 1990 is estimated to be 100 EJ, and is projected to grow to 165–205 EJ in 2025 without new measures. Although industrialized countries currently release about 60% of associated emissions, developing countries and the FSU/EE could account for 80% of all growth in building emissions during the next century.

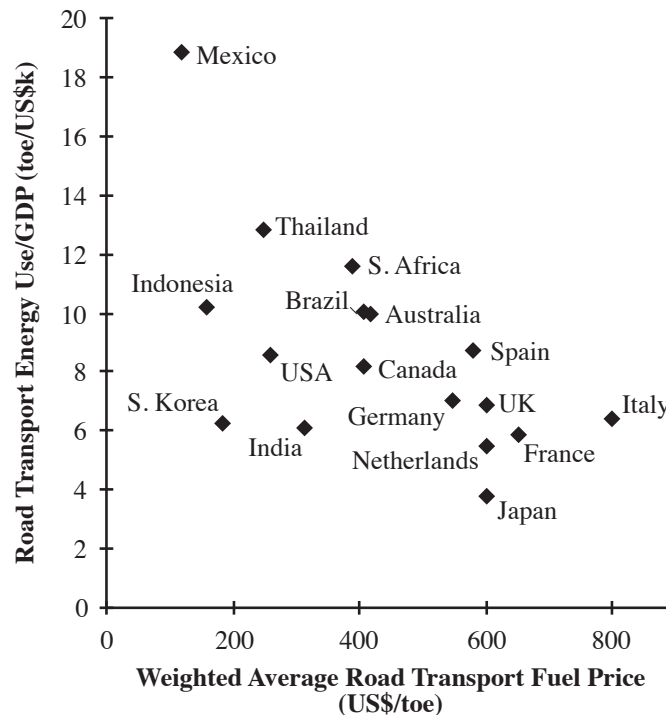
Projected energy use could be reduced by about a quarter to 126–170 EJ by 2025 without diminishing services through the use of energy efficient technology. The potential for greenhouse gas emission reductions is larger. Technical changes might include


Figure 14: Road transport energy per unit of GDP vs. average fuel price in 1990, for 17 of the world's 20 largest transport energy users. Excludes China, Russia, and Ukraine; former West and East Germany data have been combined. Sources: IEA, 1993c, 1993d, 1994a; ADB, 1994 (see Chapter 21 for complete citations).

more efficient space-conditioning and water-supply systems; reducing heat losses through building structures; more efficient lighting; more efficient appliances; and more efficient computers and supporting equipment. In addition, measures to counter trends toward higher ambient temperatures in urban areas (through increased vegetation, greater reflectivity of roofing and siding materials, and better architectural design) can yield significant reductions in the energy required for heating and air conditioning.

This assessment suggests that three types of activities could significantly reduce the growth of building-related emissions:

*   Support for energy-efficiency policies, including pricing strategies; individual, meter-based billing for energy use in multiple-family dwellings; regulatory programs including minimum energy-efficiency standards for buildings and appliances; utility demand-side management programs; and market pull and demonstration programs that stimulate the development and application of advanced technologies
*   Enhanced research and development in energy efficiency
*   Enhanced training and added support for financing efficiency programs in all countries, but especially in developing countries and transition economies.

Many energy-efficiency policies, information/education measures, and research and development programs—carried out primarily in industrialized countries—have achieved significant

reductions in energy use. Although the technical and economic potential for further efficiency improvements is high, effective implementation requires well-designed combinations of financial incentives and other government policies. Strategies to reduce emissions likely will prove more effective if they use well-integrated mixes of policies, tailored for local situations and developed through consultation with and participation by those most affected.

4.2.2. Mitigating Industrial Process and Human Settlement Emissions

Process-related greenhouse gases—including CO_2, CH_4, N_2O, halocarbons, and SF_6—are released during manufacturing and industrial processes, such as the production of iron, steel, aluminium, ammonia, cement, and other materials. Large reductions are possible in some cases. Measures include modifying production processes, eliminating solvents, replacing feedstocks or materials substitution, increased recycling, and reduced consumption of greenhouse gas-intensive materials. Capturing and utilizing CH_4 from landfills and sewage treatment facilities, and lowering the leakage rate of halocarbon refrigerants from mobile and stationary sources can also lead to significant greenhouse gas emission reductions.

4.2.3. Energy Supply

This assessment focuses on new technologies for capital investment and not on potential retrofitting of existing capital stock to use less carbon-intensive forms of primary energy. It is technically possible to realize deep emissions reductions in the energy supply sector in step with the normal timing of investments to replace infrastructure and equipment as it wears out or becomes obsolete. Many options for achieving deep reductions will also decrease the emissions of SO_2, NO_x, and VOCs. Promising approaches, not ordered according to priority, include the following:

- **Greenhouse gas reductions in the use of fossil fuels**
  - *More-efficient conversion of fossil fuels*. New technology offers considerably increased conversion efficiencies. For example, the efficiency of power production can be increased from the present world average of about 30% to more than 60% in the longer term. Also, the use of combined heat and power production replacing separate production of power and heat—whether for process heat or space heating—offers a significant rise in fuel conversion efficiency.
  - *Switching to low-carbon fossil fuels and suppressing emissions*. Switching from coal to oil or natural gas, and from oil to natural gas, can reduce emissions. Natural gas has the lowest CO_2 emissions per unit of energy of all fossil fuels at about 14 kg C/GJ, compared to oil with about 20 kg C/GJ, and coal with about 25 kg C/GJ. The lower carbon-containing fuels can, in general, be converted with higher efficiency than coal. Large resources of natural gas exist in many areas. New, low-capital-cost, highly efficient, combined-cycle

Figure 15: Historical carbon emissions resulting from energy use in the residential and commercial sectors.

technology has reduced electricity costs considerably in some areas. Natural gas could potentially replace oil in the transportation sector. Approaches exist to reduce emissions of CH_4 from natural gas pipelines and emissions of CH_4 and/or CO_2 from oil and gas wells and coal mines.

– *Decarbonization of flue gases and fuels and CO_2 storage*. The removal and storage of CO_2 from fossil fuel power-station stack gases is feasible, but reduces the conversion efficiency and significantly increases the production cost of electricity. Another approach to decarbonization uses fossil fuel feedstocks to make hydrogen-rich fuels. Both approaches generate a byproduct stream of CO_2 that could be stored, for example, in depleted natural gas fields. The future availability of conversion technologies such as fuel cells that can efficiently use hydrogen would increase the relative attractiveness of the latter approach. For some longer term CO_2 storage options, cost, environmental effects, and efficacy remain largely unknown.

- **Switching to non-fossil fuel sources of energy**
  - *Switching to nuclear energy*. Nuclear energy could replace baseload fossil fuel electricity generation in many parts of the world if generally acceptable responses can be found to concerns such as reactor safety, radioactive-waste transport and disposal, and nuclear proliferation.
  - *Switching to renewable sources of energy*. Solar, biomass, wind, hydro, and geothermal technologies already are widely used. In 1990, renewable sources of energy contributed about 20% of the world's primary energy consumption, most of it fuelwood and hydropower. Technological advances offer new opportunities and declining costs for energy from these sources. In the longer term, renewable sources of energy could meet a major part of the world's demand for energy. Power systems can easily accommodate limited fractions of intermittent generation and, with the addition of fast-responding backup and storage units, also higher fractions. Where biomass is sustainably regrown and used to displace fossil fuels in energy production, net carbon emissions are avoided as the CO_2 released in converting the biomass to energy is again fixed in biomass through photosynthesis. If the development of biomass energy can be carried out in ways that effectively address concerns about other environmental issues and competition with other land uses, biomass could make major contributions in both the electricity and fuels markets, as well as offering prospects of increased rural employment and income.

Future emissions will depend on the nature of the technologies nations choose as they expand and replace existing energy systems.

4.2.4.   *Integration of Energy System Mitigation Options*

To assess the potential impact of combinations of individual measures at the energy system level, in contrast to the level of individual technologies, variants of a low CO_2-emitting energy supply system (LESS) are described. The LESS constructions are "thought experiments," exploring possible global energy systems.

The following assumptions were made: World population grows from 5.3 billion in 1990 to 9.5 billion by 2050 and 10.5 billion by 2100. GDP grows 7-fold by 2050 (5-fold and 14-fold in industrialized and developing countries, respectively) and 25-fold by 2100 (13-fold and 70-fold in industrialized and developing countries, respectively), relative to 1990. Because of emphasis on energy efficiency, primary energy consumption rises much more slowly than GDP. The energy supply constructions were made to meet energy demand in (i) projections developed for the IPCC's First Assessment Report in a low energy demand variant, where global primary commercial energy use approximately doubles, with no net change for industrialized countries but a 4.4-fold increase for developing countries from 1990 to 2100; and (ii) a higher energy demand variant, developed in the IPCC IS92a scenario where energy demand quadruples from 1990 to 2100. The energy demand levels of the LESS constructions are consistent with the energy demand mitigation chapters of this Second Assessment Report.

Figure 16 shows combinations of different energy sources to meet changing levels of demand over the next century. The analysis of these variants leads to the following conclusions:

- Deep reductions of CO_2 emissions from energy supply systems are technically possible within 50 to 100 years, using alternative strategies.
- Many combinations of the options identified in this assessment could reduce global CO_2 emissions from fossil fuels from about 6 Gt C in 1990 to about 4 Gt C per year by 2050, and to about 2 Gt C per year by 2100 (see Figure 17). Cumulative CO_2 emissions, from 1990 to 2100, would range from about 450 to about 470 Gt C in the alternative LESS constructions.
- Higher energy efficiency is underscored for achieving deep reductions in CO_2 emissions, for increasing the flexibility of supply-side combinations, and for reducing overall energy system costs.
- Interregional trade in energy grows in the LESS constructions compared to today's levels, expanding sustainable development options for Africa, Latin America, and the Middle East during the next century.

Costs for energy services in each LESS variant relative to costs for conventional energy depend on relative future energy prices, which are uncertain within a wide range, and on the performance and cost characteristics assumed for alternative technologies. However, within the wide range of future energy prices, one or more of the variants would plausibly be capable of providing the demanded energy services at estimated costs

Figure 16: Global primary energy use for alternative Low CO$_2$-Emitting Energy Supply System (LESS) constructions: Alternatives for meeting different energy demand levels over time, using various fuel mixes.

that are approximately the same as estimated future costs for current conventional energy. It is not possible to identify a least-cost future energy system for the longer term, as the relative costs of options depend on resource constraints and technological opportunities that are imperfectly known, and on actions by governments and the private sector.

The literature provides strong support for the feasibility of achieving the performance and cost characteristics assumed for energy technologies in the LESS constructions, within the next 2 decades, though it is impossible to be certain until the research and development is complete, and the technologies have been tested in the market. Moreover, these performance and cost characteristics cannot be achieved without a strong and sustained investment in research, development, and demonstration. Many of the technologies being developed

would need initial support to enter the market, and to reach sufficient volume to lower costs to become competitive.

Market penetration and continued acceptability of different energy technologies ultimately depends on their relative cost, performance (including environmental performance), institutional arrangements, and regulations and policies. Because costs vary by location and application, the wide variety of circumstances creates initial opportunities for new technologies to enter the market. Deeper understanding of the opportunities for emissions reductions would require more detailed analysis of options, taking into account local conditions.

Because of the large number of options, there is flexibility as to how the energy supply system could evolve, and paths of energy system development could be influenced by considerations

Figure 17: Annual CO_2 emissions from fossil fuels for alternative LESS constructions, with comparison to the IPCC IS92a-f scenarios (see Figure 16 for acronym definitions).

other than climate change, including political, environmental (especially indoor and urban air pollution, acidification, and land restoration) and socioeconomic circumstances.

4.3.   *Agriculture, Rangelands, and Forestry*

Management of agricultural lands, rangelands, and forests can play an important role in reducing current emissions and/or enhancing the sinks of CO_2, CH_4, and N_2O. Measures to reduce emissions and sequester atmospheric carbon include slowing deforestation, enhancing natural forest generation, establishing tree plantations, promoting agroforestry, altering management of agricultural soils and rangelands, restoring degraded agricultural lands and rangelands, and improving the diet of ruminants. Although these are demonstrated, effective measures, a number of important uncertainties linger regarding their global potential to reduce emissions or sequester carbon. The net amount of carbon per unit area conserved or sequestered in living biomass under a particular forest-management practice and present climate is relatively well-understood. The most important uncertainties associated with estimating a global value are

(i) the amount of land suitable and available for forestation, regeneration, and/or restoration programs; (ii) the rate at which tropical deforestation can actually be reduced; (iii) the long-term use (security) of these lands; and (iv) the continued suitability of some practices for particular locations given the possibility of changes in temperature, water availability, and so forth under climate change. Management options vary by country, social system, and ecosystem type.

Proposed options for conserving and sequestering carbon and reducing other greenhouse gas emissions in the forestry and agriculture sectors are consistent with other objectives of land management—such as sustainable development, industrial wood and fuelwood production, traditional forest uses, protection of other natural resources (e.g., biodiversity, soil, water), recreation, and increasing agricultural productivity.

4.3.1.   *Carbon Dioxide*

Since the 1990 IPCC assessment, significant new information has emerged concerning the potential of forests to conserve

and sequester carbon, as well as the costs of forestry programs to promote this carbon storage. Biomass for the production of electricity or liquid fuels, continuously harvested and regrown in a sustainable manner, would avoid the release of fossil carbon. In the long run, this would offer a more efficient strategy than one based on carbon storage in vegetation and soils, which would saturate with time. The development of this mitigation option will depend critically upon the competitiveness of biomass. However, managing forests to conserve and increase carbon storage offers an effective mitigation option during the transition period of many decades necessary to stabilize atmospheric concentrations of carbon.

In the forestry sector, assuming the present climate and no change in the estimated area of available lands, the cumulative amount of carbon that could feasibly be conserved and sequestered through establishment of plantations and agroforestry, forest regeneration, sustaining existing forest cover, and slowing deforestation over the period 1995–2050 ranges between 60 and 90 Gt C. The literature indicates that the tropics have the potential to conserve and sequester the largest quantity of carbon (80% of the global total in the forestry sector), with more than half due to promoting forest regeneration and slowing deforestation. Tropical America has the largest potential for carbon conservation and sequestration (46% of tropical total), followed by tropical Asia (34%) and tropical Africa (20%). The temperate and boreal zones could sequester about 20% of the global total, mainly in the United States, temperate Asia, the former Soviet Union, China, and New Zealand. Altering the climate and land-use assumptions—for example, by increasing demand for agricultural land in the tropics or accounting for potential consequences of climate change—would reduce these estimates significantly.

Estimates of the full costs of conserving or sequestering carbon in forests should include land values as well as capital, infrastructure, and other costs. However, many of these costs are particularly difficult to generalize given the amenity value of forests, their importance in traditional economies, and their significance in maintaining regional environments and biodiversity. Costs for conserving and sequestering carbon in biomass and soil are estimated to range widely, but can be competitive with other mitigation options. Factors affecting costs include opportunity costs of land, initial costs of planting and establishment, costs of nurseries, the cost of annual maintenance and monitoring, and transaction costs. Direct and indirect benefits will vary with national circumstances and could offset the costs. Additional amounts of carbon could be sequestered in agricultural and rangeland soils over a 50-year period by improved management practices, although less is currently known about the global potential in this sector.

4.3.2. Methane and Nitrous Oxide

Nations can achieve significant decreases in CH_4 emissions from agriculture through improved nutrition of ruminant animals and better management of rice paddies (e.g., irrigation,

nutrients, new cultivars). Altering the treatment and management of animal wastes and reducing agricultural biomass burning also will decrease CH_4 releases. Combining these practices could reduce CH_4 emissions from agriculture by 25 to 100 Mt/yr. Agricultural sources of N_2O include mineral fertilizers, legume cropping, animal waste, and biomass burning. Using presently available techniques to improve the efficiency of fertilizer and manure could reduce agricultural emissions by 0.3 to 0.9 Mt of nitrogen per year.

4.4. Cross-Sectoral Issues

Cross-sectoral assessment of different combinations of mitigation options focuses on the interactions of the full range of technologies and practices that are potentially capable of reducing emissions of greenhouse gases or sequestering carbon. Current analysis suggests the following:

- *Competing uses of land, water, and other natural resources*. A growing population and expanding economy will increase the demand for land and other natural resources needed to provide, *inter alia*, food, fiber, forest products, and recreation services. Climate change will interact with the resulting intensified patterns of resource use. Land and other resources could also be required for mitigation of greenhouse gas emissions. Agricultural productivity improvements throughout the world and especially in developing countries would increase availability of land for production of biomass energy.
- *Geoengineering options*. Some geoengineering approaches to counterbalance greenhouse-induced climate change have been suggested (e.g., putting solar radiation reflectors in space, or injecting sulfate aerosols into the atmosphere to mimic the cooling influence of volcanic eruptions). Such approaches generally are likely to be ineffective, expensive to sustain, and/or to have serious environmental and other effects which are in many cases poorly understood.

4.5. Policy Instruments

Mitigation depends on reducing barriers to the diffusion and transfer of technology, mobilizing financial resources, supporting capacity building in developing countries, and other approaches to assist in the implementation of behavioral changes and technological opportunities in all regions of the globe. The optimum mix of policies will vary from country to country, depending upon political structure and societal receptiveness. The leadership of national governments in applying these policies will contribute to responding to adverse consequences of climate change. Governments can choose policies that facilitate the penetration of less greenhouse gas-intensive technologies and modified consumption patterns. Indeed, many countries have extensive experience with a variety of policies that can accelerate the adoption of such technologies.

This experience comes from efforts over the past 20 to 30 years to achieve improved energy efficiency, to reduce the environmental impacts of agricultural policies, and to meet conservation and environmental goals unrelated to climate change. Policies to reduce net greenhouse gas emissions appear more easily implemented when they are designed to address other concerns that impede sustainable development (e.g., air pollution and soil erosion). A number of policies, some of which may need regional or international agreement, can facilitate the penetration of less greenhouse gas-intensive technologies and modified consumption patterns, including:

- Putting in place appropriate institutional and structural frameworks
- Energy pricing strategies (e.g., carbon or energy taxes, and reduced energy subsidies)
- Reducing or removing other subsidies (e.g., agricultural and transport subsidies that increase greenhouse gas emissions)
- Tradable emissions permits
- Voluntary programs and negotiated agreements with industry
- Utility demand-side management programs
- Regulatory programs including minimum energy-efficiency standards, such as for appliances and fuel economy
- Stimulating research, development, and demonstration to make new technologies available
- Market pull and demonstration programs that stimulate the development and application of advanced technologies
- Renewable energy incentives during market build-up
- Incentives such as provisions for accelerated depreciation and reduced costs for consumers
- Education and training; information and advisory measures
- Options that also support other economic and environmental goals.

Accelerated development of technologies that will reduce greenhouse gas emissions and enhance greenhouse gas sinks—as well as understanding the barriers that inhibit their diffusion into the marketplace—requires intensified research and development by governments and the private sector.

5. Technical Guidelines for Assessing Climate Change Impacts and Adaptations

Working Group II has prepared guidelines to assess the impacts of potential climate change and to evaluate appropriate adaptations. They reflect current knowledge and will be updated as improved methodologies are developed. The guidelines outline a study framework that will allow comparable assessments to be made of impacts and adaptations in different regions/geographical areas, economic sectors, and countries. They are intended to help contracting parties meet, in part, their commitments under Article 4 of the UNFCCC.

Impact and adaptation assessments involve several steps:

- Definition of the problem
- Selection of the methods
- Testing the method
- Selection of scenarios
- Assessment of biophysical and socioeconomic impacts
- Assessment of autonomous adjustments
- Evaluation of adaptation strategies.

Definition of the problem includes identifying the specific goals of the assessment, the ecosystem(s), economic sector(s), and geographical area(s) of interest, the time horizon(s) of the study, the data needs, and the wider context of the work.

The selection of analytical methods(s) depends upon the availability of resources, models, and data. Impact assessment analyses can range from the qualitative and descriptive to the quantitative and prognostic.

Testing the method(s), including model validation and sensitivity studies, before undertaking the full assessment is necessary to ensure credibility.

Development of the scenarios requires, firstly, the projection of conditions expected to exist over the study period in the absence of climate change and, secondly, the projection of conditions associated with possible future changes in climate.

Assessment of potential impacts on the sector(s) or area(s) of interest involves estimating the differences in environmental and socioeconomic conditions projected to occur with and without climate change.

Assessment of autonomous adjustments implies the analysis of responses to climate change that generally occur in an automatic or unconscious manner.

Evaluation of adaptation strategies involves the analysis of different means of reducing damage costs. The methodologies outlined in the guidelines for analyzing adaptation strategies are meant as a tool only to compare alternative adaptation strategies, thereby identifying the most suitable strategies for minimizing the effects of climate change were they to occur.

6. Methods for Assessing Mitigation Options and Inventory of Mitigation Technologies

Working Group II also has prepared guidelines to assess mitigation of options. Recognizing that there are many viable approaches for mitigating greenhouse gas emissions and that countries need to identify those approaches best suited to their needs and conditions, these guidelines provide a range of analytical methods and approaches for assessing mitigation options and developing national mitigation plans and strategies. The types of methods covered include macroeconomic models, decision analysis tools, forecasting methods, costing

models, market research methods, and monitoring and evaluation methods.

In addition to descriptions of methods, the guidelines describe several broader aspects of the mitigation options assessment process, including the strategic, analytical, and informational challenges; organizational issues; and important cross-cutting issues such as top-down versus bottom-up modeling, accounting for uncertainty, and incorporating externalities.

The guidelines place a special emphasis on the needs of developing countries and countries with economies in transition. The methods and models addressed are therefore intended to match a range of analytical capabilities and resource constraints.

Research in the preparation of these guidelines has demonstrated that methods to assess mitigation options are available to all countries for use in developing strategies and evaluating programs and projects that (i) support national economic, social, and institutional development goals, and (ii) slow the rate of growth in greenhouse gas emissions. Although involving analytical challenges, these methods have been widely applied in both industrialized and developing countries. Moreover, the Global Environment Facility, other international organizations, and bilateral programs provide resources to assist developing countries and those with economies in transition in obtaining information on, testing, and using these methods. The IPCC recommends that all countries evaluate and use, as appropriate, these draft methods in preparing country studies and their national communications.

In the future, development and application of mitigation assessment methods will result in further improvements in the methods and the capabilities of countries to assess mitigation options. The IPCC, in coordination with other multilateral institutions, could accelerate the dissemination of selected information on assessment methods through seminars, workshops, and educational materials.

CONTENTS

A.1. Introduction

All living organisms in terrestrial ecosystems ultimately depend directly or indirectly upon photosynthesis for their energy requirements. Photosynthesis depends on the absorption of light and the diffusion of CO_2 from the atmosphere to the sites of photosynthesis within leaves. To take up CO_2, plants must open their stomata; this generally results in considerable water loss. Increases in atmospheric CO_2 concentration can reduce water loss and increase photosynthetic carbon gain of most plants. Plant growth is only possible if temperatures are between some lower and upper thresholds; plant growth at most locations is likely to increase with moderate increases in annual mean temperature, mainly due to lengthening of the growing season.

Plants also need inorganic nutrients from the soil, such as nitrate or ammonia and phosphate, and plant response to environmental variables is modified by the availability of these soil nutrients. Furthermore, soil-nutrient availability itself can also be affected by environmental factors.

At any site, there are usually many different plant species that interact with each other and with other organisms in a multitude of different ways. In considering the effect of climate change on any terrestrial ecosystem, it is necessary to consider not only the direct ecophysiological effects in response to climate change but also the ways in which these direct effects are modified by soil feedbacks and biological interactions between different organisms.

Because many of the responses of terrestrial plants in diverse ecosystems are similar, a general description is offered here of some of the major potential impacts of climate change on terrestrial ecosystems (see also Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, of the IPCC Working Group I volume). This primer initially provides some overview of effects of the most important climatic driving forces that are likely to change, then discusses effects on soil carbon and nitrogen dynamics, looks at soil fertility as a modifying effect on responses to external driving forces, and includes a brief discussion of soil biological factors. These broad ecosystem responses are modified by ecological interactions between the different organisms in each ecosystem; the primer provides a brief overview of the major ecological factors that must be considered in assessing the impact of climate change on terrestrial ecosystems.

A.2. Climatic Driving Forces

Solar radiation, temperature, precipitation, air humidity, and atmospheric CO_2 concentration are some of the most important external forces that drive ecosystem processes. Precipitation, air humidity, and other meteorological variables—as well as plant and soil variables—together determine water availability for plants. Of these, changes in temperature, water availability, and CO_2 concentration are likely to constitute the most significant changes for terrestrial ecosystems over the coming century. The effects of these changes are discussed in the following sections.

A.2.1. Temperature

The increase in CO_2 and other greenhouse gases is expected to cause an increase in global mean temperature, with larger increases at high latitudes than elsewhere and larger increases during winter than summer (Gates *et al*., 1992; Greco *et al*., 1994). Plant growth and health may benefit from increased temperatures because of reduced freezing and chilling damage, but plants may be harmed by increased high-temperature damage. There is some indication that higher mean temperatures in the future will be associated with more variable and more extreme temperatures (Katz and Brown, 1992). However, the increase in global mean temperature during the past half-century has been primarily a result of higher night temperature (Karl *et al*., 1993).

Net primary productivity (NPP) is generally enhanced by modest increases in temperature, especially in temperate and boreal regions (e.g., Kauppi and Posch, 1985; Cannell *et al*., 1989; Kokorin *et al*., 1993; Beuker, 1994). According to a relationship developed by Lieth (1973) based on observed net primary production in a variety of ecosystems, NPP will increase from 1% per °C increase in temperature in ecosystems with a mean annual temperature of 30°C to 10% per °C at 0°C. However, because this relationship is based on observations of NPP under present temperatures, part of the apparent increase could be the result of a correlation between higher solar radiation and higher temperature, so the actual effects of temperature change alone may be smaller.

Effects of increasing temperature on crop yields are more difficult to predict than effects of temperature on NPP because crop yields are not only affected by NPP but also by the phenology of crop development (see also Chapter 13). Increased temperature can speed phenological development, reducing the grain-filling period for crops and lowering yield—as is observed in current conditions (e.g., Monteith, 1981) and in most modeling studies (Warrick *et al*., 1986; Chapter 13). For example, Wang *et al*. (1992) modeled the growth of wheat with climate change, and found that yield decreased as temperature increased because crop development was hastened. A cultivar from a warmer region, however, responded positively to moderate increases in temperature and gave a larger yield than the cultivar from the colder region under current conditions. This suggests that current cultivars might generally perform more poorly in a warmer climate, but losses could generally be avoided by cultivar substitution.

Extreme temperatures are often more important than average temperatures in determining plant responses (Woodward, 1987). If global warming reduces the frequency of extremely low temperatures, plants may be able to survive at higher latitudes or altitudes, and agricultural plants can be grown for longer periods of the year without the danger of damaging frosts. On the other hand, many plants are adapted to the climate in their current locations, and a general warming could result in premature bud-burst and so, paradoxically, increase frost damage (Hänninen, 1991). Alternatively, plants may experience insufficient chilling exposure so that flowering and

fruit and seed production may not proceed at all, or be initiated in a season with inappropriate climate. In another study, increased temperature was found to speed bud-burst, but increasing CO_2 concentrations counteracted the effect, in some locations completely (Murray *et al.*, 1994).

Increased episodes of extremely high temperature can damage plants, especially in conjunction with water shortage. However, if sufficient soil water is available, leaf temperatures can be substantially lower than air temperature as a result of evaporative cooling. Burke *et al.* (1988) report that many plants maintain leaf temperatures within a preferred range, thereby optimizing NPP. While the amount of water consumed for leaf cooling can be substantial and highly variable, typically 200–500 water molecules may be lost for each molecule of CO_2 taken up (Sharkey, 1985). This can lead to insufficient water in plant tissues, resulting in reduced growth. Elevated CO_2 reduces stomatal conductance (Eamus, 1991) and so saves water, but this may further increase the temperature of leaves, over and above increased air temperature.

Plant membranes may be damaged at high temperature (Berry and Björkman, 1980), and membranes in plants are often modified following growth in high temperature. However, this reduces plant performance at low temperature. High temperature can affect other plant processes. Respiration rates are often increased by high temperatures, and plant respiration can account for the loss of a significant fraction of the carbon fixed in photosynthesis. However, plants may acclimate to higher temperature, and the short-term effects of temperature on respiration are often not seen when plants are grown at different temperatures (e.g., Gifford, 1994; Körner, 1995). Also, the response of leaf respiration rate to temperature can be substantially reduced in plants grown in high CO_2 and high temperature (e.g., Wullschleger and Norby, 1992). The interaction between increased temperature and increased CO_2 is substantial, and the effect of warming by itself may be modified or even reversed when CO_2 effects are considered. Other processes—such as the volatilization of hydrocarbons, which could affect carbon balance—show less acclimation to high temperature (Tingey *et al.*, 1991; Lerdau 1991). Hydrocarbon loss from leaves can exceed 10% of the carbon taken up for photosynthesis.

A.2.2.   *Precipitation and Soil Water Availability*

Active physiological processes of plants require an aqueous medium. Higher land plants are able to survive within a generally dry atmosphere because they are covered by a cuticular epidermis that minimizes water loss. For growth, however, plant leaves must take up CO_2 from the atmosphere. This need for a path for diffusion of CO_2 into the leaves also provides a path by which water is lost from leaves. Water loss is regulated by stomata whose aperture is adjusted in response to environmental variables and internal regulators.

If the soil is wet, plants can replace transpired water with water from the soil. If plants continue to extract water from the soil,

and if soil water is not replenished by rain or irrigation, then the water content of plants must eventually fall and their physiological function is impaired (Hsiao, 1973; Bradford and Hsiao, 1982). Water-stressed plants restrict further water losses by closing stomata, by adjusting the angle at which leaves are held to minimize light absorption, or by shedding leaves (Passioura, 1982). CO_2 uptake and growth is then reduced or completely prevented (Schulze and Hall, 1982). Water availability at most locations is seasonally variable, with plants experiencing at least temporary drought for some time (Woodward, 1987; Stevenson, 1990). Individual species are adapted to particular water regimes and may perform poorly and possibly die in conditions to which they are poorly adapted (e.g., Hinckley *et al.*, 1981).

Total plant growth under water-limited conditions is essentially given by the product of the amount of water used and water-use efficiency. Short-term water-use efficiency can be expressed as the ratio of the difference of CO_2 concentration between the atmosphere and the sites of photosynthesis to the difference of water-vapor concentration between the sites of evaporation within leaves and the atmosphere. Hence, anything that changes either of these concentration differences can potentially affect water-use efficiency and thus growth under water-limited conditions (Eamus, 1991).

Different plant types (see Box A-1) have different water-use efficiencies. C_3 plants have relatively poor water use efficiency. C_4 plants have higher water-use efficiency because they photosynthesize at lower internal CO_2 concentration and thereby increase the difference in CO_2 concentrations between the atmosphere and the sites of photosynthesis. In CAM plants, CO_2 uptake occurs at night, when leaves are coolest and the leaf to air water vapor concentration difference is smallest. This gives CAM plants the highest water-use efficiency of all plants.

Higher CO_2 concentration generally leads to lower stomatal conductance (Kimball and Idso, 1983; Morison, 1987) and higher leaf photosynthetic rates (Eamus and Jarvis, 1989; Arp, 1991). This improves water-use efficiency, so carbon gain for plants with limited water supply should increase with increasing CO_2 concentration (Rogers *et al.*, 1983; Idso and Brazel, 1984; Tolley and Strain, 1985; Morison, 1987; Eamus and Jarvis, 1989).

Many ecosystems experience shortage of soil water (drought) during some or most of the year, which limits their potential carbon gain (Lieth, 1973; Hinckley *et al.*, 1981; Woodward, 1987). Soil water availability can be related to the ratio of precipitation to potential evapotranspiration, or to other measures of water availability, such as the ratio of actual to potential evapotranspiration. What is important in all these measures is that soil water availability can be affected by changes in either gains (precipitation) or losses (evapotranspiration) of water.

Because warmer air can hold more water, it is likely that increasing temperature will lead to a larger difference between the water-vapor concentration inside leaves and in the air, with

---

Box A-1. Different Plant Groups

C$_3$— C$_3$ is the most basic photosynthetic mechanism. It is called C$_3$ because the first compound into which CO$_2$ is incorporated is a compound with three carbon atoms. C$_3$ plants make up the majority of species globally, especially in cooler or wetter habitats; they include all important tree and most crop species, such as wheat, rice, barley, cassava, and potato.

C$_4$— C$_4$ plants have a special CO$_2$-concentrating mechanism within their leaves by which they can increase the CO$_2$ concentration to several times above ambient levels. This is done by CO$_2$ first being incorporated into a 4-carbon compound. This allows these plants to maintain lower intercellular CO$_2$ concentrations than C$_3$ plants. C$_4$ plants tend to grow in warmer, more water-limited regions, and include many tropical grasses and the agriculturally important species maize, sugarcane, and sorghum.

CAM—Crassulacean acid metabolism, CAM, is a variant of C$_4$ photosynthesis in which CO$_2$ is not only concentrated but also stored for half a day. CAM plants, such as cacti, often grow in deserts, but they also include more common plants such as pineapple. In these plants, CO$_2$ uptake occurs at night. The CO$_2$ is then stored for use in normal photosynthetic reactions during the next day.

---

little effect on the difference in CO$_2$ concentrations—thus lowering water-use efficiency. If the absolute humidity increases in line with the saturated humidity at the diurnal minimum temperature, and if both diurnal minimum and maximum temperatures change similarly with global warming, then the leaf-to-air water-vapor concentration differences will increase by about 5–6% per °C warming. However, if nighttime temperatures were to increase more than daytime temperatures—as has been the case over recent decades (Karl *et al*., 1993)—then the concentration difference will increase by less than 5–6% per °C.

General circulation models (GCMs) suggest that there are likely to be regions where precipitation will increase by more than the global average and where the additional rainfall may be more than sufficient to meet increased evaporative demand, whereas other regions may receive less rainfall than at present (Mitchell *et al*., 1990; Greco *et al*., 1994); this is further complicated by feedbacks from the biosphere. Henderson-Sellers *et al*. (1995), for example, show that inclusion of stomatal closure in response to increasing CO$_2$ concentration led to a reduction in the predicted increase in precipitation from 7.7% for doubled CO$_2$ to only 5.0%. The timing of water availability within ecosystems may also change. For example, earlier melting of snowpacks may mean that less water is available during summer (Mitchell *et al*., 1990; Hayes, 1991). There will therefore almost certainly be some regions with improved and others with worse water balances than at present.

Potential evapotranspiration rates can be estimated using a variety of meteorological formulae with varying physical rationales. Some workers have used the Thornthwaite method, which is based on correlations between evapotranspiration and temperature in the current climate (e.g., Thornthwaite, 1948; Le Houerou *et al*., 1993). Based on the Thornthwaite method, these workers conclude that water may become more limiting with temperature increase in the future (e.g., Gleick, 1987; Rind *et al*., 1990; Leichenko, 1993). However, the formulae that have the soundest physical bases—the Penman, Priestley and Taylor, and Penman-Monteith equations (Jarvis and

McNaughton, 1986; Martin *et al*., 1989)—predict that potential evapotranspiration would increase with warming by an amount similar to the anticipated increase in precipitation (McKenney and Rosenberg, 1993), provided other factors such as radiation balance and surface resistance do not change. There would then be little change in the global incidence of drought conditions.

Where climate change leads to annual or seasonal changes in water availability, agricultural and forest productivity could change. Significant reductions in soil water availability could lead to forest decline. There could also be indirect problems, such as more floods and greater erosion hazards caused by more intense rainfall. Wind erosion could increase if drought lengthens the time that the ground is bare of vegetation. Changes in the ratio of precipitation to potential evapotranspiration could also affect water discharge into rivers and groundwater reservoirs.

If water runs off the surface instead of infiltrating the soil, the amount available to plants is reduced; this may also lead to erosion. Water infiltration rates are affected by soil texture and structure, slope, vegetation cover, soil surface roughness, surface crusting, and land management. Infiltration is also controlled by soil water content because saturated soils are unable to absorb water and very dry soils can be slow to re-wet. Aggregated soils with good structure facilitate infiltration, and aggregation is strongly affected by the organic matter content of the topsoil. Surface runoff is also strongly dependent on the amount and intensity of rainfall, which in most regions is likely to increase with climate change (e.g., Gordon *et al*., 1992).

The water-retention capacity of different soil types can influence the intensity of water stress experienced by plants. Soil water retention is significantly affected by soil organic-matter content, particle-size distribution, bulk density, and soil structure. Thus, any decrease in the quantity of soil organic matter as a result of faster decomposition could reduce infiltration rates and soil water retention and accentuate plant water stress.

Waterlogging can develop because of rising groundwater tables or because of the presence of partially permeable layers within the soil profile. Waterlogging can affect plant growth in both agricultural and natural environments by limiting the diffusion of oxygen to plant roots and soil organisms. Excess soil wetness can also be a considerable hindrance in agriculture by impeding soil tillage (Rounsevell and Jones, 1993), and climate change can thus affect crop production by affecting soil workability (Rounsevell *et al.*, 1994).

A.2.3.   *Direct Effects of CO_2 Concentration*

Atmospheric CO_2 is a basic substrate for photosynthesis, which underlies plant growth. In the response of plants to CO_2 concentration, it is important to distinguish between plants with the C_3 and C_4 photosynthetic pathways. Increasing CO_2 concentration directly affects photosynthesis in three ways. Firstly, the carboxylating enzyme for carbon reduction in all plants, Rubisco, has a poor affinity for CO_2. The present atmosphere results in CO_2 concentrations in chloroplasts that are well below half-saturation (Farquhar and von Caemmerer, 1982). Consequently, the photosynthetic rate is very responsive to small increases in CO_2 concentration in C_3 plants. Secondly, oxygen competes with CO_2 for the active site on Rubisco, leading to photorespiration (Farquhar and von Caemmerer, 1982). The rise in atmospheric CO_2 concentration will progressively reduce photorespiration and enhance quantum yield of carbon fixation in C_3 plants. This will not occur in C_4 plants, which have a CO_2-concentrating mechanism that already suppresses photorespiration. Thirdly, stomata in many species progressively close as the atmospheric CO_2 concentration increases, thus reducing water loss relative to carbon gain. This gain may be offset to some extent by increased leaf temperature. It has also been argued that CO_2 will alter respiratory activity. Experimental evidence demonstrates both increases and decreases in response to increasing atmospheric CO_2 concentration (e.g., Amthor, 1991; Poorter *et al.*, 1992).

It is well-established that short-term photosynthetic rates in C_3 plants increase by 25–75% for a doubling of CO_2 concentration (Kimball, 1983; Cure and Acock, 1986; Eamus and Jarvis, 1989; Allen, 1990; Bazzaz, 1990; Bowes, 1993; Luxmoore *et al.*, 1993). There are fewer data available for C_4 plants. While some workers have found little response (e.g., Morison and Gifford, 1983; Henderson *et al.*, 1992), others have found increases of 10–25% in photosynthetic rate for a doubling of CO_2 concentration (e.g., Wong, 1979; Pearcy *et al.*, 1982; Polley *et al.*, 1992). The sensitivity of C_3 photosynthesis to CO_2 concentration increases with increasing temperature (Long, 1991; Bowes, 1993; Kirschbaum, 1994); hence, the stimulation of plant growth by increasing CO_2 concentration is likely to be larger at higher temperatures (Idso *et al.*, 1987; Rawson, 1992), with little stimulation and sometimes even inhibition at low temperatures (Kimball, 1983).

The increased photosynthetic rate and decreased water require-

ment translate into increased growth and crop yield of C_3 plants (Kimball, 1983; Cure and Acock, 1986), increased growth of C_4 plants (Poorter, 1993), and increased tree seedling growth (Luxmoore *et al.*, 1993). However, this connection can be confounded by many factors. Firstly, acclimation of photosynthesis may occur such that photosynthetic capacity is diminished. An average 21% decrease in photosynthetic capacity has been observed in tree species (Gunderson and Wullschleger, 1994), although this may be an artifact of pot size (Arp, 1991; Thomas and Strain, 1991; Sage, 1994). Despite this decline in capacity, photosynthetic rate per unit leaf area was on average 44% higher in elevated than in ambient CO_2 (Gunderson and Wullschleger, 1994). Where reductions in photosynthetic capacity cannot be due to restricted rooting volumes, they are most likely a consequence of nitrogen shortage and reduction in Rubisco activity (e.g., Ceulemans and Mousseau, 1994).

Secondly, it is generally observed that carbon partitioning is altered, resulting in plants in elevated CO_2 having lower leaf area per unit of plant dry weight (e.g., Poorter, 1993), and the proportional increase in aboveground growth is less than the increase in photosynthesis or total growth. Responses may also differ in conjunction with other environmental limitations and between species (Gifford, 1992; Luxmoore *et al.*, 1993).

Because the atmospheric CO_2 concentration has already increased from a preindustrial concentration of about 280 ppmv to about 360 ppmv at present, there should be evidence of increased growth of plants under natural conditions. However, the evidence from tree-ring chronologies is unclear (Innes, 1991). For example, Graumlich (1991) found no growth enhancements at five subalpine sites in the Sierra Nevada (California), but LaMarche *et al.* (1984), Kienast and Luxmoore (1988), Hari and Arovaara (1988), Cook *et al.* (1991), West *et al.* (1993), and Graybill and Idso (1993) observed varying degrees of growth enhancement in recent times compared with preindustrial times. However, part or all of that increase can probably be explained by more favorable temperatures and nitrogen fertilization by moderate levels of industrial pollution, especially as some of the observed increases are far greater than would be expected from CO_2 enrichment alone (Luxmoore *et al.*, 1993).

There is increasing experimental evidence available on the effects of CO_2 enrichment on ecosystem dynamics, although much is still unpublished. The few results available to date give a divergent picture (Körner, 1995). For example, in a warm and nutrient-rich temperate wetland in Maryland, a high and persistent increase in growth has been observed (Curtis *et al.*, 1989; Drake, 1992). Körner and Arnone (1992) observed an 11% increase in biomass over 100 days in an artificial tropical ecosystem; shoot biomass increased by 41% in a California grassland (Jackson *et al.*, 1994), and midseason CO_2 uptake increased substantially in a Swiss alpine grassland (Diemer, 1994). On the other hand, almost no response to CO_2 enrichment has been observed in a cold and nutrient-limited tundra environment (e.g., Tissue and Oechel, 1987). In summarizing

ecosystem experiments, Körner (1995) found generally enhanced net CO_2 assimilation but little or no increase in aboveground biomass or leaf area and a likely increase in soil carbon.

Because water-use efficiency can be greatly enhanced by increased CO_2 concentration (Rogers *et al.*, 1983; Tolley and Strain, 1985; Morison, 1987; Eamus and Jarvis, 1989), relative plant responses to increases in CO_2 should be most pronounced under water-limited conditions (e.g., Gifford, 1979; Allen, 1990). This difference between well-watered and water-limited conditions should be most pronounced for C_4 plants (Samarakoon and Gifford, 1995). Growth enhancement by CO_2 is also evident under severe nutrient limitation (e.g., Wong, 1979; Norby *et al.*, 1986; Idso and Idso, 1994; Lutze and Gifford, 1995). In addition to growth responses, it is highly likely that species composition will change as a result of increasing CO_2 concentration (e.g., Bazzaz *et al.*, 1989; Wong and Osmond, 1991).

Results obtained with different species and experimental conditions have shown that plant responses to increasing CO_2 concentration are likely to differ greatly among the ecosystems of the world. An assessment of the role of increasing CO_2 concentration in the global context requires quantification of the various factors that may increase or decrease the response of plants to CO_2 concentration. Most of the feedback effects are still inadequately understood and poorly quantified. However, plant-growth responses to doubled CO_2 concentration do not generally exceed 30% enhancement, even without negative feedback effects. The realized growth enhancements in response to the gradually increasing CO_2 concentration, therefore, are likely to amount to only a small gradual impact on terrestrial ecosystems.

A.3.   Soil Processes and Properties

Changes in climate will affect a number of crucial soil processes that will affect the ability of the soil to support particular natural or agricultural communities. The extent of these effects could have far-reaching consequences for the future distribution of fauna and flora, greatly changing distribution patterns and possibly resulting in new combinations of soils and vegetation (Tinker and Ingram, 1994). Soil development is likely to lag behind climate and vegetation change, so that in the medium term of decades to centuries, vegetation classes will probably often occur on soil types on which they are not currently found. It is not clear what consequences this mismatch between vegetation and soils will have for ecosystem function in the longer term.

Soil is formed through the interaction of many variables, the most important being parent material, climate, organisms, relief, and time (Jenny, 1941, 1980; Bridges, 1970; White, 1987). The strength and interactions of these variables differ across the world, producing many different soil types, each forming the basis of different habitats and each with different productive potential. Natural soil-forming processes (pedogen-

esis) occur slowly, but changes in the physical environment can lead to fundamental changes in soil types. Pedogenesis and the weathering of inorganic soil components in response to climate change have received insufficient scientific attention in the past, although these are very important for the development of new soil types, for nutrient release, and for many of the physical characteristics of soils (Arnold *et al.*, 1990; Brinkman and Sombroek, 1995).

The rates of change of soil processes and properties resulting from climate change are likely to be different for different soil types (Stewart *et al.*, 1990). Scientific assessments of the impacts of climate change on soils have largely been directed at soil processes that will respond most rapidly (over periods of months or years) and are thought to have the greatest effect on ecosystem functioning. These are principally changes in the soil water regime and turnover of organic matter and the related mineralization or immobilization of nitrogen and other nutrients.

Temperature has only marginal effects on reaction rates of most inorganic reactions in the soil, such as ion exchange, adsorption, and desorption, and increasing temperature itself, therefore, is unlikely to be important for the dynamics of inorganic nutrients. A change in soil moisture content, however, could significantly affect rates of diffusion and thus the supply of mineral nutrients such as P and K to plants. This could well alter the species composition of plants in natural systems and may require adjustments to nutrient management and fertilizer use in agriculture.

A.3.1.   Carbon Dynamics

The global pool of soil organic matter is estimated to contain about 1500 Gt of carbon (C) (Melillo *et al.*, 1990; Adams *et al.*, 1990; Anderson, 1992; Eswaran *et al.*, 1993). This compares with estimates of 600–700 Gt C in aboveground biomass of vegetation (Melillo *et al.*, 1990; Sombroek, 1990; Anderson, 1992; Schimel *et al.*, 1994), 800 Gt C in the atmosphere, and about 40,000 Gt C in the oceans (Watson *et al.*, 1990; Schimel *et al.*, 1994). Most carbon in soils is associated with organic matter, although carbonate-C can also be significant in calcareous soils, and charcoal may be an important constituent in ecosystems subject to frequent fires. The amount of organic matter in soils is influenced by soil type, land use, and climate affecting the release or sequestration of CO_2 (see Box A-2 and Chapters 23 and 24).

Changes in organic carbon contents of the soil are determined by the balance between carbon inputs and carbon losses by organic-matter decomposition (soil respiration) rates. All terrestrial carbon inputs originate from plant products reaching the soil either as root exudates, dead roots, leaf litter, dead branches, or trees or indirectly as feces or bodies of animals. The annual input of carbon is thereby given by the amount of annual NPP minus the fractions of carbon that are removed from the system (e.g., in agricultural produce), lost during fires, respired by herbivores, or stored in increasing wood vol-

Box A-2. Terms Defining Carbon Dynamics

The amount of carbon taken up in photosynthesis is defined as the gross primary production (GPP). Some of this carbon is returned to the atmosphere as CO_2 during plant metabolism (autotrophic respiration), giving a net gain of carbon—the net primary production (NPP). Death and shedding of plant parts adds organic carbon to the soil, where it is decomposed by soil animals, fungi, and bacteria (heterotrophic respiration). The difference between NPP and heterotrophic respiration is the net gain or loss of carbon by the ecosystem and is termed the net ecosystem production (NEP).

umes on the site.

The great bulk of organic matter reaching the soil is respired by soil organisms within a few years, with the exact time course depending on climatic conditions and litter quality. The remaining organic matter is transformed into different forms with different decomposability. Some of it is highly resistant to decomposition, so it remains in the soil for hundreds to thousands of years even if conditions change greatly. Other material is slightly more labile, and some changes can greatly enhance its decomposition rate, leading to a loss of this fraction over years to decades (see the modeling studies of van Veen and Paul, 1981; Parton *et al*., 1987; Jenkinson, 1990).

Changes in climatic conditions and land use generally affect both NPP and the rate of organic-matter decomposition. Soil organic matter increases if NPP increases more than decomposition rate, and soil organic matter decreases if decomposition rate increases more than NPP. However, any such changes in soil organic-matter content are very difficult to verify by direct measurements because of the high inherent variability of soil organic-matter content and because likely changes constitute only a very small fractional change of the amounts that are already in the soil.

Comprehensive data for soil organic-matter content in different soils across the Earth have shown that it increases with increasing water availability, and, for a given water status, it increases with decreasing temperature (Post *et al*., 1982, 1985; Buol *et al*., 1990). Both NPP and organic-matter decomposition are likely to be enhanced by increasing temperature, as all microbiologically facilitated processes are strongly affected by moisture and temperature. Annual soil respiration rates are likely to increase because of the lengthened season for breakdown of plant material and because increasing temperature strongly stimulates organic-matter decomposition (e.g., Berg *et al*., 1993; Lloyd and Taylor, 1994; Kirschbaum, 1995), especially in arctic regions subject to permafrost (Reynolds and Leadly, 1992). Organic-matter decomposition is likely to be stimulated more than NPP (Kirschbaum, 1995). Consequently, although global NPP is likely to increase with global warming, soil carbon storage is likely to decrease at the same time, and this

could add more CO_2 to the atmosphere (e.g., Schimel *et al*., 1990; Jenkinson *et al*., 1991; Thornley *et al*., 1991; Kirschbaum, 1993, 1995). On the other hand, none of these studies deals with the interactive effect of temperature and moisture limitations on decomposition rates. Should warming generally lead to moisture becoming more limiting for decomposition, then the effect of warming may be less pronounced than is suggested by these studies, which implicitly assume that moisture limitations will remain the same.

Other lines of evidence suggest that the carbon-storage potential of the terrestrial biosphere may not diminish in the future. Terrestrial carbon storage appears to have increased since the last glacial maximum (e.g., Bird *et al*., 1994), and models of the possible distribution of biomes under future climatic scenarios with their associated observed carbon storage generally suggest increased carbon-storage potential in the future (e.g., Prentice and Fung, 1990; Smith *et al*., 1992; King and Neilson, 1992).

Experimental work on the effect of increasing CO_2 concentration on soil processes has yielded divergent results (reviewed by van Veen *et al*., 1991), but modeling studies (e.g., Thornley *et al*., 1991; Kohlmaier *et al*.,1991; Rastetter *et al*., 1991; Polglase and Wang, 1992; Gifford, 1992; Kirschbaum, 1993) have consistently led to the result that increasing CO_2 concentration, via increased NPP, would lead to increases in soil carbon storage.

An important feedback is the mineralization of nitrogen and phosphorus (see also Section A.3.2). If increases in NPP lead to enhanced immobilization of nitrogen and phosphorus in soil organic matter, then the higher NPP will subsequently be reduced and the increased carbon input into the soil will not be sustained (Comins and McMurtrie, 1993; Kirschbaum *et al*., 1994). Soil organic matter will then increase only marginally. On the other hand, if increasing CO_2 concentration can stimulate biological nitrogen fixation and mycorrhizal phosphorus uptake, then large and sustained increases in carbon input and consequently soil organic-matter content are possible. Limited experimental evidence suggests that nitrogen fixation may be enhanced by increasing CO_2 concentration (e.g., Norby, 1987; Arnone and Gordon, 1990; Thomas *et al*., 1991; Gifford, 1994), so increasing CO_2 concentration may not make nitrogen more limiting as long as nitrogen-fixing plants are present in the ecosystem.

Photosynthesis in C_3 plants is more responsive to CO_2 concentration in warm than in cool conditions. At the same time, equilibrium amounts of soil organic matter change more with temperature at lower than higher temperatures (Jenny, 1980; Post *et al*., 1982, 1985; Kirschbaum, 1995), so the net balance of effects may lead to soil organic-matter pools increasing in warm regions of the world and decreasing in cool regions (Kirschbaum, 1993).

Land use is significant in determining the balance between soils as a source and as a sink for carbon dioxide. Typically, about half the carbon is lost from soils after conversion of undisturbed for-

est or grassland to annually plowed cropland (e.g., Schlesinger, 1977, 1986; Buringh, 1984; Allen, 1985)—although this figure varies significantly with region, soil type, and kind of land-use change (e.g., Detwiler, 1986), and there may be greater carbon retention under minimum-tillage practices. A change in land use in the opposite direction can lead to sequestration of carbon in soils (see Chapters 23 and 24), although sequestration of carbon tends to be slower than carbon loss (e.g., King and Neilson, 1992; Smith and Shugart, 1993; Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, of the IPCC Working Group I volume). Conversion of forest or grassland soils high in organic matter to arable agriculture will inevitably cause a decline in soil organic-matter content and cause additional CO_2 to be released to the atmosphere. The associated mineralization of nutrients may allow increased plant growth, but large release of inorganic ions, especially if it is not synchronized with crop uptake, can add to the current problem of nitrate leaching into aquifers.

Soils are an important source of methane, contributing more than half the total emissions of 535 ± 75 Mt CH_4 yr^{-1} (Prather *et al.*, 1994; see also Chapter 23). Soil methane comes from four main sources: (1) natural wetland soils (55–150 Mt yr^{-1}); (2) microbial degradation of organic substrates in paddy rice soils (20–100 Mt yr^{-1}); (3) landfills (20–70 Mt yr^{-1}); and (4) termites (10–50 Mt yr^{-1}). Soils also provide sinks for methane of 30 ± 15 Mt CH_4 yr^{-1} (Prather *et al.*, 1994). The capacity of soils to oxidize CH_4 interacts in a complex manner with pH, land use, and the soil nitrogen cycle (Hütsch *et al.*, 1994; King and Schnell, 1994). Future temperature increases in polar regions might lead to the release of methane currently contained in gas hydrates in permafrost regions both on the surface and in submerged regions (Collett *et al.*, 1990; Kvenvolden, 1993).

The balance between the microbial processes of methanogenesis and methane consumption (Knowles, 1993) controls whether soils and paddy systems are a source or sink for methane. These biologically mediated processes are influenced by variables such as organic substrate supply, temperature, hydrologic conditions, pH, redox potential, aeration, and salinity—all of which are affected by climate change. Increasing temperature can alter methane fluxes by changing the rate of methane formation in lakes and wetlands and by altering the ratio of methane synthesis to methane oxidation. In addition, increased NPP provides more substrate for methane production, either from decaying plant matter or root exudations, and will provide more conduits for methane escape from lake and wetland sediments through the emergent plants, especially rice (Schütz *et al.*, 1991).

A.3.2.   *Soil Nitrogen Dynamics*

Nitrogen can be added to the soil as inorganic fertilizer and organic manures and by wet and dry deposition from the atmosphere, or it can also be transferred from the atmosphere by biological nitrogen fixation (e.g., Bradbury and Powlson, 1994). Nitrogen is also released (mineralized) by the microbial decomposition of soil organic matter. Mineral nitrogen may be taken up by plants or re-absorbed by soil microorganisms; it may be leached as nitrate to ground and surface waters or emitted to the atmosphere in gaseous forms after nitrification, denitrification, or volatilization of NH_3 (Bradbury and Powlson, 1994). These processes are strongly influenced by temperature, soil moisture, plant characteristics, and, indirectly, by atmospheric CO_2 concentrations.

Nitrous oxide (N_2O) is formed in soils by denitrification and nitrification. Natural soils emit about 6 Mt N yr^{-1} and cultivated soils 3.5 Mt N yr^{-1}; together they probably contribute more than half of the total N_2O emitted to the atmosphere (Prather *et al.*, 1994; Chapter 23). Much of the recent increase of atmospheric concentration of N_2O is attributed to increased use of legumes and N-fertilizers (Chapter 23). Soils also emit 12 Mt N yr^{-1} as NO_x, which constitutes about 25% of total NO_x emissions (Prather *et al.*, 1994). Numerous environmental variables and agricultural practices influence the biological processes responsible for N-emissions from soils (Armstrong Brown *et al.*, 1995). Environmental variables include soil temperature, moisture content, and aeration status, and agricultural management practices include fertilizer regime, cultivation method, and cropping systems (Chapter 23). Mineralization/immobilization requires moist soil, and denitrification requires water-saturated (anaerobic) soil or, at least, saturated microsites. Denitrification rates consequently increase with increasing soil water content. Soils are also likely to be a small sink for N_2O, although the size of this sink has not yet been satisfactorily quantified.

Nutrient-limited ecosystems, including most natural systems and many subsistence or low-input farming systems, are to some extent buffered against effects of global change: If climatic and atmospheric conditions become more favorable for plant growth, nutrient shortage will impose more serious limitations, whereas if climatic conditions change adversely, nutrients will become less limiting (Shaver *et al.*, 1992). Consequently, NPP and total carbon storage of nutrient-limited systems is likely to be less affected by climate change than that of systems that are not nutrient limited.

Rastetter *et al.* (1992) have argued that NEP can only be positive if the total amount of nutrients in the ecosystem increases, if nutrient distribution changes from components with low ratios of carbon to nutrients to those with higher ratios, or if the carbon-to-nutrient ratio changes within vegetation or the soil.

The total amount of nutrients in an ecosystem may change as a result of altered rates of either inputs or losses. Nutrient losses may be prevented by immobilization in soil organic matter (although this also makes them temporarily unavailable for plants). Nitrogen gains may result from more favorable growth conditions that stimulate biological nitrogen fixation. Other nutrients may be gained through enhanced weathering of soil minerals. Nutrient availability may be increased through more extensive root growth and enhanced activity of mycorrhizal associations.

Levels of nitrogen and sulfur deposition are also increasing in many regions of the world through inputs from industrial pollution and other human activities such as agriculture. This may be having beneficial effects on NPP of many ecosystems, especially chronically nitrogen-deficient forests in high northern latitudes. While low rates of nitrogen input may have beneficial effects, ongoing inputs may reverse the initial gains through development of nutrient imbalances and further acidification of the soil (e.g., Ulrich, 1991, 1994; Linder and Flower-Ellis, 1992; Heath *et al*., 1993).

A shift of nitrogen from vegetation to the soil has frequently been observed in CO_2-enrichment studies (e.g., Norby *et al*., 1992; Diaz *et al*., 1993). This is consistent with the theoretical notion that transiently increased productivity could lead to greater nutrient immobilization in soil organic matter and thereby shift the nutrient capital from the vegetation to the soil (Comins and McMurtrie, 1993; Kirschbaum *et al*., 1994). Conversely, warming of soils with large organic-matter content may enhance decomposition rates and lead to the mineralization of nutrients (van Cleve *et al*., 1981, 1990; Melillo *et al*., 1993). This may stimulate plant growth and redistribute nutrients from soils to plants.

Carbon-to-nutrient ratios within soils are generally fairly stable, although they may differ between different ecosystems. Post *et al*. (1985), for example, document C:N mass ratios ranging from 9 to 30 in a comprehensive analysis of different global systems.

Although climate change may lead to small changes in the nutrient capital of soils or the ratio of carbon to nutrients, large changes are unlikely in the short term. Significant short-term changes in carbon storage are only possible where nutrient distribution changes between the soil and high C:N components, such as wood. Hence, in most systems, nutrient limitations will cause total carbon storage and associated NPP to remain similar to what they are currently. Only in the longer term (centuries) is the nutrient capital of soils likely to change so that climate again provides the essential determinant for NPP and total ecosystem carbon storage.

A.3.3.   Soil Biodiversity

Climate change could change the abundance of species within the soil microbial and faunal populations, although the direct effects from changes in soil moisture or temperature will be much smaller than those caused by changes in land use. It is not possible to predict whether there would be a change in biodiversity. However, in mid-northern latitudes (especially Europe), high inputs of industrial nitrogen are associated with major losses of mycorrhizal fungi (e.g., Arnolds and Jansen, 1992). These losses may make forests more vulnerable to drought and disease, which could be further exacerbated by climate change. The increasing concentration of atmospheric CO_2 could also change the composition of organic carbon compounds entering the soil from roots and root exudates, in addition to increasing its quantity. This may alter the species composition of the rhizosphere population—which, in turn, could alter the extent to which plant roots are infected by soil-borne pathogens. Whether such changes would be beneficial or harmful, however, is not known.

The question of whether microflora will change in line with the conditions or lag well behind them has not yet been fully addressed. Previous comparisons of microbial communities across different biomes have been largely confined to fungi and show that species composition is clearly related to biome type, even for the same biome in different continents (Kjoller and Struwe, 1982). Soil organisms with more specific characteristics—such as plant pathogens, symbiotic organisms—and soil fauna, may well be slower in adjusting to new conditions and may generally have slower migration speeds than higher plants. For plant pathogens and symbiotic organisms, there is the additional complication that they are dependent, to varying degrees, upon specific types of vegetation. A vegetation zone shift caused by temperature/precipitation changes will only have reached full equilibrium when both the vegetation and the appropriate microorganisms have established themselves together.

A.4.   Ecological Processes

Organisms interact not only with their physical environment but also with other organisms. The complicated sequence of dependencies and interactions among organisms has led to the description of ecology as the study of the "web of life." Impacts on a component of this web may be absorbed by a small part of the web, or they may lead to a cascade of effects throughout the web. This uncertainty makes predictions about the effect of climate change on complex ecological systems very difficult. In the following sections, we discuss some of the processes and interactions that most affect the response of ecological communities to climate change.

A.4.1.   Niche

All organisms have preferred places in which to live. These places, called the species' habitat, can be depicted on a map. A species' living requirements can be defined in a more abstract way based on aspects of the environment that define its habitat. These aspects may include a certain range of temperature, precipitation, soil conditions, and so forth. Each of these variables can be thought of as describing an axis in a multidimensional space, and the area or volume that describes the preferred habitat of a species is its niche (e.g., Austin *et al*., 1990, Begon *et al*., 1990). A species' "fundamental niche" encompasses all the environmental conditions in which it could potentially grow and reproduce if it were subject to no competition or other effects from other species (e.g., herbivory, disease). The fundamental niche is a consequence of an organism's basic physiological tolerances and ecological traits. In most ecosystems, where organisms compete and interact with

others, a species occupies a smaller space, called its "realized niche" (Hutchinson, 1957).

Climate change may cause the distribution of suitable habitats on a map to change. If temperature, moisture, or other climate variables at a particular location change, individuals at that location may find themselves now to be outside their fundamental niche. If a particular location falls outside the fundamental niche of a species, it is certain that individuals of this species will not be able to continue to reproduce and persist at this site. In other cases, the location may still fall within the fundamental niche but outside the realized niche. In this case, it is difficult to predict whether the species will be able to persist at this location because that will depend on which other species are able to persist or invade that site. In other cases, the location may still fall within the realized niche, and it is likely that the species will be able to continue to live at this site—although it may still be affected by changes in the distribution of other species. These assumptions are the basis of a number of models that attempt to predict the redistribution of organisms across the globe as a consequence of climate change (Box, 1981; Emanuel *et al.*, 1985; Prentice *et al.*, 1992, Cramer and Leemans, 1993).

A.4.2. *Interactions*

A.4.2.1. *Competition*

Individual organisms compete with each other for essential resources such as light, nutrients, and food, and for specific needs such as nesting space. Climate change may alter the competitive balance between species at a site by differentially affecting their effectiveness in the capture of resources or their efficiency in using them. Climate change may also result in the addition or loss of species from the site, thus changing the outcome of future competitive interactions. Higher CO_2 concentrations are predicted to favor C_3 species over C_4 species. Limited experimental results have shown that, although high CO_2 tends to favor C_3 over C_4 species, there is a wide range of responses and competitive outcomes even among C_3 species (Bazzaz, 1990). The fertilizing effect of widespread nitrogen deposition from industrial areas is a useful analogy for the impacts of climate change on the competitive interactions between species. In areas affected by heavy deposition, rapidly growing species of grasses and forbs are favored over slower growing, nitrogen-efficient shrubs (Chapin, 1980; Field *et al.*, 1992).

A.4.2.2. *Herbivory*

Several aspects of herbivory might be affected by climate change. Some insect herbivores require cold periods during their life cycle, and these might be affected by warming. Higher rates of carbon fixation (see Section A.2.3) may provide more food for herbivores, but the quality of the food will be affected. It is likely that increased atmospheric CO_2 concentration will lead plants to produce tissue with a higher ratio of carbon to nitrogen (C:N) than under current conditions (Bazzaz, 1990; Field *et al.*, 1992). Many herbivores, especially insects, are limited by not being able to gather enough nitrogen in their diet (Scriber and Slansky, 1981), and a higher C:N ratio will force them to consume more carbon in order to gain a given amount of nitrogen. Some herbivores will increase the amount of tissue they consume to maintain their nitrogen uptake. In this case, damage by herbivores to their plant hosts is likely to increase. In other cases, herbivores will not be able to consume and digest enough plant tissue to maintain their required nitrogen intake. Their nutrition will suffer, and their population numbers will fall; they may even die out (Watt *et al.*, 1995). Some plants may also produce more defensive compounds, such as tannins and phenolics, when grown in elevated CO_2 (e.g., Lavola and Julkunen-Tiitto, 1994). Thus, in those cases, damage by herbivores will decrease in response to increased C:N ratios. Changes in the amount of herbivory will affect the nutrient cycle because nitrogen is cycled more rapidly but is also more likely to be lost to the atmosphere through volatilization when it passes through the guts of herbivores than through litter-decomposing organisms (Chapin and McNaughton, 1989).

Many insect herbivores have a boom–bust population cycle. They build up through several generations, with each generation larger, depleting their plant resources until the population is checked by lack of food, the onset of unsuitable weather (e.g., winter or drought), or natural enemies. If conditions after climate change allow the herbivore population to build up faster, much higher population levels and much greater damage may occur before they are checked. Conversely, some insect herbivores may be disadvantaged by climate change if, for example, the new conditions are more favorable to their enemies or the timing of growth or flowering of their food plants change. There is some evidence that stressful periods such as droughts that lead to reduced photosynthesis also lead to reduced production of compounds that normally help to control insect populations. Thus, some have predicted that under changed climatic conditions, stress periods will be more common and insect outbreaks more frequent (Mattson and Haack, 1987).

A.4.2.3. *Other Interactions*

There are many other complex interactions within ecological systems. Parasites, disease organisms, and mutualists (i.e., organisms that mutually benefit each other, such as flowering species and their pollinating insects) are subject to the same constraints in relation to niche as other species. Climate change may advantage or disadvantage these species, with significant consequences for their host species. Schemes that help in the assessment of the likely effects of climate change on host–pest interactions are being developed (Landsberg and Stafford Smith, 1992).

A.4.3. *Communities and Their Dynamics*

A.4.3.1. *Community*

Any patch of land or ocean contains an assemblage of different

species that interact with each other in a variety of different ways. These assemblages are called communities. Just which species are part of a community depends on their niches—that is, whether they can tolerate the physical conditions of the patch and persist in interaction with the other species of the community.

There has long been a debate about the nature of communities and the degree to which they could be described as discrete entities. Communities were once compared with living organisms and described as tightly integrated assemblages of interacting species. Thus, a community was seen as an entity in its own right. If a community was perturbed by the loss or addition of some species, it would tend to recover to its previous composition or change to another discretely recognizable assemblage. The alternative view is that communities are essentially a collection of species, with each species behaving and interacting according to its own physiological and ecological potential. In this view, a community is a more fortuitous collection of species. Species continually invade or are lost from the community as populations fluctuate in response to weather, disturbances, and competitors.

These views about communities represent the end points of a continuum of ideas. Current thinking favors the view that communities are a collection of individual species, but an important ecological research theme is to identify rules that govern community structure (Drake, 1990; Keddy, 1992) and to seek groups of species that are ecological equivalents (sometimes called functional types; Smith *et al.*, 1993).

A.4.3.2.   Succession

Communities are always changing, both as a result of a changing balance of interactions between the component species and in responses to disturbances. However, there are some patterns in the way communities respond to disturbances and change over time (i.e., succession). Succession was originally described as a sequence of organism-like communities, with one replacing another according to more-or-less strict rules (Clements, 1936). The endpoint of this succession of communities was called the climax community—determined, it was argued, by long-term climatic and soil conditions. Now succession is more often described as the outcome of a series of species losses and invasions as disturbances occur and conditions change (Whittaker, 1975). More emphasis is now placed on the stochastic nature of vegetation change, especially in ecosystems where disturbances such as fire or intense winds are common (Noble and Slatyer, 1980; Shugart, 1984).

The view of communities affects the methods used for predictions of ecological changes in response to global change. If communities change more like "organisms," it would be likely that under climate change one community will be replaced by another already known from elsewhere. This allows simple modeling by matching communities to environmental conditions and assuming that they will redistribute themselves with climate change (see the discussion of Holdridge, etc., in Section A.4.4.2).

However, with a changed climate and disturbance regimes at a given location, conditions for some individuals will remain within their niche space, and they will continue to survive and reproduce at that location. Some species will be lost from the community relatively quickly as existing individuals die under the changed conditions (e.g., extreme temperatures, droughts, waterlogging) or disturbances (e.g., fires). Individuals of other species will be able to survive but not reproduce, and—although some individuals of long-lived species may persist at the site for decades or centuries—the species will eventually be lost from that location.

The loss of individuals from a community creates opportunities for others to invade. However, species best adapted to new conditions will not necessarily be among the early invaders because they may lack the dispersal ability to reach the site. The ability of species to invade new suitable locations varies greatly. Thus, it is unlikely that communities will move en masse. What is more likely is a sequence of invasions and losses leading to completely new communities, as was apparently the case over the past 10,000 years following the last Ice Age (e.g., Davis *et al.*, 1986; Webb and Bartlein, 1992).

A.4.3.3.   Migration and Dispersal

As the climate changes, zones with suitable habitats for species will move in space. For example, as a result of warmer conditions, a species' niche space will be displaced away from the equator or further up mountains. An important issue in determining the nature of communities in the future is which species will be able to keep up with shifting climate zones.

Most plant species have poor dispersal ability, with the vast majority of seeds falling close to the parent plant. These species migrate very slowly—in most cases, far slower than anticipated shifts in climate zones—and they depend mainly on rare long-distance dispersal events to spread or invade new habitats. The rate at which many species spread after past disturbances, such as the ice ages, can be estimated by mapping the distribution of pollen left behind in bogs, lake sediments, and so forth (e.g., Davis *et al.*, 1986). Most species migration rates, estimated to be 10–30 km per century, are at least an order of magnitude less than the anticipated rates of shift in climate zones of 100 to 600 km over the next century (e.g., Solomon and Cramer, 1993). However, past migration rates are only a poor guide to the future because past rates may have been limited by the rate at which the climate changed. Also, the future potential for species migration is different than it was in the past. On the one hand, landscapes are now much more dissected by human activities than in the past, and this will hinder natural migration rates (di Castri and Hansen, 1992). On the other hand, human activities and technologies, such as motor vehicles and aircraft, provide sources of long-distance dispersal that were not present in the past.

Some species are already adapted to disperse widely and exploit any opportunity for invasion. They are often fast growing and quick to mature. These are often called tramp or ruderal species. They might be expected to do well during any reorganization of communities.

A.4.4. Ecosystems and Biomes

A.4.4.1. Ecosystems

A community and its abiotic environment is called an ecosystem. The abiotic and biotic components of an ecosystem interact, including significant effects of the biotic on the abiotic. For example, plant and animal communities often modify the soils. This process takes many decades or much longer but can eventually result in soils with properties that are closely matched with the communities they support. Where climate change causes significant spatial shifts of the range of species, these relationships may not be retained.

Ecosystem-level feedbacks may either dampen or amplify the growth response to individual climatic variables (Field *et al.*, 1992). The response of the ecosystem may depend on how the complex chain of interactions affects the cycling of nutrients and the efficient use of light and water. For example, if the availability of any one resource, such as carbon, increases, then other resources, such as nutrients, become relatively more limiting. Plants may respond to this by increased root growth, and this allocation shift may reduce the growth response of aboveground biomass to increasing CO_2 concentration.

Furthermore, if growth is determined more by the rate at which nutrients rather than carbon can be obtained, then even total plant production may not be increased. These constraints might eventually restrict the growth response of whole ecosystems to less than might be expected from short-term experiments on single plants or small communities (Körner, 1993). The overall functioning of the ecosystem may sometimes be insensitive to changes in particular species composition. One or more species may be replaced by others with more appropriate temperature optima or responses to CO_2, but the system as a whole may continue to function with broadly the same structure, physiognomy, and physiology.

Conversely, biological nitrogen fixation may be stimulated by more favorable growing conditions and lessen nutrient limitations. In systems that are not strongly nutrient limited, initial growth responses may allow greater leaf-area development, which allows greater light interception and further increases growth responses beyond that predicted from leaf-level responses.

More complex ecosystem responses may also occur. Initially increased growth may lead to reduced palatability of plant tissue for insect herbivores, which may either reduce or increase insect damage (see Section A.4.2.2) and thereby either act as positive or negative feedback on the initial response.

A.4.4.2. Biomes

Most observers readily recognize the similarity of ecosystems in the deserts of the world, no matter where they occur and how far apart they are. There are subtle differences between desert communities, such as the presence of cacti in some deserts and not in others and the diversity of reptiles between different deserts. However, all desert ecosystems operate within similar constraints, and their biota show similar adaptations to deal with these constraints. These similar ecosystems have been described with many different terms (e.g., biomes, life zones, biogeoclimatic zones) and emphases. Many studies relating to the global distribution of biomes and their redistribution under climate change define from 10 to 40 or more classes. Originally, their descriptions were based on the structure and appearance of the vegetation (Walter, 1962), but more recently climatic information has been used (e.g., Box, 1981; Cramer and Leemans, 1993).

A classification of biomes commonly used in global-change research was developed by Holdridge (1947). He used annual biotemperature (a measure related to the sum of temperatures above freezing throughout the year) and total precipitation to classify the vegetation of the world into 14 life zones or biomes. His scheme has been used as the basis for some predictions of the global-scale impacts of changed climates (e.g., Emanuel *et al.*, 1985), although more complex schemes have also been developed based on a wider range of climatic and soil parameters and a wider range of assumptions about the important variables delimiting the vegetation zones of the world (Box, 1981; Prentice *et al.*, 1992; Woodward, 1993; Neilson *et al.*, 1992).

As an example, Figure A-1 shows where some of the world's major biomes are found in relation to temperature and rainfall. In looking at the distribution of any biome in relation to climate, it must be recognized that annual mean values of temperature and precipitation provide only a rough guide to the requirements or tolerances of vegetation classes. In many instances, the distribution of classes also depends on seasonal factors, such as the length of a dry season or the lowest absolute minimum temperature, and on soil factors, such as water-holding capacity.

A.4.4.3. Ecosystem Breakdown

There has been progress in modeling the equilibrium distributions of biomes, which implicitly assumes that communities have time to sort themselves out. But the process of migration and reassembly may well lag behind the rate of climate change. Thus, climate-change studies based on the use of these equilibrium models can provide only a first indication of the direction or magnitude of expected changes.

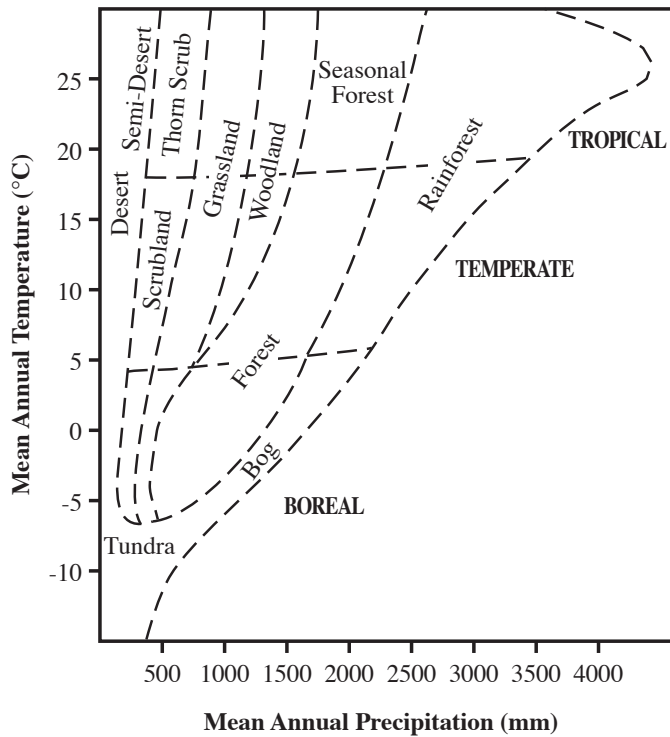
In addition, there might be rapid breakdown of the existing


Figure A-1: This figure illustrates that mean annual temperature and mean annual precipitation can be correlated with the distribution of some of the world's major biomes. While the role of these annual means in affecting this distribution appears to be important, it should be noted that the distribution of biomes may also strongly depend on seasonal factors such as the length of the dry or the lowest absolute minimum temperature, on soil properties such as water-holding capacity, on land-use history such as agriculture or grazing, and on disturbance regime such as the frequency of fire (modified from Whittaker, 1975).

community structure via the loss of some species and invasion by others. The invading species will tend to be those best adapted to dispersing and invading, but not necessarily those best adapted to the most efficient use of resources in the prevailing conditions. This could lead to transient periods with less efficient use of light and water and less efficient recycling of nutrients. Temporarily lower biomass and transient release of carbon is likely to result from such a breakdown. Considerable scientific uncertainty remains about the length of these transients and the magnitude of the fluxes, but the fluxes could be significant (King and Neilson, 1992; Smith and Shugart, 1993).

A.5.   Conclusion

The preceding discussion offers a very brief overview of some of the main factors to be considered in relation to climate change. It describes the response of terrestrial ecosystems to the main aspects of climate change, and how these initial responses are affected by feedbacks from the soil and from interactions between different organisms. The importance of these factors varies greatly among different natural and socioe-

conomic systems. This will be discussed in greater depth in the following chapters of this report.

CONTENTS

B.1. Introduction

This Energy Primer introduces concepts and terms used in the energy-related chapters of this Second Assessment Report that deal with adaptation to and mitigation of climate change. Some of the more important terms also are defined in the Glossary. The Energy Primer also describes some of the more commonly used energy units; most measurements, including energy, are expressed in the International System of Units (SI) and SI-derived units.

Section B.2 describes the global energy system and documents 1990 energy-consumption patterns and carbon dioxide (CO_2) emissions. Thereafter, the concept of energy efficiency is introduced and 1990 global efficiencies are provided along with some estimates of maximum efficiencies that could be achieved under ideal conditions, indicating the theoretical efficiency improvement potential. Section B.3 describes and documents the historical development of energy consumption and associated CO_2 emissions for the world and for major regions. It concludes with a comparison of historical and current energy consumption, estimates of fossil and nuclear energy reserves

and resources, and potentials of renewable energy sources. Section B.4 of this Energy Primer gives a brief introduction to the following chapters, which assess energy-related mitigation and adaptation options and measures.

B.2. Energy Systems

B.2.1. The Global Energy System

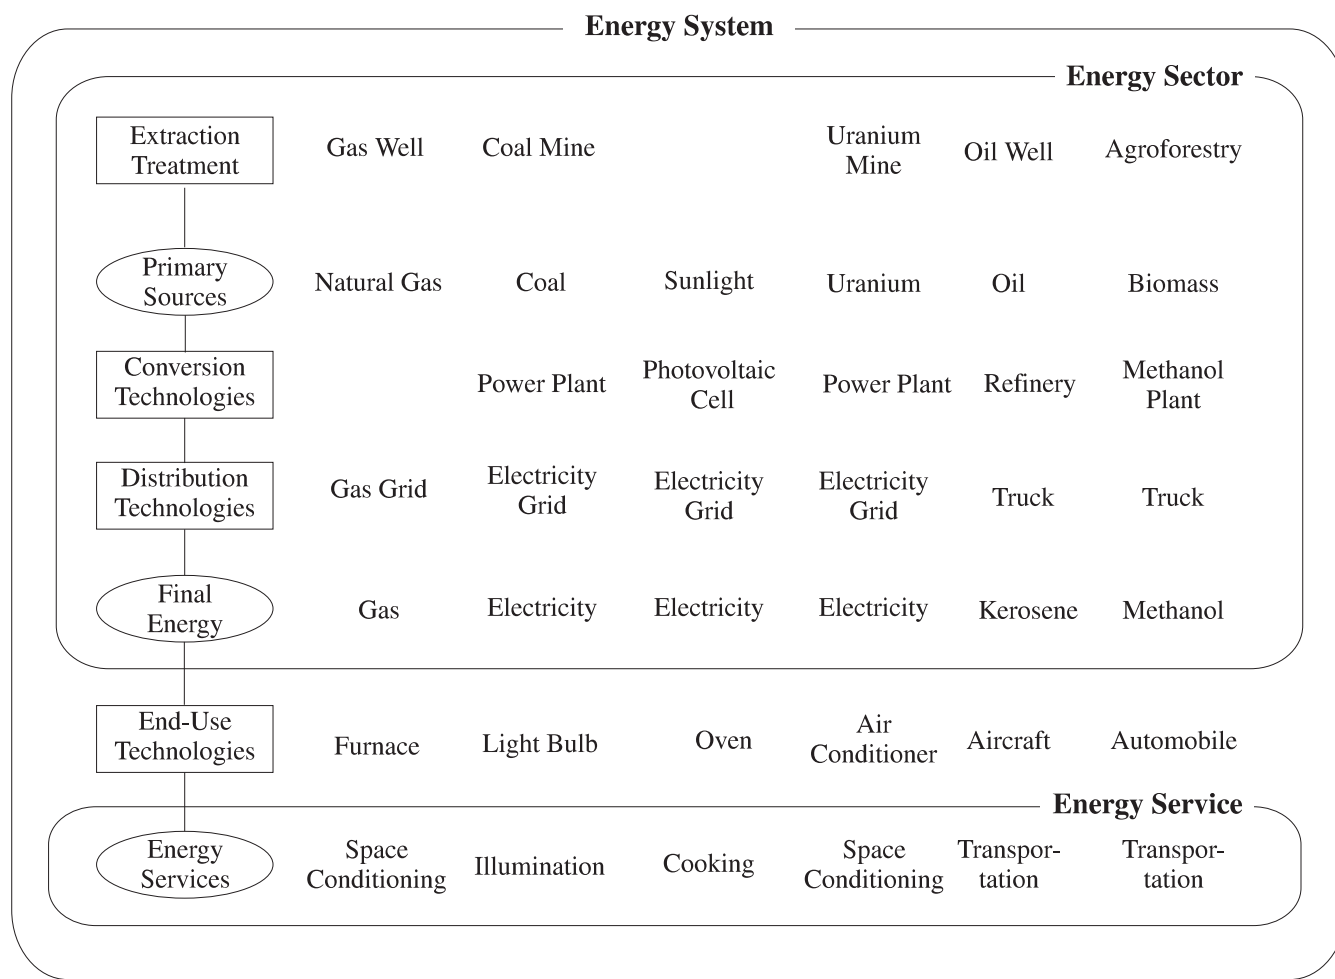
An *energy system* comprises an energy supply sector and energy end-use. The energy supply sector consists of a sequence of elaborate and complex processes for extracting energy resources, converting these into more desirable and suitable forms of energy, and delivering energy to places where the demand exists. The end-use part of the energy system provides energy services such as cooking, illumination, comfortable indoor climate, refrigerated storage, transportation, and consumer goods. The purpose, therefore, of the energy system is the fulfillment of demand for energy services. Figure B-1 illustrates schematically the architecture of an energy system as a series of linked stages connect-


Figure B-1: The energy system: schematic diagram with some illustrative examples of the energy sector and energy end-use and services. The energy sector includes energy extraction, treatment, conversion, and distribution of final energy. The list is not exhaustive, and the links shown between stages are not "fixed" (e.g., natural gas is also used to generate electricity, and coal is not used exclusively for electricity generation). Source: Adapted from Rogner, 1994.

ing various energy conversion and transformation processes that ultimately result in the provision of goods and services. A number of examples are given for energy extraction, treatment, conversion, distribution, end-use (final energy), and energy services in the energy system. The technical means by which each stage is realized have evolved over time, providing a mosaic of past evolution and future options.

Primary energy is the energy that is embodied in resources as they exist in nature: the chemical energy embodied in fossil fuels (coal, oil, and natural gas) or biomass, the potential energy of a water reservoir, the electromagnetic energy of solar radiation, and the energy released in nuclear reactions. For the most part, primary energy is not used directly but is first converted and transformed into electricity and fuels such as gasoline, jet fuel, heating oil, or charcoal.

Final energy is the energy transported and distributed to the point of final use. Examples include gasoline at the service station, electricity at the socket, or fuelwood in the barn. The next energy transformation is the conversion of final energy in end-use devices, such as appliances, machines, and vehicles, into *useful energy,* such as work and heat. Useful energy is measured at the crankshaft of an automobile engine or an industrial electric motor, by the heat of a household radiator or an industrial boiler, or by the luminosity of a light bulb. The application of useful energy provides *energy services,* such as a moving vehicle, a warm room, process heat, or light.

Energy services are the result of a combination of various technologies, infrastructures (capital), labor (know-how), materials, and energy carriers. Clearly, all these input factors carry a price tag and, within each category, are in part substitutable for one another. From the consumer's perspective, the important issues are the quality and cost of energy services. It often matters little what the energy carrier or the source of that carrier is. It is fair to say that most consumers are often unaware of the "upstream" activities of the energy system. The energy system is service-driven (i.e., from the bottom up), whereas energy flows are driven by resource availability and conversion processes (from the top down). Energy flows and driving forces interact intimately. Therefore, the energy sector should never be analyzed in isolation: It is not sufficient to consider only how energy is supplied; the analysis also must include how and for what purposes energy is used.

Figure B-2 illustrates schematically the major energy and carbon flows through the global energy system across the main stages of energy transformation, from primary energy to energy services. Energy and carbon estimates represent global averages in 1990. For definitions of energy and carbon-emissions units, see Boxes B-1 and B-2.

In 1990, 385 EJ of primary energy produced 279 EJ of final energy delivered to consumers, resulting in an estimated 112 EJ of useful energy after conversion in end-use devices. The delivery of 112 EJ of useful energy left 273 EJ of rejected energy. Most rejected energy is released into the environment as
Figure B-2: Major energy and carbon flows through the global energy system in 1990, EJ and Gt C [(billion tons) or Pg C (10^{15} grams) elemental carbon]. Carbon flows do not include biomass. Sources: Marland *et al.*, 1994; IEA, 1993; Marland and Rotty, 1984; Nakicenovic *et al.*, 1993; WEC, 1992a.

low-temperature heat, with the exception of some losses and wastes such as the incomplete combustion of fuels.

More than half of the anthropogenic greenhouse gas (GHG) emissions originate from the energy system (both in terms of mass and in terms of radiative forcing). The predominant gas is CO_2, which represents more than half of the increase in radiative forcing from anthropogenic GHG sources. The majority of this CO_2 arises from the use of fossil fuels, which in turn make up about 75% of the total energy use. The global energy consumption of 385 EJ in 1990 was small compared with the solar radiation of about 5.4 million EJ intercepted annually by Earth. Although small in relation to natural energy flows, the emissions of energy-related GHGs create a danger of anthropogenic interference with Earth's radiative balance (energy budget).

The carbon content of fossil energy in 1990 was about 6 (±0.5) Gt C [(billion tons) or Pg C (10^{15} grams) elemental carbon], of which about 2.3 Gt C were emitted by the energy sector during conversion to fuels and electricity and distribution to final use. The remainder, about 3.7 Gt C, was emitted at the point of end-use. Included are 0.3 Gt C that were extracted from fossil sources without contributing directly to net carbon emissions. This carbon was embodied in durable hydrocarbon-based materials such as plastics, asphalt, lubricants, and pharmaceuticals. The carbon flows in Figure B-2 are simplifications because the carbon in fossil fuels is not completely oxidized to CO_2 during combustion. Eventually, however, most hydrocarbons and other combustion products containing carbon are converted to CO_2. There is some ambiguity concerning the amount of CO_2 emissions from feedstocks embodied in chemical products, as well as the unsustainable use of biomass. Carbon is released by the burning of biomass,

Box B-1. Energy Units and Scales

Energy is defined as the capacity to do work and is measured in joules (J), where 1 joule is the work done when a force of 1 newton (1 N = 1 kg m/s²) is applied through a distance of 1 meter. Power is the rate at which energy is transferred and is commonly measured in watts (W), where 1 watt is 1 joule per second. Newton, joule, and watt are defined as units in the International System of Units (SI). Other units used to measure energy are toe (ton of oil equivalent; 1 toe = 41.87 x 10^9 J), used by the oil industry; tce (ton of coal equivalent; 1 tce = 29.31 x 10^9 J), used by the coal industry; and kWh (kilowatt-hours; 1 kWh = 3.6 x 10^6 J), used to measure electricity. Figure B-3 shows some of the commonly used units of energy and a few examples of energy consumption levels, along with the Greek names and symbols for factors to power of ten (e.g., exa equals 10^{18} and is abbreviated as E; in 1990, the global primary energy consumption was 385 EJ).

joule

	10^{21}	world energy consumption in 1990
		giga ton oil equivalent (Gtoe)
exajoule (EJ)	10^{18}	Quad (10^{15} btu)
		New York City area, annual energy consumption
		million ton of oil equivalent (Mtoe)
		power plant (700 MW$_e$), annual electricity generation
petajoule (PJ)	10^{15}	
		small village in India, annual energy consumption
terajoule (TJ)	10^{12}	family house, annual energy consumption
		ton of coal equivalent (tce)
		barrel of oil equivalent (boe)
gigajoule (GJ)	10^9	fuel consumption of a car per 100 km
		m³ natural gas
		cooking, for one hour
megajoule (MJ)	10^6	kilowatt-hour (kWh)
kilojoule (kJ)	10^3	British thermal unit (Btu)
		calorie (cal)
joule (J)	1	newton-meter (Nm) = watt-second (Ws)

Figure B-3: Examples of some human energy needs and energy conversion devices, in joules, on a logarithmic scale. Sources: Adapted from Starr, 1971; Swedish National Encyclopedia, 1993.

including energy-related uses. Houghton and Skole (1990) estimate the latter to result in gross emissions of 0.7 Gt C per year. The extent of annual net emissions from nonfossil CO_2 is difficult to determine due to forest regrowth and the fact that the majority of biomass use is renewable. For simplification, we assume that feedstocks lead to CO_2 emissions—because even materials like asphalt and durable plastics will eventually be oxidized over a very long time—and that all biomass used as a source of energy is renewable and therefore does not result in net CO_2 emissions.

The 1990 global economic output is estimated at about US$21 x 10^{12} (World Bank, 1993; UN, 1993); therefore, the average energy intensity was about 18 MJ/US$, and energy-related carbon intensity was about 250 g C/US$. In 1990, the average person consumed about 73 GJ of energy and emitted about 1.1 t C (tons carbon or Mg C).

B.2.2.   Energy Efficiency

Energy is conserved in every conversion process or device. It can neither be created nor destroyed, but it can be converted from one form into another. This is the first law of thermodynamics. For example, energy in the form of electricity entering

---

Box B-2. CO$_2$ Emission Factors

CO$_2$ emissions are measured in tons (10^6 grams) of elemental carbon. For example, in 1990, global CO$_2$ emissions were 6 Gt C [(billion tons) or Pg C (10^{15} grams) of elemental carbon]. In the literature, CO$_2$ emissions also are reported as the mass of the actual molecule (1 kg C corresponds to 3.67 kg of CO$_2$).

Table B-1: *Carbon-emissions factors for some primary energy sources, in kg C/GJ.*

		OECD/IPCC 1995 (1)	Literature Range	Sources
Wood	HHV	–	26.8–28.4	
	LHV		28.l–29.9	(5),(3)
Peat	HHV	–	30.3	(3)
	LHV	28.9		
Coal (bituminous)	HHV	–	23.9–24.5	(2),(3)
	LHV	25.8	25.1–25.8	(2),(3)
Crude Oil	HHV	–	19.0–20.3	(3),(4)
	LHV	20.0	20.0–21.4	(3),(4)
Natural Gas	HHV	–	13.6–14.0	(2),(5)
	LHV	15.3	15.0–15.4	(2),(5)

Notes: HHV is the higher heating value and LHV the lower; the difference is that HHV includes the energy of condensation of the water vapor contained in the combustion products.

---

an electric motor results in the desired output—say, kinetic energy of the rotating shaft to do work—and losses in the form of heat as the undesired byproduct caused by electric resistance, magnetic losses, friction, and other imperfections of actual devices. The energy entering a process equals the energy exiting. Energy efficiency is defined as the ratio of the desired (usable) energy output to the energy input. In the electric-motor example, this is the ratio of the shaft power to the energy input electricity. In the case of natural gas for home heating, energy efficiency is the ratio of heat energy supplied to the home to the energy of the natural gas entering the furnace. This definition of energy efficiency is sometimes called *first-law efficiency*.

A more efficient provision of energy services not only reduces the amount of primary energy required but, in general, also reduces adverse environmental impacts. Although efficiency is an important determinant of the performance of the energy system, it is not the only one. In the example of a home furnace, other considerations include investment, operating costs, lifetime, peak power, ease of installation and operation, and other technical and economic factors. For entire energy systems, other considerations include regional resource endowments, conversion technologies, geography, information, time, prices, investment finance, operating costs, age of infrastructures, and know-how.

The overall efficiency of an energy system depends on the individual process efficiencies, the structure of energy supply and conversion, and the energy end-use patterns. It is the result of compounding the efficiencies of the whole chain of energy supply, conversion, distribution, and end-use processes. The weakest link in the analysis of the efficiency of various energy chains is the determination of energy services and their quantification, mostly due to the lack of data about end-use devices and actual patterns of their use.

In 1990, the global efficiency of converting primary energy sources to final energy forms, including electricity, was about 72% (279 EJ over 385 EJ—see Figure B-2). The efficiency of converting final energy forms into useful energy is lower, with an estimated global average of 40% (Nakicenovic *et al*., 1990;

Gilli *et al.*, 1995). The resulting average global efficiency of converting primary energy to useful energy, then, is the product of the above two efficiencies, or 29%. Because detailed statistics for most energy services do not exist and many rough estimates enter the efficiency calculations, the overall efficiency of primary energy to services reported in the literature spans a wide range, from 15 to 30% (Olivier and Miall, 1983; Ayres, 1989; Wall, 1990; Nakicenovic *et al.*, 1990; Schaeffer and Wirtshafter, 1992; and Wall *et al.*, 1994).

How much energy is needed for a particular energy service? The answer to this question is not so straightforward. It depends on the type and quality of the desired energy service; the type of conversion technology; the fuel, including the way the fuel is supplied; and the surroundings, infrastructures, and organizations that provide the energy service. Initially, energy-efficiency improvements can be achieved in many instances without elaborate analysis through common sense, good housekeeping, and leak-plugging practices. Obviously, energy service efficiencies improve as a result of sealing leaking window frames or installing a more efficient furnace. If the service is transportation—getting to and from work, for example—using a transit bus jointly with other commuters is more energy-efficient than taking individual automobiles. After the easiest improvements have been made, however, the analysis must go far beyond energy accounting.

Here the concept that something may get lost or destroyed in every energy device or transformation process is useful. This "something" is called "availability," which is the capacity of energy to do work. Often the availability concept is called "exergy."[1]

The following example should help clarify the difference between energy and exergy. A well-insulated room contains a small container of kerosene surrounded by air. The kerosene is ignited and burns until the container is empty. The net result is a small temperature increase of the air in the room ("enriched" with the combustion products). Assuming no heat leaks from the room, the total quantity of energy in the room has not changed. What has changed, however, is the quality of energy. The initial fuel-air combination has a greater potential to perform useful tasks than the resulting slightly warmer air mixture. For example, one could use the fuel to generate electricity or operate a motor vehicle. The ability of a slightly warmed room to perform any useful task other than space conditioning is very limited. In fact, the initial potential of the fuel-air combination or the "exergy" has been largely lost.[2] Although energy is conserved, exergy is destroyed in all real-life energy conversion processes. This is what the second law of thermodynamics expresses.

Another, more technical, example should help clarify the difference between first-law (energy) and second-law (exergy) efficiencies. Furnaces used to heat buildings are typically 70 to 80% efficient, with the latest, best-performing condensing furnaces operating at efficiencies greater than 90%. This may suggest that little energy savings should be possible, considering the high first-law efficiencies of furnaces. Such a conclusion is

incorrect. The quoted efficiency is based on the specific process being used to operate the furnace—combustion of fossil fuel to produce heat. Because the combustion temperatures in a furnace are significantly higher than those desired for the energy service of space heating, the service is not well-matched to the source, and the result is an inefficient application of the device and fuel. Rather than focusing on the efficiency of a given technique for the provision of the energy service of space heating, one needs to investigate the theoretical limits of the efficiency of supplying heat to a building based on the actual temperature regime between the desired room temperature and the heat supplied by a technology. The ratio of theoretical minimum energy consumption for a particular task to the actual energy consumption for the same task is called exergy or *second-law* (of thermodynamics) *efficiency.*

Consider an example: Providing a temperature of 30°C to a building while the outdoor temperature is 4°C requires a theoretical minimum of one unit of energy input for every 12 units of heat energy delivered to the indoors. To provide 12 units of heat with an 80% efficient furnace, however, requires 12/0.8, or 15, units of heat. The corresponding second-law efficiency is the ratio of ideal to actual energy use (i.e., 1/15 or 7%).

The first-law efficiency of 80% gives the misleading impression that only modest improvements are possible. The second-law efficiency of 7% says that a 15-fold reduction in final heating energy is theoretically possible.[3] In practice, theoretical maxima cannot be achieved. More realistic improvement potentials might be in the range of half of the theoretical limit. In addition, further improvements in the efficiency of supplying *services* are possible by task changes—for instance, reducing the thermal heat losses of the building to be heated via better insulated walls and windows.

What is the implication of the second law for energy efficiencies? First of all, it is not sufficient to account for energy-in

---

[1] Exergy is defined as the maximum amount of energy that under given (ambient) thermodynamic conditions can be converted into any other form of energy; it is also known as availability or work potential (WEC, 1992b). Therefore, exergy defines the minimum theoretical amount of energy required to perform a given task.

[2] An alternative example: In terms of energy, 1 kWh of electricity and the heat contained in 43 kg of 20°C water are equal (i.e., 3.6 MJ). At ambient conditions, it is obvious that 1 kWh electricity has a much larger potential to do work (e.g., to turn a shaft or to provide light) than the 43 kg of 20°C water. See also Moran, 1989.

[3] For example, instead of combusting a fossil fuel, Goldemberg *et al.* (1988) give the example of a heat pump, which extracts heat from a local environment (outdoor air, indoor exhaust air, groundwater) and delivers it into the building. A heat pump operating on electricity can supply 12 units of heat for 3 to 4 units of electrical energy. The second-law efficiency improves to 25–33% for this particular task— still considerably below the theoretical maximum efficiency. Not accounted for in this example, however, are energy losses during electricity generation. Assuming a modern gas-fired, combined-cycle power plant with 50% efficiency, the overall efficiency gain is still a factor of two compared with a gas furnace heating system.

versus energy-out ratios without due regard for the quality difference (i.e., the exergy destroyed in the process). Minimum exergy destruction means an optimal match between the energy service demanded and the energy source. Although a natural-gas heating furnace may have an energy efficiency of close to 100%, the exergy destruction may be very high, depending on the temperature difference between the desired room temperature and the temperature of the environment. The second-law efficiency, defined as exergy-out over exergy-in, in this natural-gas home heating furnace example is some 7%—that is, 93% of the original potential of doing useful work (exergy) of the natural gas entering the furnace is lost. Here we have a gross mismatch between the natural-gas potential to do useful work and the low-temperature nature of the energy service, namely space conditioning.

There are many difficulties and definitional ambiguities involved in estimating the exergy efficiencies for comprehensive energy source-to-service chains or entire energy systems. There are many examples for the analysis of individual conversion devices; for instance, losses around a thermal power plant are described in Yasni and Carrington (1989). A few attempts have also been made to analyze energy systems efficiencies to useful energy or even to energy services. All indicate that primary-to-service (second-law or exergy) efficiencies are as low as a few percent. AIP (1975) and Olivier and Miall (1983) were among the first to give detailed assessments of end-use exergy efficiencies, including service efficiencies. Ayres (1989) calculates an overall primary exergy to service efficiency of 2.5% for the United States. Wall (1990) estimates a primary-to-useful exergy efficiency in Japan of 21%, and Wall *et al*. (1994) calculate a primary-to-useful exergy efficiency of less than 15% for Italy. Schaeffer and Wirtshafter (1992) estimate a primary-to-useful energy efficiency of 32% and an exergy efficiency of 23% for Brazil. Other estimates include Rosen (1992) for Canada, and Özdogan and Arikol (1995) for Turkey. Estimates of global and regional primary-to-service exergy efficiencies vary from ten to as low as a few percent (Gilli *et al*., 1990, 1995; Nakicenovic *et al*., 1990, 1993).

The theoretical potential for efficiency improvements is very large; current energy systems are nowhere close to the maximum levels suggested by the second law of thermodynamics. However, the full realization of this potential is impossible. Friction, resistance, and similar losses never can be totally avoided. In addition, there are numerous barriers and inertias to be overcome, such as social behavior, vintage structures, financing of capital costs, lack of information and know-how, and insufficient policy incentives.

The principal advantage of second-law efficiency is that it relates actual efficiency to the theoretical (ideal) maximum. Although this theoretical maximum can never be reached, low-exergy efficiencies identify those areas with the largest potentials for efficiency improvement. For fossil fuels, this suggests the areas that also have the highest emission-mitigation potentials.

B.3. Energy Use, CO_2 Emissions, and Energy Resources

B.3.1. Past and Present Energy Use

Global primary energy consumption has grown at an average annual rate of about 2% per year for almost 2 centuries—doubling, on average, about every 3 decades. This estimate includes all sources of commercial energy and fuelwood. There is a considerable variation in energy consumption growth rates over time and between different regions. For example, the global fossil energy consumption grew at 5% per year between 1950 and 1970, 3.3% annually between 1970 and 1990, and only 0.3% per year between 1990 and 1994. Emissions and other environmental effects of energy supply and end-use increased at somewhat slower rates than primary energy consumption.

Figure B-4 shows global annual primary energy consumption by source since 1860; Figure B-5 shows the relative shares of each source in total consumption. With the emergence of the coal age and steam power, global primary energy use evolved from a reliance on traditional energy sources, such as fuelwood, to fossil energy. Subsequently, coal was replaced by oil as the dominant primary energy source. Energy conversion also changed fundamentally with internal combustion, electricity generation, steam and gas turbines, and chemical and thermal energy conversion. The dynamics of structural changes in the global energy system, illustrated in Figure B-5, can be characterized by relatively slow rates of change, which are typical for infrastructures. It took about half a century before coal was replaced by crude oil as the dominant global energy source. At the global level, the "time constant" for fundamental energy transitions has been on the order of 50 years. At the regional level and for individual energy technologies and devices, the characteristic time constants are usually shorter, as a result of faster capital turnover, among other factors.

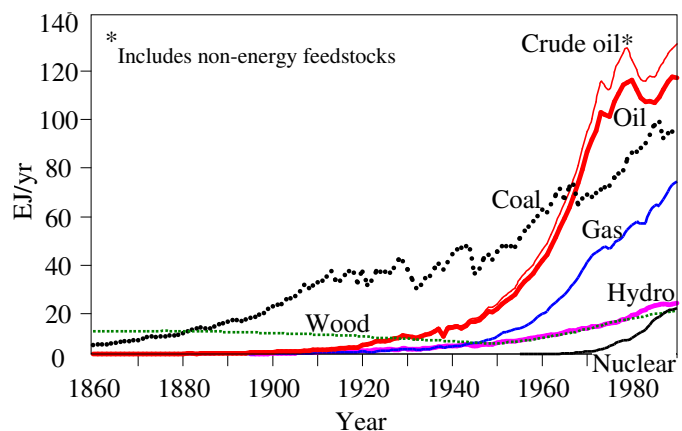
Much of the historical increase in global primary energy consumption has occurred in the more developed countries. About


Figure B-4: Global primary energy consumption by source, and total in EJ/yr (data for crude oil include non-energy feedstocks). Sources: BP, various volumes; IEA, 1993; Marchetti and Nakicenovic, 1979.
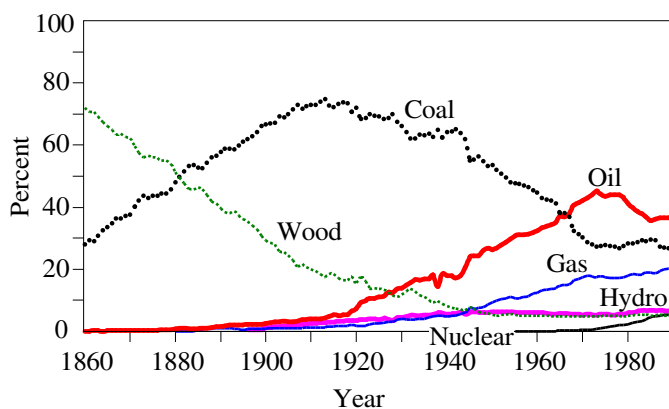

Figure B-5: Shares of energy sources in total global primary energy consumption, in percent of the total.

25% of the world's population consume almost 80% of the global energy. Cumulative consumption is even more unevenly distributed: About 85% of all energy used to date has been consumed by less than 20% of the cumulative global population (measured in cumulative person-years) since 1860. The differences in current per capita commercial energy consumption are more than a factor of 20 between the highest (North America) and the lowest (Africa) energy-consuming regions in the world—but more than a factor of 500 between individual countries. Another important difference is in the structure of energy supply, especially the strong reliance on traditional and noncommercial sources of energy in the developing countries (Hall, 1991).

Table B-2 shows the 1990 energy balance for the world from primary to final energy consumption, by energy carrier and sector. Crude oil is the dominant primary energy source in the world, accounting for 33% of the total, followed by coal and natural gas with 24 and 18% shares, respectively. Hydropower and nuclear energy are regionally important; they contribute more than 19 and 15% to global electricity supply, respectively. About 13% of the final energy is delivered as electricity.

The largest final energy share of 38% is taken by oil products, half of them being used in the transport sector and constituting 96% of all the energy needs in this sector. The largest final energy carrier in industry is coal at 30%, accounting for almost 70% of all the direct uses of coal. Two-thirds of primary coal is used for electricity generation. About 30% of natural gas is used for electricity generation; the rest is divided almost equally between industrial uses and those in the household, commercial, and agricultural sectors. Electricity is also almost equally divided between these end uses. Most traditional biomass is used locally, with little or no conversion, and is shown under the "other" sector category in Table B-2. Primary energy consumption is well-documented in both national and international statistics. An exception is the use of traditional noncommercial energy (biomass). Larger uncertainties surround sectoral disaggregations of final energy consumption, due to a lack of detailed statistics in many countries. The numbers on sectoral final energy use given in Table B-2 are estimates. In some cases, alternative estimates are presented in individual chapters that deal with sectoral energy issues.

The historical shifts from traditional energy sources and coal to crude oil and natural gas were accompanied by the development of elaborate conversion systems for the production of more suitable forms of final energy, such as electricity. These structural changes, together with improvements in the performance of individual energy technologies, have resulted in significant efficiency improvements. Efficiency improvements in converting primary sources to final and useful energy forms, along with economic structural change, have contributed to a reduction of specific primary energy needs for generating a unit of economic output, usually measured in terms of gross domestic product (GDP) or gross national product (GNP). This ratio is often called energy intensity. Figure B-6 illustrates the changes in energy intensity for a number of world regions and countries and shows that, on average, 1% less energy per year was required every successive year to generate a unit of economic output. Actual variations of energy intensities and their improvement rates are large—depending, for instance, on the

Table B-2: *Global energy consumption in 1990 by energy source and by sector, in EJ/yr.*

	Coal	Oil	Gas	Nuclear	Hydro[a]	Electricity	Heat	Biomass	Total
Primary	91	128	71	19	21	–	–	55	385
Final	36	106	41	–	–	35	8	53	279
Industry	25	15	22	–	–	17	4	3	86
Transport	1	59	0	–	–	1	0	0	61
Others	10	18	18	–	–	17	4	50	117
Feedstocks[b]	0	14	1	–	–	–	–	0	15

Notes: Primary energy is recovered or gathered directly from natural sources (e.g., mined coal, collected biomass, or harnessed hydroelectricity), then is converted into fuels and electricity (e.g., electricity, gasoline, and charcoal), resulting in final energy after distribution and delivery to the point of consumption.

measure adopted to compare GDP between countries and regions, geographical factors, energy prices, and policies.

B.3.2.   Past and Present CO$_2$ Emissions

CO$_2$ emissions from fossil energy consumption in 1990 are estimated at about 6.0 (±0.5) Gt C (Marland *et al*., 1994; Subak *et al*., 1993). This represents 70 to 90% of all anthropogenic sources of CO$_2$ in that year (IPCC, 1992).

Figure B-7 shows fossil energy CO$_2$ emissions by major world regions (emission factors are given in Box B-2). Developed countries contribute most to present global CO$_2$ emissions and also are responsible for most of the historical increase in concentrations. Although they are at lower absolute levels, emissions are growing more rapidly in developing countries than in

developed regions. The largest single source of energy-related carbon emissions is coal, with about a 43% share, followed by oil with about 39%, and natural gas with 18%. Adding non-energy feedstocks reverses the shares to 40% for coal and 42% for oil. Due to the lack of data, these shares do not include energy-related deforestation or CO$_2$ emissions from unsustainable use of biomass.

Figure B-8 shows 1990 per capita CO$_2$ emissions in a number of world regions by source and relates these to the respective population size. Estimates of nonfossil sources of CO$_2$ are included.[4] The current levels of per capita fossil-fuel carbon

---

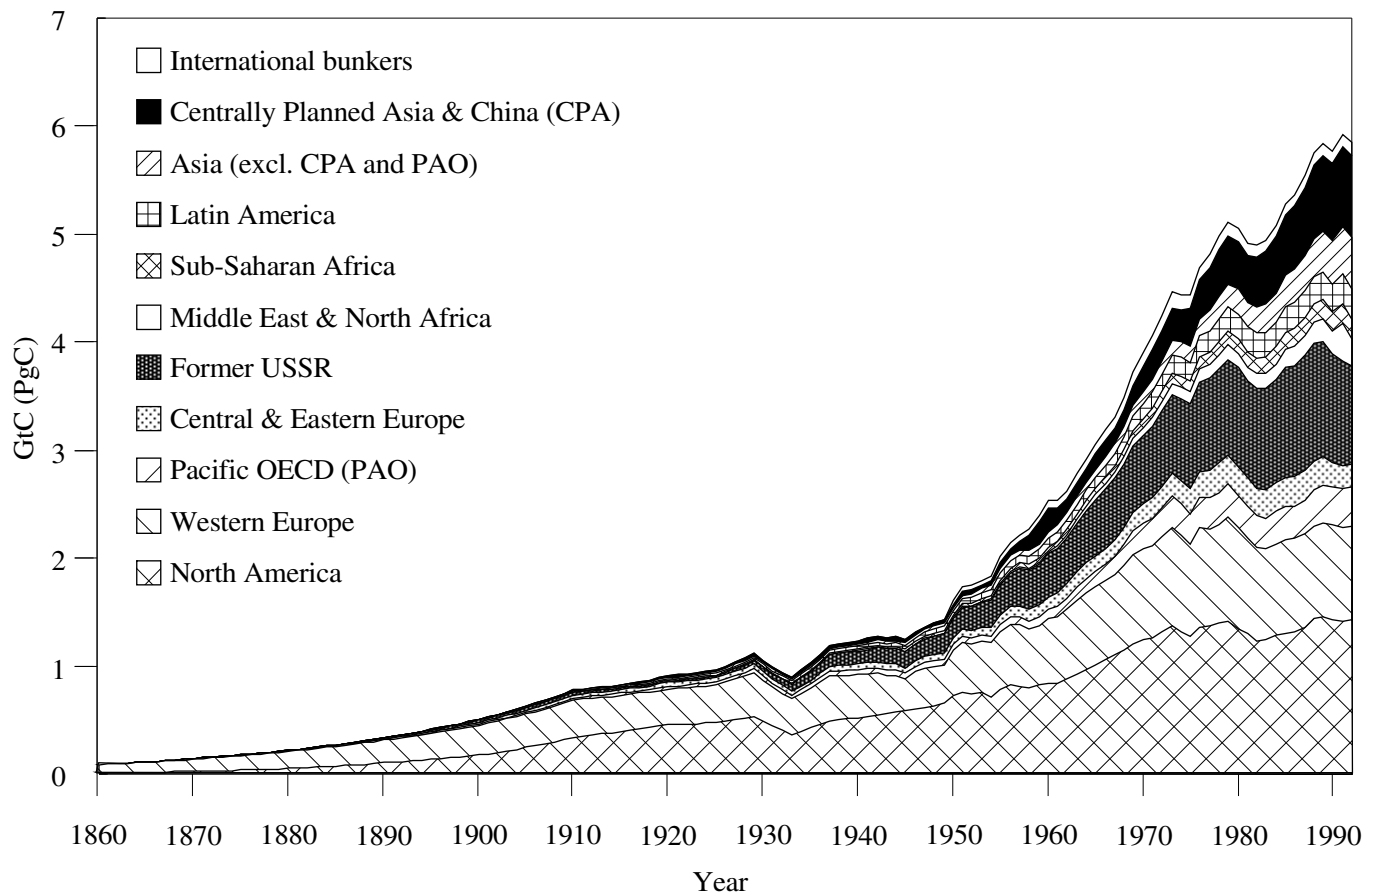
[4] Including CO$_2$ emissions from land-use changes such as deforestation (1.6±1 Gt C—IPCC, 1992). The extent of annual net emissions from nonfossil CO$_2$ sources is difficult to determine due to forest regrowth and the fact that the majority of biomass use is renewable.


Figure B-7: Global energy-related CO_2 emissions by major world region in Gt C/yr (Pg C/yr). Sources: Keeling, 1994: Marland *et al.*, 1994; Grübler and Nakicenovic, 1992; Etemad and Luciani, 1991; Fujii, 1990; UN, 1952.

emissions in the world regions shown in Figure B-8 differ by a factor of 30. A persistent per capita emission gap remains after including carbon emissions from tropical deforestation, currently estimated to range between 0.6 and 2.6 Gt C/yr throughout the 1980s (IPCC, 1990, 1992; Ferreira and Marcondes, 1991; Houghton *et al.*, 1987).

The CO_2 emission intensity of both energy and economic activities is decreasing. Figure B-9 illustrates the extent of "decarbonization" in terms of the ratio of average carbon emissions per unit of primary energy consumed globally since 1860. The ratio has decreased due to the replacement of fuels with high carbon content, such as coal, by those with lower carbon content, such as natural gas, and by those with zero carbon content, such as nuclear power (see Figure B-5).[5] Energy

development paths in different countries and regions have varied enormously and consistently over long periods. The overall tendency has been toward lower carbon intensities, although intensities are currently increasing in some developing countries. At the global level, the reduction in carbon intensity per unit value added has been about 1.3% per year since the mid-1800s—about 1.7% short of that required to offset the growth in global economic output of about 3% per year during that period (hence, global CO_2 emissions have grown at approximately 1.7%/yr).

B.3.3. Energy Reserves, Resources, and Potentials

Energy *occurrences* and their potential recoverability cannot be characterized by a simple measure or single numbers. They comprise quantities along a continuum in at least three, interrelated, dimensions: geological knowledge, economics, and technology. McKelvey (1972) proposed a commonly used diagram with a matrix structure for the classification along two dimensions: decreasing geological certainty of occurrence and decreasing economic recoverability.

Reserves are those occurrences that are identified and measured as economically and technically recoverable with current technologies and prices. *Resources* are those occurrences with

---

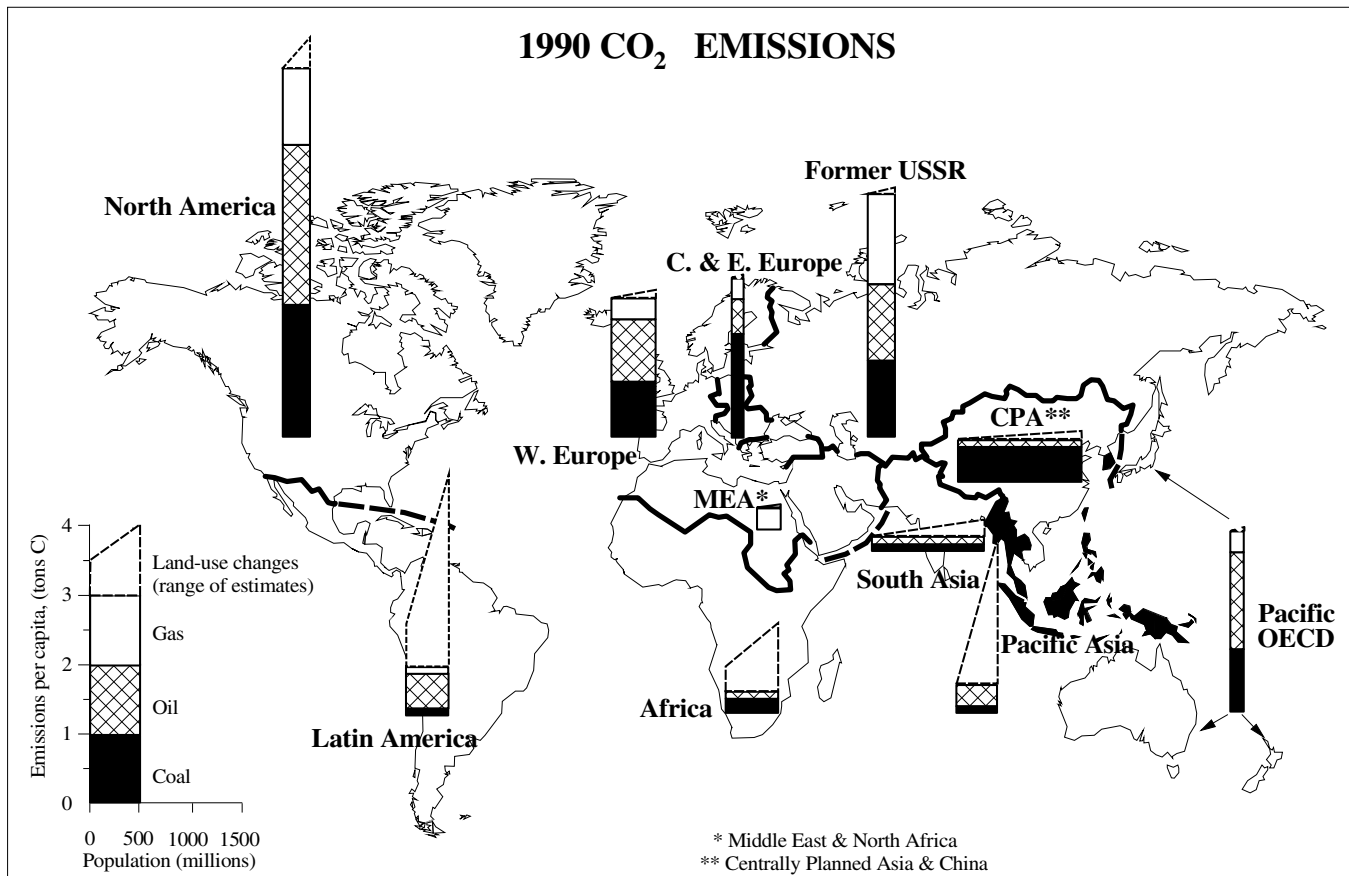
[5] It should be noted that so-called zero-carbon energy sources can result in some CO_2 and other GHG emissions, either because fossil energy is embodied in their construction materials (e.g., concrete in the structures of a nuclear power plant or a hydroelectric dam) or because fossil energy is required for operation and maintenance of energy facilities (e.g., gasoline and diesel vehicles). Some renewable sources also can entail CO_2 and other GHG emissions during operation. Examples include CO_2 emissions from geothermal; CH_4 emissions from anaerobic decay of biomass in flooded hydropower reservoirs; or CH_4, CO, and N_2O emissions from biomass burning.


Figure B-8: 1990 per capita CO_2 emissions by region and source, fossil fuels, and range for biota sources (includes sustainable use of biomass that does not contribute to atmospheric concentration increase). Sources: IEA, 1993; Marland *et al.*, 1994; Nakicenovic *et al.*, 1993; Subak *et al.*, 1993; IPCC, 1990, 1992; Bos *et al.*, 1992; Houghton *et al.*, 1987.

less-certain geological and/or economic characteristics, but which are considered potentially recoverable with foreseeable technological and economic developments. The resource base includes both categories.[6] Additional quantities with unknown certainty of occurrence and/or with unknown or no economic significance in the foreseeable future are referred to here simply as "additional occurrences." For example, such additional occurrences include methane hydrates and natural uranium in seawater, both inferred to exist in large quantities but with unknown economic and/or technological means for extraction. Occurrences comprise all of the above three categories: reserves, resources, and additional occurrences.

Improved geological knowledge, both scientific and experimental (e.g., reservoir theories and exploration); improved technology; and changing prices have continuously served to increase the fossil energy resource base and have led to numerous large discoveries. Additions to reserves from resources have historically outpaced consumption. However, transfers

from resources to reserves require investments. This adds a financial constraint on the expansion of reserves, so that from an economic point of view it makes little sense to invest in maintaining reserves for more than 20 years of production. For oil, this has indeed been the case. Therefore, there is a lot of exploration that still can be done but that has been deferred to the future for economic reasons. This is an important point when trying to understand energy reserves and why significant discoveries are still being made.

B.3.3.1. *Fossil and Nuclear Reserves and Resources*

Currently identified global fossil energy reserves are estimated to be about 50,000 EJ. This quantity is theoretically large enough to last 130 years at the 1990 level of global energy consumption of 385 EJ. It is five times larger than cumulative fossil energy consumption since the beginning of the coal era in the mid-19th century. Coal accounts for more than half of all fossil reserves. Table B-3 summarizes past and current consumption levels and estimates of global fossil and nuclear energy reserves, resources, and additional occurrences.

Estimates of resources and additional occurrences of fossil energy are much larger but more uncertain than reserves. Table B-3

---

[6] The fossil fuel resource-base estimates include potentially recoverable resources of coal, conventional oil, natural gas, unconventional oil (oil shale, tar sands, and heavy crude), and unconventional natural gas (gas in Devonian shales, tight sand formations, geopressured aquifers, and coal seams).
Figure B-9: Global decarbonization of energy since 1860 (including gross carbon emissions from fuelwood), in g C/MJ of primary energy. Source: Nakicenovic *et al.*, 1993.

recoverable conventional oil and gas resources remaining to be discovered at 95%, 50%, and 5% probability levels, ranging between from 1,800 and 5,500 EJ for oil and 2,700 and 10,900 EJ for gas (Masters *et al.*, 1991, 1994).

Methane resources are of particular interest because they have the lowest specific carbon emissions per unit energy of all fossil fuels. They are also of interest because methane is the second most important GHG associated with energy use and with anthropogenic activities in general. Because methane has a higher radiative forcing than CO_2 as a GHG, its climate effects are significantly reduced if it is oxidized into CO_2 (i.e., burned) instead of being released into the atmosphere. The reserves of unconventional gas are of the same magnitude as those for oil. The unconventional gas resource base is larger than that of unconventional oil, whereas the conventional resource bases are about the same. Additionally, there are large gas occurrences in the form of hydrates in permafrost areas and offshore continental-shelf sediments—in the range of 800,000 EJ (Kvenvolden, 1993; MacDonald, 1990).

The fossil resource base and additional occurrences are the ultimate global "carbon endowment" available to future generations, a number larger than 25,000 Gt C (Pg C). Fossil energy reserves correspond to 1,000 Gt C—exceeding the current carbon content of Earth's atmosphere (about 770 Gt C, or an atmos-

shows the global fossil resource-base estimate to be about 186,000 EJ, with additional occurrences of almost 1 million EJ. Included in the conventional resources are estimates of ultimately

Table B-3: *Global fossil energy reserves, resources, and occurrences, in EJ.*

[c] Resource base is the sum of reserves and resources. Conventional resources remaining to be discovered at probability of 50% are included for oil and gas.
[d] MacDonald, 1990.
[e] Natural uranium reserves and resources are effectively 60 times larger if fast breeder reactors are used. Calculated from natural uranium reserves and resources (OECD/NEA and IAEA, 1993) into thermal equivalent for once-through fuel cycle with average factor of 1,700 g per TJ thermal or 4,440 g natural uranium per TJ of electricity (16 Mg natural uranium per TWh$_e$ electricity).

pheric concentration of 358 ppm in 1994). The resource base of conventional oil, gas, and coal, with some 3,500 Gt C, is about five times as large as the current atmospheric carbon content.

Uranium reserves, recoverable at costs less than US$130/kg, were evaluated at 3 million tons of natural uranium in January 1993 (OECD/NEA and IAEA, 1993). This corresponds to about 600 EJ of electricity—or about 1,800 EJ thermal equivalent if used in convertor reactors with a once-through fuel cycle (i.e., without reprocessing or final disposal of spent fuel) or to more than 100,000 EJ if used in fast breeder reactors (see Table B-3). In addition, some 4 million tons of natural uranium (corresponding to 2,300 EJ thermal) are known to exist; part of this supply is in countries where recovery costs have not been estimated. Uranium resources recoverable from unconventional ore bodies or as a byproduct amount to some 7 million tons of natural uranium (4,100 EJ thermal). Resources, estimated through geological assessment, amount to some 10 to 11 million tons of natural uranium (5,800 to 6,400 EJ thermal). Additional occurrences that cannot be exploited with current technologies include seawater, with an estimated natural uranium energy content exceeding one million EJ. Thorium reserves and resources are reported only for a few countries, and on that basis are estimated at 4 million tons. Geological information suggests that the resources may be much larger.

B.3.3.2.   Renewable Energy Potentials and Natural Flows

In contrast to fossil energy sources, renewable energy forms such as solar, wind, and hydro can be either carbon-free or carbon-neutral. The sustainable use of biomass, for example, is carbon-neutral. Solar photovoltaic electricity generation is carbon-free. One must be careful, of course, to examine the full life cycle of the system when comparing the GHG implications of different energy systems because, for example, all energy systems currently rely on fossil fuels to construct devices, transport material, and dispose of waste.

Figure B-10 provides a schematic illustration of annual global energy flows without anthropogenic interference (Sørensen, 1979), and Table B-4 gives a summary of the annual (global) natural flows of renewable energy worldwide and their technical recovery potentials, as well as estimates for more practical potentials that could be achieved by 2020–2025 with current and near- to medium-term technologies and cost structures. The concept of technical potential can be used in a similar fashion as the concept of energy resources, and potentials by 2020 as the concept of energy reserves. The fundamental difference, of course, is that renewable potentials represent annual flows available, in principle, on a sustainable basis indefinitely, whereas fossil energy reserves and resources, although expanding in time, are fundamentally finite quantities. Life-cycle analyses remain important because although the energy flows are sustainable they still require materials like concrete and copper and the commitment of land and other resources. The renewable energy potentials identified in Table B-4 are theoretically large enough to provide the current primary energy needs for the world, and the technical potentials are large enough to cover most of the conceivable future growth of global energy demand.

Table B-4: *Global renewable energy potentials by 2020–2025, maximum technical potentials, and annual natural flows, in EJ thermal equivalent.*[a]

Figure B-10: Global energy balance and flows without anthropogenic interference. The energy flows are in units of 1,000 EJ/yr. Numbers in parentheses are uncertain or rounded. Source: Sørensen, 1979.

Hydropower is currently the most-developed modern renewable energy source worldwide. Table B-4 shows that the maximum technical potential is almost as large as the total final electricity consumption in 1990 as given in Table B-2 (WEC, 1993b; Moreira and Poole, 1993).

The technology to harness geothermal resources is established. Its current total use is about 0.2 EJ of electricity (Arai, 1993; Häfele *et al.*, 1981). There are four types of geothermal occurrences: hydrothermal sources, hot dry rock, magma, and geopressurized sources. The total accessible resource base of

geothermal energy to a depth of 5 km is more than 126 million EJ (Palmerini, 1993), but occurrences within easily accessible layers of the crust reduce the technical potential. The annual flow from Earth is estimated at about 800 EJ/yr (Sørensen, 1979). The long-term technical potential could be greater than 20 EJ—especially if deep drilling costs can be reduced, as these are a major limitation to this energy source.

The energy flux of the atmosphere corresponds to about 200,000 EJ/yr of wind energy. The height limitations of wind converters, the distance of offshore sites, and insufficient wind velocities and land use all limit the practical potential. The ultimate potential of wind-generated electricity worldwide could indeed be very large: Some estimates place it at 50 times current global final electricity consumption (Grubb and Meyer, 1993; WEC, 1993b; Cavallo *et al*., 1993; Gipe, 1991; Häfele *et al*., 1981). Wind electricity is produced at many sites, and it is often also an economic option for electricity generation. The conversion efficiency is not the real barrier to the successful operation of wind-powered electricity generators. The technological challenge is that wind velocity is not constant in magnitude and direction. To utilize much higher windspeeds offshore, one option is to install floating windmills and to transport the electricity generated directly to the location of consumption or to use it for on-board hydrogen production.

Ocean energy flows include thermal energy, waves, tides, and the sea-freshwater interfaces as rivers flow into oceans. The low temperature gradients and low wave heights lead to an annual flow up to 300 EJ/yr of electricity. The technical potential is about 10 to 100 times smaller (Cavanagh *et al*., 1993; WEC, 1993b; Baker, 1991; Sørensen, 1979).

All conceivable human energy needs could be provided for by diverting only a small fraction of the solar influx to energy use, assuming that a significantly large area could be devoted to solar energy gathering because of low spatial energy densities. Solar thermal and photovoltaic demonstration power plants are operating in a number of countries. Many gigawatts (GW) of installed electric capacity could be constructed after a few years of development. The main challenge is to reduce capital costs. Other proposals also have been made—for instance, placing solar power satellites in space.

Four general categories of biomass energy resources are used for fuels: fuelwood, wastes, forests, and energy plantations. Biomass wastes originate from farm crops, animals, forestry wastes, wood-processing byproducts, and municipal waste and sewage. The potential of biomass energy crops and plantations depends on the land area available, the harvestable yield, its energy content, and the conversion efficiency. Biomass potentials by 2020–2025 in Table B-4 are based on a literature survey of estimates and scenarios (Johansson *et al*., 1993; WEC, 1993b; Hall, 1991). The technical potential of biomass energy crops and plantations is especially difficult to estimate. Based on land-use capacity studies, estimates of the land available for tropical plantations range between 580 and 620 million ha (Houghton *et al*., 1991; Grainger, 1990).

B.4.   Energy-Related Chapters

A number of chapters in this report are devoted to the assessment of energy-related impacts of and adaptation to climate change and to energy-related mitigation options. Vulnerability to climate change (including impacts and adaptation) concerning the energy, industry, and transportation sectors is considered in Chapter 11; human settlements are covered in Chapter 12. The general conclusion is that the sensitivity of the energy, industry, and transportation sectors is relatively low, whereas the capacity for autonomous adaptation is expected to be high if climate change is relatively gradual and not too drastic. Infrastructure and activities in these sectors would be susceptible to sudden changes and surprises; however, the subsectors most sensitive to climate change include agroindustry, renewable energy production including hydroelectric generation, construction, and manufacturing heavily dependent on water supplies. The most vulnerable human settlements are located in damage-prone areas of the developing world that do not have resources to cope with impacts.

Energy-related options for controlling the sources and enhancing the sinks of GHGs have an important role, to a varying degree, in all of the mitigation chapters. Chapter 19 assesses energy supply mitigation options, and the following three chapters, 20 through 22, consider individual sectors—industry, transportation, and human settlements, respectively. In addition, mitigation options related to energy supply and use (e.g., biomass) are considered in Chapters 23 and 24 on agriculture and forestry, respectively.

Energy-related emissions account for the largest share of CO_2 sources and have varying importance in the emissions of other GHGs. Global primary energy needs are expected to increase anywhere between 540 and 2,500 EJ by 2100, according to the IS92 IPCC scenarios. A detailed assessment and evaluation of IPCC and other energy and emissions scenarios is provided in *An Evaluation of the IPCC IS92 Emission Scenarios* (Alcamo *et al*., 1995). With increases in global primary energy, GHG emissions will continue to grow unless they are mitigated. The general conclusion in Chapters 19 to 24 is that the technological potential to achieve significant emission reductions is indeed large, but there are important uncertainties regarding the ease, timing, and cost of implementing mitigation options and measures.

Implementation depends on successful research and development, the existence of the right market and institutional conditions, and timely market penetration, as well as the adoption of new technologies and practices by firms and individuals. Government policies are an important element in the creation of appropriate market conditions and incentive structures.

Chapter 25, the last of the mitigation options chapters, evaluates strategies that emphasize land use and highlights some key cross-cutting themes related to implementation and energy supply and use. It concludes with a discussion of nontraditional mitigation options such as "geoengineering," which might be involved as "last resort options" for the future.

The last two chapters of the report, Chapters 27 and 28, describe methods for assessing mitigation options and offer an inventory of mitigation technologies, respectively. These methods can be used to develop mitigation strategies and evaluate mitigation projects and, together with the inventory, are available to all countries.

CONTENTS

EXECUTIVE SUMMARY

Forests are highly sensitive to climate change. This has been shown by observations from the past, experimental studies, and simulation models based on current ecophysiological and ecological understanding. In particular, the following was concluded:

- Sustained increases of as little as 1°C in mean annual air temperature can be sufficient to cause changes in the growth and regeneration capacity of many tree species. In several regions, this can significantly alter the function and composition of forests; in others, it can cause forest cover to disappear completely (Medium Confidence).
- Suitable habitats for many species or forest types are likely to shift faster with climate change than the maximum natural rate at which many species can migrate and establish. Consequently, slow-growing species, such as late successional species, or those with restricted seed dispersal will be replaced by faster-growing, highly adaptable or more mobile species (High Confidence).
- Forests are particularly vulnerable to extremes of water availability (either drought or waterlogging) and will decline rapidly if conditions move toward one of the extremes (High Confidence).
- Forced by a doubled carbon dioxide (2 x CO_2) climate, global models project that a substantial fraction of the existing forests will experience climatic conditions under which they do not currently exist; eventually, large forested areas will have to change from the current to new major vegetation types (High Confidence). Averaged over all zones, the models predict that 33% of the currently forested area could be affected by such changes; in the boreal zone, one model projects it to be as high as 65% (Medium Confidence). Yet it is currently not possible to predict transient forest responses at a regional to global scale.
- Although net primary productivity may increase, the standing biomass of forests may not increase because of more frequent outbreaks and extended ranges of pests and pathogens and increasing frequency and intensity of fires (Medium Confidence).
- Mature forests are a large store of terrestrial carbon. Because the maximum rate at which carbon can be lost is greater than the rate at which it can be gained, large amounts of carbon may be released transiently into the atmosphere as forests change in response to a changing climate and before new forests replace the former vegetation. The loss of aboveground carbon alone has been estimated to be 0.1–3.4 Gt yr[-1] or a total of 10–240 Gt (Medium Confidence).

The following regional assessments were primarily based on transient climate-change scenarios for 2050 (Greco *et al.*, 1994).

Tropical Forests

- Tropical forests are likely to be more affected by changes in land use than by climate change as long as deforestation continues at its current high rate (High Confidence).
- Any degradation of tropical forests, whether it is caused by climate or land-use changes, will lead to an irreversible loss in biodiversity (High Confidence).
- CO_2 fertilization may have its greatest effect in the tropics and may lead to a gain in net carbon storage in undisturbed forests, especially in the absence of nutrient limitations (Medium Confidence).
- Tropical forests are likely to be more affected by changes in soil water availability (caused by the combined effects of changes in temperature and rainfall) than by changes in temperature *per se*. Decreases in soil moisture may accelerate forest loss in many areas where water availability is already marginal. In other areas, increasing precipitation may be more than adequate to meet increased evaporative demand and may even lead to erosion (Medium Confidence).

Temperate Forests

- Compared with other latitudinal zones, the potential area for temperate forests is projected to change the least; however, many existing forests will still undergo significant changes in their species composition (High Confidence).
- Water availability will change in many regions, and in some regions where water supply is already marginal, forests may be lost in response to increased summer droughts (Medium Confidence).
- While warming and elevated CO_2 are likely to increase net primary productivity of many forests, net carbon storage may not increase because of the associated stimulation of soil organic matter decomposition by soil warming (Medium Confidence).
- Temperate forests are currently a carbon sink, mainly because of regrowth that started in many regions in the 19th century. However, these forests could become a source if they degrade due to climate change or other causes such as air pollution (Medium Confidence).

- Most temperate forests are located in developed countries with resources to reduce the impacts of climate change on their forests through integrated fire, pest and disease management, and/or encouraging reforestation (Medium Confidence).

Boreal Forests

- Because warming is expected to be particularly large at high latitudes, and boreal forests are more strongly affected by temperature than forests in other latitudinal zones, climate change is likely to have its greatest impact on boreal forests (High Confidence).

- Northern treelines are likely to advance slowly into regions currently occupied by tundra. (High Confidence).
- Increased fire frequency and pest outbreaks are likely to decrease the average age, biomass, and carbon store, with greatest impact at the southern boundary where the boreal coniferous forest is likely to give way to temperate-zone pioneer species or grasslands (Medium Confidence).
- The net primary productivity of forests not limited by water availability is likely to increase in response to warming, partly mediated by increased nitrogen mineralization. However, there may be a net loss of carbon from the ecosystem because of associated increases in soil organic matter decomposition (Medium Confidence).

1.1. Introduction

Forests are among those ecosystems on Earth that remain the least disturbed by human influences. They are of great socioeconomic importance as a source of timber, pulpwood for paper making, fuel, and many non-wood products (see Chapter 15). Furthermore, forests provide the basis for a broad range of other economic and non-economic values, such as resources for tourism, habitat for wildlife, or the protection of water resources. Forests harbor the majority of the world's biodiversity (mainly in the tropics) and, as such, they represent indispensable, self-maintaining repositories of genetic resources. These are essential for improvements in crop and timber selection and in medicine. Finally, aside from special economic interests, forests are also of spiritual importance to many indigenous people.

Globally, forests in 1990 covered about one-fourth of the Earth's land surface (3.4 Gha: FAO, 1993b), although estimates differ due to the exact definition of forests (e.g., 4.1 Gha: Dixon *et al.*, 1994; or, in a very wide definition, 5.3 Gha: Sharma *et al.*, 1992). About 17% of high-latitude, 20% of mid-latitude, and 4% of low-latitude forests can be considered actively managed (see Chapter 24), but only about 100 Mha (~2%) consist of intensively managed plantations (Dixon *et al.*, 1994). The forest regions have been broadly subdivided into latitudinal zones (i.e., the tropical, temperate, and boreal zones).

Forests are ecosystems in which trees interact with each other, with other plants like shrubs and grasses, and with animals or other heterotrophic organisms such as insects or fungi. At a broad scale, forest structure is modified by processes ranging from almost continuous change due to the death of individual trees and the subsequent recruitment of seedlings, to catastrophic events such as fire, insects, wind-fall or logging that kill whole stands of trees simultaneously. At any given moment, a forest represents the outcome of long-lasting past processes, often covering many centuries.

As components of the global climatic system, forests play a major role in the present and projected future carbon budget, since they store about 80% of all aboveground and 40% of all belowground terrestrial organic carbon (e.g., Melillo *et al.*, 1990; Dixon *et al.*, 1994) and can act as sources through deforestation and degradation, as well as sinks through forestation and possibly enhanced growth (see Chapter 23 on the role of forests for mitigation of greenhouse gas emissions). Moreover, forests can directly affect the climate system from local up to continental scales: They influence ground temperatures, evapotranspiration, surface roughness, albedo, cloud formation, and precipitation (e.g., Henderson-Sellers *et al.*, 1988; Gash and Shuttleworth, 1991).

Forest ecosystems respond to environmental changes with time constants ranging from hours to decades and up to millennia (see Box 1-1); they are among the components of the biosphere that respond most slowly to climatic change. The role of forest dynamics in the global climatic system is likely to be long lasting, complex, and difficult to predict. Because of their longevity and because adaptive measures, such as replacement of species, are harder to implement than in agricultural systems, forests may be particularly vulnerable to climatic change.

Sections 1.2.1 and 1.2.2 present assessments of direct forest responses to climatic change, including possible secondary effects on forest pests, fire, and other issues, which may cause forests

---

Box 1-1. Scales and Equilibrium Assumptions

Climatic changes affect forests on spatial scales ranging from leaves to the canopy and on temporal scales from minutes to centuries; relevant climatic changes occur at all levels, from short-term weather fluctuations creating disturbances (such as frosts) to longer-term changes in average climatic conditions (such as moisture availability or the length of the growing season) or the frequency of extreme events (such as droughts, fires, or intense storms). Current climate models (GCMs) do not fully match these levels, since they are best at simulating average conditions at a relatively coarse spatial resolution and are usually not yet run for longer than a century. Changes in frequencies of extreme events are highly uncertain, as are local-scale climate changes, although both are of high relevance to forests.

Some of the limitations caused by this problem can be overcome in local analyses using downscaling techniques (e.g., Gyalistras *et al.*, 1994), but for global applications the implicit assumption must be made that the probability of extreme events will remain unchanged. Most transient changes in the structure of forests, such as the decline of certain tree species, are driven by a combination of climatic changes and are modified by local, biological interactions acting on temporal scales ranging from months to centuries. It is currently very difficult, therefore, to assess the likely rates of climate-driven, transient change in forests. However, possible future equilibrium conditions can be more adequately predicted.

Equilibrium projections of forest responses implicitly assume the climate to have stabilized at a new steady state, which is not likely to occur soon in reality. However, GCM-derived climate scenarios arbitrarily held constant (e.g., for 2050) allow an assessment of the direction and magnitude of the expected change. Equilibrium projections for future forests, therefore, represent conservative interpretations of minimal changes likely to occur sooner or later and hence include the potential of even greater biospheric changes than the ones currently simulated by the forest models.

Box 1-2. Temperature Thresholds

Trees have widely differing responses to temperature. Some tropical tree species suffer chilling injury at temperatures below +12°C (Lyons, 1973; Lyons *et al*., 1979), whereas species of colder regions can survive -5°C without ice formation but are sterile at lower temperatures. Classic examples for this phenomenon are *Ilex* and *Hedera* (Iversen, 1944). Broad-leaved evergreen perennials can survive to a limit of about -15°C by supercooling, whereas broad-leaved deciduous trees can supercool to about -40°C (Arris and Eagleson, 1989). Evergreen needle-leaved trees can survive to about -60°C, below which only deciduous species survive. Apart from these killing temperatures, many species require certain minimum numbers of degree days to complete essential life-cycle processes such as bud initiation, pollen formation, flowering, or others (Stern and Roche, 1974). Others require particular sequences of cool temperatures to become frost-hardy at the optimum time and a minimum duration of chilling temperatures to break winter dormancy (Cannell, 1990). Insect pests and other biotic agents that affect forest health may have critical threshold subzero temperatures for winter survival and thermal times to complete a generation. Warming may have positive effects on the growth of many trees and their survival, but by being beneficial to insect pests it also may reduce tree survival or put cold-adapted species at a competitive disadvantage.

---

either to grow more vigorously or to decline[1] in a changing climate. These assessments are based on the current general understanding of the basic ecophysiological and ecological responses; the latter will be addressed on levels ranging from the stand to the globe. In the three remaining sections, we summarize more specific effects in the tropical, temperate and boreal forest zones.

1.2.   Climate and Forests

1.2.1.   *Sensitivities to Expected Climate Change*

Forests are highly dependent on climate in their function (e.g., growth) and structure (e.g., species composition). Forest distribution is generally limited by either water availability or temperature. The ratio of actual evapotranspiration (the amount allowed by available precipitation) to potential evapotranspiration (the amount the atmosphere would take up if soil moisture were not limiting) determines the maximum leaf area index that can be supported (Woodward, 1987). Forests are also usually absent where the mean temperature of the warmest month falls below 10°C (Köppen, 1936) or where the temperature sum above a 5°C threshold is less than 350 degree-days (Prentice *et al*., 1992).

The survival of many species depends critically on temperature thresholds ranging from +12° to -60°C (e.g., Woodward, 1987; Prentice *et al*., 1992; Box 1-2). Many species have narrow temperature niches for growth and reproduction. A sustained increase in mean annual temperature of 1°C may cause significant changes in the species composition of stands and hence the distribution of many tree species (Davis and Botkin, 1985; see also Section 1.3). Trees are also sensitive to changes in water availability during the growing season, and leaf area indices, volume growth, and the range boundaries of most tree species are strongly related to water availability (Holdridge, 1967; Hinckley *et al*., 1981; Gholz, 1982; Austin *et al*., 1990; Stephenson, 1990).

In addition to thresholds for growth, reproduction, and survival at a given site, there are limitations to the rate at which species

can migrate unassisted. Current projected rates of climatic change may exceed these thresholds, as discussed in Section 1.3.5. Climatic warming and associated lower humidities and increase in the frequency and severity of droughts would increase the incidence and severity of wildfires, especially in the boreal region. Changes in fire or storm frequencies are likely to have major impacts on the composition, age-distribution, and biomass of forests (see Sections 1.5.4.5 and 1.6.4.4).

1.2.2.   *Expected Climatic Changes in Forested Areas*

Future forest characteristics are likely to depend on a few specific aspects of the range of climatic changes that could occur. The most relevant are the following:

- Changes in the regional or seasonal pattern of climate, such as the temperature increases that are expected to be greatest at high latitudes, and there, greatest in winter (Greco *et al*., 1994). Due to this, impacts on forests at high latitudes may be greater than elsewhere.
- Water shortages during the growing season. Decreasing summer precipitation together with increased evaporative demand would lead to decreases in soil water, especially in many mid-latitude regions where water is most critical for growth. It is important to note that water shortages can develop even with unchanged rainfall amounts, due to increasing temperatures causing increased evaporative demand. We expect significant regional variation, with water availability changing only marginally in some regions and improving in others, whereas in many other regions water availability may decrease drastically.

---

[1] Decline is defined here as "an episodic event characterized by premature, progressive loss of tree and stand vigor and health over a given period without obvious evidence of a single clearly identifiable causal factor such as physical disturbance or attack by an aggressive disease or insect" (Ciesla and Donaubauer, 1994).

- Changes in climate forcing are expected to be one or two orders of magnitude faster than rates of climatic change experienced by forests during most of the past 100,000 to 200,000 years, except, perhaps, during the Younger Dryas Event 10,000 years ago (Dansgaard *et al*., 1989; Webb III and Bartlein, 1992; Gates, 1993). Such rapid climatic change would have particular impacts on forests. For example, there may be forest decline, interruption of tree life cycles, loss of slowly migrating species, and increasing abundance of more aggressive, early successional species.

1.3. Forests in a Changing Climate

For a detailed assessment of the effects of a changing climate on forest ecosystems, it is necessary to investigate this response to the simultaneous changes in several climatic variables (e.g., temperature, moisture availability, and ambient CO_2 concentrations). Current understanding of ecological relationships and ecophysiological mechanisms allows a comprehensive study of forests at three hierarchical levels of scale, connecting temporal and spatial resolution to the nature of the processes that are being considered (Table 1-1).

At the ecophysiological level, plant organs like stomata and leaves respond almost instantaneously to their environment. This mainly affects forest functions, such as net primary productivity. Some structural aspects, such as leaf area, may respond over a number of years, whereas others, such as species composition, may take centuries to respond to altered conditions. Typically, each species or plant functional type (PFT) is affected differently by climatic change: Some species or PFTs will remain unaffected, some will become more and others less competitive (Smith *et al*., 1993). Dynamic forest models can be used to simulate this transient behavior of forests (e.g., Shugart, 1984; Prentice *et al*., 1993). Landscape-scale processes such as the lateral interactions between neighboring patches (e.g., migration or fire) play an important role for possible changes in the local to regional pattern of many forest ecosystems. However, they become less relevant when aggregated to national or continental assessments. At the global level, it is currently possible to investigate only how climatic change might affect the potential geographic equilibrium distribution of biomes—i.e., biogeographic regions (e.g., Emanuel *et al*., 1985; Prentice *et al*., 1992)—or to study the major fluxes of trace gases into and out of these biomes (Melillo *et al*., 1993; Plöchl and Cramer, 1995), with research underway on dynamic modelling (see also Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, in the Working Group I volume).

The current models can be used with climatic inputs generated by general circulation models (GCMs) for future climate scenarios, including regionally differentiated, high-resolution scenarios (e.g., Gyalistras *et al*., 1994). However, current understanding of the physical and biological interactions between environment and organisms is still rather limited, so these techniques enable us only to project future responses as consequences of given assumptions and scenarios and not to make precise forecasts.

1.3.1. Ecophysiological Responses

1.3.1.1. Tree Responses to Temperature and Water Availability

When they are well supplied with water, trees of most temperate and boreal species respond to increased temperature (e.g., from year to year, or when planted at a slightly warmer location) by growing faster (e.g., Cannell *et al*., 1989; Beuker, 1994), and they reach their largest mass near the warmest boundaries of their geographic ranges (Korzukhin *et al*., 1989). Generally, there is a positive correlation between net primary productivity and temperature (Box, 1978; Kauppi and Posch, 1985; Kokorin *et al*., 1993; Morikawa, 1993) or between net primary productivity and actual evapotranspiration (Rosenzweig, 1968; Raich *et al*., 1991).

However, these potential growth responses to warming may be constrained by other factors. Increasing temperature increases evaporative demand; if rainfall does not increase, more severe water stress will result, which will adversely affect growth and may increase the risk of drought and fire. To what extent this can be compensated by increased water-use efficiency due to increasing CO_2 concentration is not yet known (see Section 1.3.1.2 and Chapter A). Photoperiodic limitations might also

Table 1-1: Hierarchical levels at which it is currently possible to study and model the impact of climatic change on forest ecosystems. Note that transient responses of trees and forests can currently only be studied at the first two levels.

Level	Focus	Time		Space	
		Resolution	Scope	Resolution	Scope
Ecophysiological Processes	Plant Metabolism	min..h	1..10 yr	0..100 m	locations
Individuals, Populations, Forest Stands	Ecosystem Dynamics	d..yr	$1..10^3$ yr	~100 m	regions to continents
Plant Functional Types, Vegetation, Vegetation Complexes, Biomes	Biospheric Equilibrium	–	$\geq 10^3$ yr	$\sim 10..10^3$ km	globe

apply in areas where temperature becomes warm enough for tree growth (e.g., Heide, 1974, 1993), and increasing temperature might increase the range of insect pests, which could cause considerable damage.

GCMs suggest a globally averaged increase in precipitation of about 2.5% per degree warming (Mitchell *et al*., 1990; Greco *et al*., 1994), which may not be sufficient to meet the increased water requirements of forests. Most GCMs indicate significant declines in net soil moisture over continental areas during the growing season (e.g., Manabe and Weatherald, 1987; Greco *et al*., 1994). There are likely to be considerable regional differences, however, with some regions likely to receive increased rainfall sufficient to meet increased evaporative demand and other regions receiving even less rainfall than at present. Because the present distribution of species and plant functional types is strongly determined by the total (Holdridge, 1967; Box, 1981; Hinckley *et al*., 1981; Austin *et al*., 1990) and seasonal availability of water (Stephenson, 1990; Prentice *et al*., 1992), any changes in water availability are likely to greatly affect the distribution of species (see Section 1.3.2).

1.3.1.2.   Tree Responses to Increased CO_2 Concentration

The importance of CO_2 fertilization continues to be controversial (e.g., Körner, 1993; Idso and Idso, 1994; see also Chapter A). While the response of photosynthesis to CO_2 concentration can be readily observed at the single-leaf or isolated plant level (Kimball, 1983; Cure and Acock, 1986; Mooney *et al*., 1991; Luxmoore *et al*., 1993; Wullschleger *et al*., 1995), it has been argued that this initial benefit may be negated by the various feedbacks in the plant and soil (e.g., Bazzaz and Fajer, 1992; Diaz *et al*., 1993; Körner, 1993). Quantification of some of these feedbacks has been attempted (e.g., Comins and McMurtrie, 1993; Kirschbaum *et al*., 1994) but has not yet been possible for the great diversity of natural habitats, in which most of the feedback effects are still inadequately understood. Experimental approaches have not yet resolved this controversy because of the enormous costs and technical difficulties involved. Only a small number of open-air CO_2 enrichment experiments have been conducted with mature natural populations—and none on forests.

Because atmospheric CO_2 has already increased from a preindustrial concentration of about 280 ppmv to about 360 ppmv at present, increased growth should be observable in the growth of plants under natural conditions. However, the evidence from tree-ring chronologies is unclear, and no generalizations can be made (Innes, 1991). Where growth increases have been observed, part or all of that probably could be explained by more favorable temperatures, water relations, successional age, or nitrogen fertilization by moderate levels of industrial pollution (Innes, 1991; Luxmoore *et al*., 1993).

When plants have access to limiting amounts of water, growth is limited by the amount of CO_2 that can be obtained in the diffusive gas exchange during photosynthesis. Once the available water has been used up, tissue water potentials fall below threshold levels and growth ceases. Growth under these conditions is determined by the amount of available water multiplied by water use efficiency (WUE). Because WUE can be greatly enhanced by increased CO_2 concentration (Rogers *et al*., 1983; Tolley and Strain, 1985; Morison, 1987; Eamus and Jarvis, 1989), relative plant responses to increases in ambient CO_2 should be most pronounced under water-limited conditions (e.g., Gifford, 1979; Allen, 1990). While increasing CO_2 concentration may be beneficial for plant growth, some researchers rank it of less importance than changes in temperature and/or precipitation, which can have large impacts when critical thresholds of drought, chilling, or degree-days are reached (e.g., Solomon, 1988).

1.3.1.3.   Carbon Storage and Nutrient Availability

Although increasing temperature may lead to higher net primary productivity (NPP), net ecosystem productivity (NEP) may not increase, and may even become negative, because warmer temperatures also greatly stimulate soil organic matter decomposition (e.g., Raich and Schlesinger, 1992; Lloyd and Taylor, 1994; Kirschbaum, 1995; Chapter A). This could release large amounts of CO_2 to the atmosphere (e.g., Jenkinson *et al*., 1991; Kirschbaum, 1993, 1995; Schimel *et al*., 1995; Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, in the Working Group I volume). However, the direct effect of increasing CO_2 concentrations may partly offset or in some cases even reverse this effect and make NEP positive.

Enhanced decomposition of soil organic matter also should have the effect of mineralizing nutrients—especially nitrogen and phosphorus—that are held in soil organic matter and making them available for plant growth (e.g., Shaver *et al*., 1992; Melillo *et al*., 1993). This is likely to be of greatest importance in cool regions of the world, which are mostly nitrogen-limited and often contain large amounts of organic matter (Post *et al*., 1982). This could sometimes lead to an increase in total carbon storage in systems if nutrients are redistributed from components with low C:N ratios (i.e., soil organic matter) to components with high C:N ratios (i.e., woody stems) (Rastetter *et al*., 1992; Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, in the Working Group I volume). In industrialized regions, nitrogen deposition from the atmosphere may enhance NPP and NEP, leading to increased total carbon storage in forest ecosystems (Kauppi *et al*., 1992), provided deposition has not reached levels that cause forest decline (Durka *et al*., 1994).

1.3.2.   Species Distributions

Species have responded individually to past environmental changes (Huntley and Birks, 1983; Davis and Zabinski, 1992; Solomon and Bartlein, 1992; Gates, 1993). The set of all possible environmental conditions in which a given species survives

Box 1-3. Ecological Niches and Climatic Change

Any species' survival is influenced by many factors, and the set of environmental conditions in which it can exist and reproduce is called its niche. A distinction must be made between a species' fundamental niche and its realized niche (Hutchinson, 1957; Malanson *et al*., 1992). The fundamental niche encompasses all environmental conditions in which a species could potentially grow and reproduce with its specific physiological characteristics. The realized niche encompasses those conditions in which a species is actually found. The latter is usually a subset of the fundamental niche due to competition by other species (see Chapter A). Only rarely does the realized niche coincide with the fundamental one (Woodward, 1987; Booth *et al*., 1988; Austin *et al*., 1994). Examples of typical environmental factors that determine a species' niche are temperature and precipitation (see Figure 1-1).

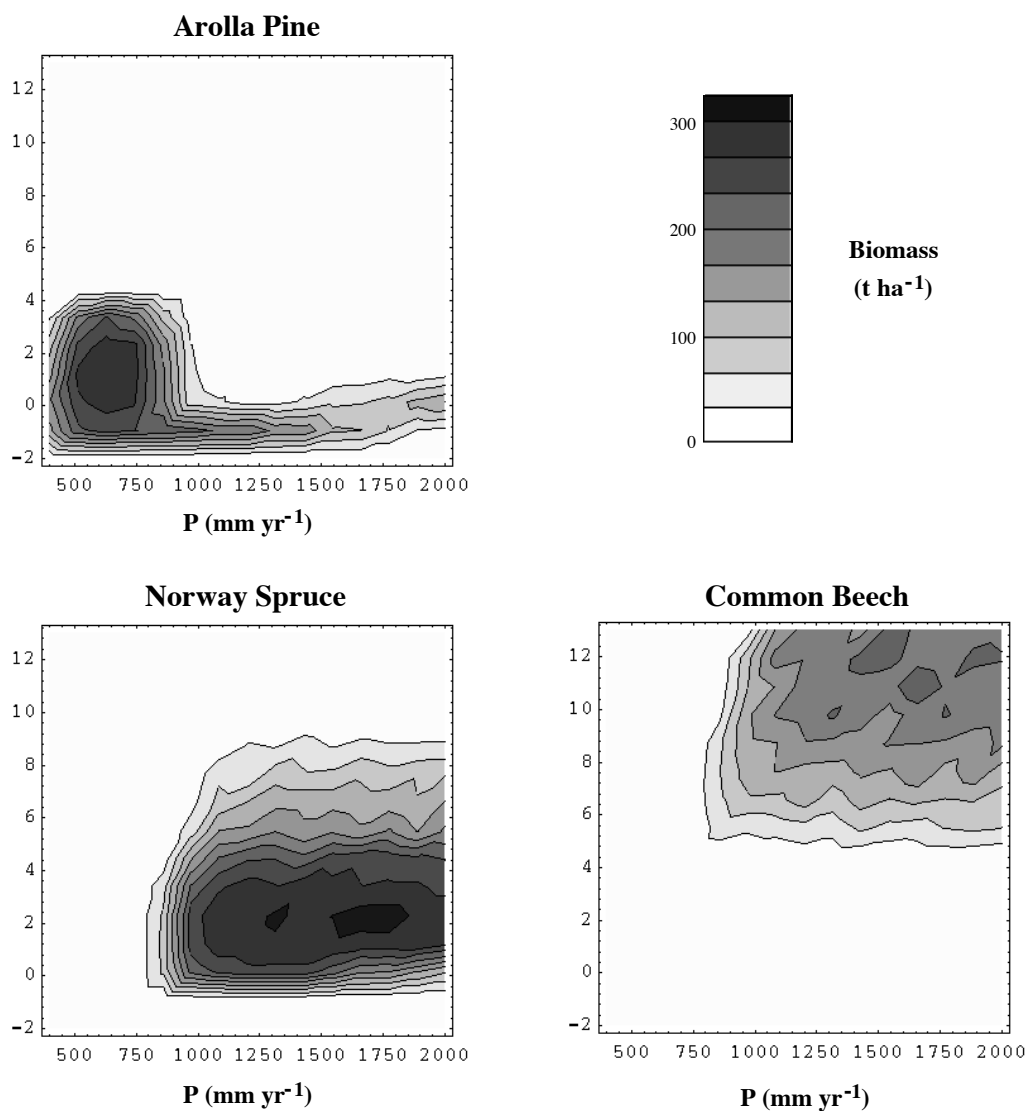
Species with narrow niches are potentially very sensitive to climatic changes. A sustained temperature increase of only 1°C could have a major effect on the probability of occurrence of many species (e.g., Arolla pine, Figure 1-1), and in some instances a temperature increase of 2°C can be sufficient to change the environment for some species from very suitable to totally unsuitable (e.g., Whitehead *et al*., 1993).


Figure 1-1: Simulated realized niches of three tree species [*Pinus cembra* L. (Arolla Pine), *Picea abies* (L.) KARST. (Norway Spruce), and *Fagus sylvatica* L. (Common Beech)] plotted as biomass versus annual means of temperature (T) and precipitation (P) (after Bugmann, 1994). The realized niches can be rather narrow (e.g., Arolla pine) and are usually smaller than the corresponding fundamental niches. For example, Norway spruce can easily be planted in climatic conditions where it naturally would be outcompeted by beech.

and reproduces (but without evolving—that is, changing its inherited characteristics such as physiological traits), is called its fundamental ecological niche (Hutchinson, 1957; Malanson *et al.*, 1992). In field conditions, species often survive only in a sub-set of the fundamental niche, the realized niche (Grubb, 1977; Booth *et al.*, 1988; Malanson *et al.*, 1992), owing especially to competitive interactions with other species (see Box 1-3).

With rapid climatic change, conditions may become unsuitable to complete one or more stages of the life cycle, especially if some climate variables were to change significantly more than other variables. For example, pollen and seed development require minimum heat sums and are sensitive to frosts (Stern and Roche, 1974). Seedlings are particularly vulnerable to short-term droughts, saplings to the presence or absence of sunlight, and mature trees to the availability of growing-season soil water. Populations could appear quite healthy while losing the ability to complete their life cycles.

Trees whose seedlings can now survive at a particular site will grow into adults in climates that may be unsuitable in 50–100 years; conversely, adults that could grow in an area in 50–100 years time must grow from seedlings that may be unable to survive current climatic conditions at those sites. A net ecosystem-level impact may be the loss of slow-growing species and the selection of species that complete their life cycles more quickly, such as early successional trees and shrubs. The ability to reach reproductive maturity in a short time favors early successional species that grow in full sun, whereas slower-growing species that begin their life cycles as understory species under closed canopies may be lost. Some model simulations have indicated that this opening of closed forests could result in the loss of three quarters of the trees and aboveground carbon in current temperate-zone forests (e.g., Solomon, 1986).

1.3.3. *Transient Responses in Species Compositions*

Concerns about the future of forest ecosystems relate not only to the geographic distribution of areas potentially suitable for forests and the performance of trees under different environmental conditions but also to the effect of climate change on the functioning and structure of ecosystems during the transient phase. For instance, it is well known that changing ambient conditions can reduce growth in forest ecosystems (e.g., Solomon and Webb III, 1985; Shugart *et al.*, 1986; Solomon, 1986; Woodwell, 1987; Prentice *et al.*, 1991b; Botkin and Nisbet, 1992; Davis and Zabinski, 1992). Moreover, the magnitude of climate change will subject many species assemblages, within a life cycle of their main species and in most of their distribution area, to climates that now occur outside their current ecological range (e.g., Solomon *et al.*, 1984; Roberts, 1989; Davis and Zabinski, 1992).

The transient response of species to such climatic changes can currently be assessed only with forest succession models (see Box 1-4). Despite some of their deficiencies (e.g., Moore, 1989; Bonan, 1993; Bugmann and Fischlin, 1994; Fischlin *et*

al., 1995), these models can be used to project transient changes in species composition of selected forest types for scenarios of climatic change in the past (Solomon *et al.*, 1981; Lotter and Kienast, 1992) or future (Pastor and Post, 1988; Kienast, 1991; Friend *et al.*, 1993; Bugmann, 1994; Bugmann and Fischlin, 1994; Smith *et al.*, 1994; see Box 1-4). These simulations suggest that climate change could cause widespread tree mortality within a few decades (Solomon *et al.*, 1984; Solomon, 1986; Solomon and West, 1987; Pastor and Post, 1988; Kienast, 1991; Prentice *et al.*, 1991b; Bugmann, 1994; Bugmann and Fischlin, 1994). Solomon and Bartlein (1992) and Pastor and Post (1993), for example, show how lags in population responses to climatic change could result in transient decreases in NPP before better-adapted species eventually replace the original vegetation and result in enhanced growth. It also should be noted that many simulations show species compositions that are not present in existing forests (Bugmann, 1994; Bugmann and Fischlin, 1994; Smith *et al.*, 1994).

Regrowth of better-adapted species or forest types requires many decades to centuries (Dobson *et al.*, 1989; Kienast and Kräuchi, 1991; Bugmann and Fischlin, 1994). Consequently, regions with forests in decline could release large amounts of carbon (e.g., Smith and Shugart, 1993), producing a large transient pulse of CO_2 into the atmosphere (e.g., Neilson, 1993; Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, in the Working Group I volume). Whereas some authors have estimated this carbon pulse from aboveground carbon alone to fall within a range of 0.1 to 3.4 Gt yr^{-1} for the annual flux, or 10 to 240 Gt for the accumulated pulse (King and Neilson, 1992), others have estimated a total carbon pulse from above and belowground C as high as 200 to 235 Gt, to be released to the atmosphere during a few decades to a century (see Section 1.3.4; Neilson, 1993; Smith and Shugart, 1993). Such responses, although debatable in their magnitude, are plausible because climatic changes also have been implicated in past episodes of forest and species decline (Cook *et al.*, 1987; Hamburg and Cogbill, 1988; Johnson *et al.*, 1988; Auclair *et al.*, 1992).

1.3.4. *Potential Biome Distributions*

Patch dynamics models cannot currently be used to simulate the transient behavior of forests in a changing climate on a global scale. This is because they require a large set of species-specific information that is not available from all regions of the world, especially not from the tropical zone. However, on the biospheric level (Table 1-1), several static global vegetation models have recently become available that enable us to make estimates of vegetation-climate equilibria (Box, 1981; Emanuel *et al.*, 1985; Prentice *et al.*, 1992; Smith *et al.*, 1992a; Cramer and Solomon, 1993; Leemans and Solomon, 1993; Monserud *et al.*, 1993b; Tchebakova *et al.*, 1993; Leemans and van den Born, 1994; Neilson *et al.*, 1994) based on earlier related studies (e.g., Köppen, 1936; Holdridge, 1947; Woodward, 1987).

Given any past or present climate, such vegetation models can be used to map the distribution of biomes (e.g., Prentice *et al.*,

---

Box 1-4. Forest Succession Models

Most forest succession models are based on the gap dynamics hypothesis (Watt, 1947; Bray, 1956; Shugart, 1984). They simulate the establishment, growth, and death of individual trees as a mixture of deterministic and stochastic processes within small—often $^1/_{12}$ ha—patches and average the actual forest succession at the ecosystem level from the successional patterns simulated for many individual plots (Shugart, 1984). Earlier work on the potential effects of climatic change on forests had to rely on spatial correlations between forest composition and climatic variables (e.g., Davis, 1986). Similarly, models that do not explicitly account for the differential effects of climatic change on different species may give optimistic projections of the effect of climatic change on ecosystem productivity. The more complex succession models that include the feedbacks between climate and ecosystem processes provide a more pessimistic outlook (see Figure 1–2).

On the other hand, most of these models do not include direct effects of increasing CO_2 concentration, which can ameliorate projected forest decline (e.g., Post *et al*., 1992). Also, because of the limited availability of data on the fundamental niche of most species, these models are parameterized with information about the realized niche only (Austin, 1992). It has been argued that this might cause succession models to overestimate the extent of forest decline during the transient phase (e.g., Malanson *et al*., 1992). Despite these caveats, patch models are the best tools currently available to study transient effects during climatic and other changes. Their simulations for current forests in response to past climatic changes provide fairly realistic assessments of likely future conditions (e.g., Solomon and Bartlein, 1992; Bugmann, 1994), although they cannot be interpreted as actual forecasts.
Figure 1-2: Transient response in species compositions simulated by the model FORCLIM-E/P (Bugmann, 1994; Fischlin *et al*., 1995) at a site in Switzerland (47.5°N/8.5°E) under current climatic conditions (years 0–800) and under a scenario of climatic change derived from output of the GFDL GCM (years 900–1,800). A linear change of climatic parameters was assumed for the years 800–900. The graph shows the average cumulative biomass from 200 simulation runs (after Bugmann and Fischlin, 1996).

1992) or biospheric carbon storage (e.g., Solomon *et al*., 1993) and to compare the simulated patterns with the present vegetation as provided by the few available global databases (Matthews, 1983; Olson *et al*., 1983); see Figures 1-3, 1-5 (top), 1-6 (top), and 1-7 (top). Although these models are at an early stage of development (Leemans *et al*., 1995), there is good statistical agreement between simulated and observed distributions of vegetation classes (e.g., Prentice *et al*., 1992), except in areas where agriculture dominates. Although global models never can be strictly validated, their recent development toward inclusion of improved bioclimatic driving variables and mechanistic response functions offers increasing confidence in the magnitude of the results they generate. More

about the nature and limitations of these models can also be found in Chapter 15.

The more recent models, such as BIOME (Prentice *et al*., 1992), MAPSS (Neilson *et al*., 1992), or TVM from IMAGE 2.0 (Leemans and van den Born, 1994), all attempt to simulate vegetation distribution considering ecophysiological traits and their relationship to particular climatic variables. This makes it possible to generate projections of vegetation distributions under past (Prentice, 1992; Prentice *et al*., 1994; Figure 1-4), present [Prentice *et al*., 1992; Neilson, 1993; Solomon *et al*., 1993; Prentice and Sykes, 1995; Figures 1-5 (top), 1-6 (top), and 1-7 (top)], or future climates [Cramer and Solomon, 1993;

Leemans and Solomon, 1993; Neilson, 1993; Solomon *et al.*, 1993; Leemans *et al.*, 1995; Figures 1-5 (bottom), 1-6 (bottom), and 1-7 (middle)]. Apart from being used for climate-change impact assessment studies, they are now also used as a dynamic representation of the land surface for sensitivity studies of GCMs (see Claussen, 1994; Claussen and Esch, 1994; Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, in the Working Group I volume).

The models differ in their emphasis on particular processes and relationships (Leemans *et al.*, 1995). For example, BIOME (Prentice *et al.*, 1992) includes physiologically important aspects such as seasonality and moisture balance, and is based on PFTs, which to some extent simulate interspecific competition. MAPSS, on the other hand, couples the rate of transpiration to the conductance of the canopy by simulating maximum leaf-area index and stomatal conductance (Neilson *et al.*, 1994; Neilson and Marks, 1994). The latter makes it possible to incorporate ecophysiological responses such as CO_2 fertilization and WUE, but all species-specific information is lumped. These models use somewhat different vegetation classification schemes [e.g., compare Prentice *et al.* (1992) and Neilson (1993)], which usually makes direct comparisons possible only if some classes are aggregated (compare Figures 1-5 to 1-7 and Table 1-2 with Prentice *et al.*, 1992; Neilson, 1993; or Leemans and van den Born, 1994). Consequently, the vegetation distributions projected for a changed climate may differ substantially (Table 1-2).

One of these models, IMAGE 2.0, also has been used to incorporate the effect of climate change superimposed to the impacts of land-use changes (Alcamo, 1994; Figure 1-7). Its vegetation part (Leemans and van den Born, 1994) makes it possible to assess global forest distributions for the present [Figure 1-7 (top)] as well as the future [e.g., according to the conventional wisdom scenario of Figure 1-7 (middle and bottom)]. However, the potential natural vegetation is essentially modeled in a manner similar to BIOME (Prentice *et al.*, 1992).[2]

Although none of these models deals with transient forest responses, they offer the advantage of providing quantitative estimates for changes in a future climate on the scale of the distinguishable vegetation classes (Table 1-2; Figures 1-3 to 1-7). Due to the limited range of vegetation classes—BIOME and IMAGE, for instance, distinguish 20 (Prentice *et al.*, 1992; Leemans and van den Born, 1994; Prentice *et al.*, 1994); MAPSS distinguishes 33 (Neilson, 1993)—the projected changes (Table 1-2) tend to underestimate actual changes. Changes within a class remain by definition undetected and would have to be modeled by means of more detailed vegetation models.

The total area currently forested is likely to change significantly, if the changes occur according to any of the three models, from its present to a new vegetation class (Table 1-2, D). These estimates range from small changes [e.g., 7.5% (tropical rain forest)] to large ones [e.g., 65.1% (boreal forest)]—both estimated using the BIOME model. Net changes (Table 1-2, D*)— that is, the difference between the total forested area in the future versus the current climate—range from losses of 50.0% (IMAGE/TVM—tropical dry forest) to gains as large as 22.2% (MAPSS—tropical dry forest).

Except for MAPSS in the version shown here (i.e., without considering the partially compensating, increased WUE; Neilson and Marks, 1994), for the tropical zone models project a net

---

[2] More information about this class of biosphere models can be found in Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, in the Working Group I volume, and in Chapters 15 and 24 of this volume.

Table 1-2: *Likely changes in forested areas (Mha) within four biogeographical zones according to three different vegetation models: BIOME (Prentice et al., 1992), MAPSS (Neilson, 1993), and terrestrial vegetation model (TVM) (Leemans and van den Born, 1994) from IMAGE 2.0 (Alcamo, 1994).*

Boreal	952	511	-379	1231	1117	-529	42	1128	-33	40.4	-17.1

Notes: The first two models are used with a 2 x CO_2 equilibrium climate-change scenario generated by the GFDL GCM (Wetherald and Manabe, 1986). TVM from IMAGE 2.0 generated the changed climate internally, based on comparable assumptions (Conventional Wisdom Scenario) about greenhouse gas concentrations (Alcamo, 1994) and land-use changes as driven by population developments. All numbers relate to a potential forest vegetation in equilibrium with the climate, a steady state that is unlikely to be reached for many centuries. All figures were compiled by using the maximum number of vegetation classes as supported by the models (i.e., more than the 10 classes shown in Figures 1-3 to 1-7). D = Total forested area in transition from current type into a new one; s_o = Total forested area remaining within the same vegetation class; D* = Net change (data compiled by R. Leemans). The last two columns show means over all models as percentages of the currently forested area.

Figure 1-5: Present (top) and future (bottom) potential natural vegetation according to the BIOME model (Prentice *et al*., 1992; Prentice *et al*., 1994). The present climate is given by the IIASA climate database (Leemans and Cramer, 1991). The projected shifts in the boundaries of the vegetation classes are due to climatic changes as projected by the difference between a GFDL GCM control run and a 2 x CO_2 scenario (Wetherald and Manabe, 1986). They represent responses of plant functional types to cold tolerance, chilling requirements, and heat and water requirements of global vegetation (Solomon *et al*., 1993; Prentice and Sykes, 1995).

gain in the potential area of forest distribution. Mainly IMAGE-TVM projects large net losses in the tropical rainforests. These losses are not due to climatic change, however, but are mainly caused by deforestation and other land-use changes (Zuidema *et al*., 1994).

Although BIOME and MAPSS indicate relatively small net changes (Table 1-2, D*) in tropical dry forests, the actual changes encompass large gross losses (D), which are compensated by similarly large gross gains (not shown in Table 1-2). This is also partly true for the temperate zone, where MAPSS, for example, projects only relatively small net losses (D*); however, the associated gross losses (D) irrespective of gains (not shown) are more than six times larger. Mapped distributions indicate that temperate forests are likely to replace a large area of boreal forest, mainly due to the increase in winter temperatures (Figures 1-5 and 1-6). This allows temperate-zone vegetation to expand poleward into regions from which it is currently excluded by the -40°C threshold for the coldest month (Figures 1-5, 1-6, and 1-7).

The boreal regions, especially, are expected to undergo large vegetation shifts, with both MAPSS and BIOME projecting large changing areas (Table 1-2, D). Both models show large losses in area for current boreal forests, despite their encroachment into current tundra. Shrinkage in total area due to the geographically limited poleward shift leads to a net loss between 379 Mha (25.9%) and 529 Mha (22.5%).[3] The IMAGE model is an exception in this case; it projects much smaller losses of only 33 Mha (2.9%) (Figures 1-5, 1-6, and 1-7). This is mainly due to the structure of the model, in which vegetation change is primarily driven by human land use—which is not an important factor in the boreal zone.

In summary, all models suggest that the world's forests are likely to undergo major changes in the future, affecting more than a third of tropical dry (37.2%), temperate (35.7%), and boreal (40.4%) forests. Except in the temperate zone, the models suggest that there may be a net loss of forest area (Table 1-2, %D*).

Figure 1-7: Present (top), future (middle), and differing (bottom) potential natural vegetation influenced by human land use as generated by the terrestrial vegetation module (TVM; Leemans and van den Born, 1994) from the integrated climate change assessment model IMAGE 2.0 (Alcamo, 1994). The areas shown represent a projection starting with the year 1970 (top) and the internal, dynamic changes calculated by IMAGE 2.0 by the year 2050 (middle). The bottom graphic shows the new class for all areas that are predicted to change from one to another vegetation class. The simulation results generated by IMAGE 2.0 incorporate the effect of land-use changes (e.g., deforestation) as driven by the dynamics of human populations and economic development. Note that IMAGE 2.0, unlike the other models, simulates climatic change independently from a GCM, since it generates its climate internally. The vegetational part (Leemans and van den Born, 1994) of the IMAGE model is similar to BIOME (Prentice *et al*., 1992) and represents a mixture between a transient and a static response of vegetation to internally as well as externally generated changes.

Averaged over all zones, this net loss amounts to 9.1% of the currently forested area. This is partly due to the fact that some regions are likely to lose forests for climatic reasons, while climatic gains in other regions might not be realized due to land-use pressures (IMAGE), and some models even predict a net loss (MAPSS). Averaged over all zones and all models, the projections indicate that 33% of the currently forested area is likely to change from the current vegetation class to a new one in response to climate forcing as generated by the GFDL 2 x CO_2 scenario. Compared with other GCMs, the latter represents a medium global warming scenario.

All models tend to underestimate potential changes, since they model only transitions among a limited number of vegetation classes. More importantly, as equilibrium models, none of them reflects the asymmetry between a temporary loss and the subsequent, much slower regrowth of forests in a new climate (see Section 1.3.3).

1.3.5. *Past and Future Species Migration Rates*

Shifts in the distribution of forest zones take place with significant time lags. The area occupied by different forest types has been quite plastic in the past 100,000 years, responding to changing environments with changes in species associations, structural properties of stands, and areas occupied (Solomon and Webb III, 1985; Webb III and Bartlein, 1992). Unlike the Pleistocene climatic changes, which occurred over thousands of years, future climatic changes of about the same magnitude are expected to take place over 100 years or less.

The change in annual mean temperature that occurs when one moves 100 km poleward may be as high as 0.7°C in mid- and high latitudes, but less at low latitudes. For summer temperatures and toward the interior of the continents, this value may be higher. With altitude, temperature changes of about 0.5–0.7°C per 100 m are also common (see also Chapter 5). With an expected warming between 0.1 and 0.35°C per decade, this means that species would have to migrate 1.5–5.5 km toward the poles per year or increase elevation by 1.5–5.5 m per year in order to remain within similar climatic conditions. Many studies of past changes have estimated natural rates of migrations of trees ranging from 40 to 500 m per year (Davis, 1976, 1981, 1986; Huntley and Birks, 1983; Solomon *et al*., 1984; Gear and Huntley, 1991; Torii, 1991). Similarly, Gear and Huntley (1991) calculated from several sites in Britain migration rates for Scots pine of only 40–80 m yr[-1]. However, for other species, such as white spruce, much faster dispersal rates of up to 1–2 km yr[-1] also have been reported (e.g., Ritchie and MacDonald, 1986). It is not always clear whether the observed past rates were maximal rates of migration or whether they were limited by the rate at which the climate

---

[3] The apparent lack of coincidence between relative and absolute changes is due to different definitions of the vegetation class "boreal forest." The MAPSS model has a greater area characterized as boreal forest than the BIOME model.

changed (Prentice *et al*., 1991a; Prentice, 1992). Nevertheless, it is unlikely that future rates of species migration could match those required by the currently expected rates of climatic change in large areas. Pollen, on the other hand, may be dispersed much faster than seeds (e.g., Ennos, 1994), so the movement of genes of different ecotypes within a species might be able to match the speed of climatic change.

Migration of a tree species involves movement of propagules to new locations, establishment of seedlings, growth of individuals to reproductive maturity (which may take from years to decades), and production of new propagules. For long-distance migration, these stages need to be repeated. Several bottlenecks may be encountered: Strong competitors along the route may suppress the completion of full life cycles or specific, mandatory biological symbionts [e.g., the right species of mycorrhizal fungi (Perry *et al*., 1987, 1990)], or specific pollinators for cross-fertilization may be absent at some point. Seed production, in particular, often depends on a phased sequence of development over at least 2 years, including many steps from floral bud differentiation to seed ripening (Fenner, 1991). Many stages in this sequence could be disrupted by unsuitable climatic conditions (Innes, 1994): With further warming, some species may fail to be chilled sufficiently to release dormancy (Murray *et al*., 1989; Cannell, 1990), or dormancy may be released too early, which paradoxically could result under some circumstances in greater frost damage (Hänninen, 1991). Conversely, many trees flower profusely following hot, dry conditions (Stern and Roche, 1974). Hence, differential seed production by different species may limit rates of migration and drive substantial changes in species distributions.

Since each stage of a tree's life cycle requires specific environmental conditions, rapid climatic change is less likely to offer sufficiently favorable conditions to complete complex life cycles. This is especially true for some slow-growing species. More flexible species, such as those with wider seed dispersal, or a more invasive growth habit, may be able to move to more favorable habitats, whereas less mobile species are likely to be left behind and would be at a disadvantage as their former habitat becomes climatically unsuitable. Such a decoupling of climate determinants from species and community distributions probably has occurred already many times and at many places during the last millennia (Davis, 1986). The result has been a temporary absence of certain species for hundreds and thousands of years from regions in which they were previously capable of growing. Despite this, species diversity also could be transiently enhanced during a time of change because forests might form a richer mosaic of patches, consisting of some remaining old trees and a variety of invaders that are successful because of locally more favorable conditions.

In the future, human activities may to a certain extent enhance the migration of certain species, especially that of commercially important ones. On the other hand, natural migration of all other forest species will be further hampered by the fragmentation of natural habitats by human infrastructure, farmland, or exotic tree plantations, especially at mid-latitudes.

1.3.6.   *Biodiversity*

To date, only about 1.4–1.7 million of an estimated total of 5–30 million species have been scientifically described (Wilson, 1985, 1992; May, 1990; Ehrlich and Wilson, 1991; Erwin, 1991; Gaston, 1991; Pimm *et al*., 1995), and fewer than 100,000 are known well (e.g., Wilson, 1988; Pimm *et al*., 1995). About 20% of the estimated total of 250,000 plant species are woody or tree species (e.g., Groombridge, 1992; Reid, 1992; Pimm *et al*., 1995). There is poor understanding of the factors responsible for maintenance of high biodiversity (e.g., Grubb, 1977; Stork, 1988; Groombridge, 1992; Norton and Ulanowicz, 1992; Myers, 1995; Pimm *et al*., 1995), but it is understood that biodiversity can only be managed indirectly through habitat and ecosystem management (e.g., Wilson, 1992). In this respect, forests are of paramount importance because they harbor about two-thirds of all species on Earth (Ehrlich and Wilson, 1991); tropical forests alone harbor at least half of all species (Raven, 1988; Ehrlich and Wilson, 1991; Webb, 1995). Species diversity generally increases strongly as one moves from colder to warmer sites (e.g., Groombridge, 1992), although the reasons for that trend are not well understood. When the size of an ecosystem is reduced to about 10% of its former size, about 50% of the species originally present generally will become extinct. Based on that relationship, it has been estimated, for instance, that a temperature rise of 2°C would cause 10–50% of the animals currently extant in the boreal Great Basin mountain ranges to be lost (Dobson *et al*., 1989).

Climatic change can affect biodiversity either directly through altering the physiological responses of species or indirectly by altering interspecific relationships (e.g., Woodward, 1987; Tallis, 1990; Peters and Lovejoy, 1992). Whenever these changes lead to a habitat degradation, biodiversity will eventually be adversely affected (e.g., Peters and Lovejoy, 1992; Vitousek, 1994). Furthermore, biodiversity is affected not only by climate change but also by deforestation and other land-use changes that cause further habitat degradation and fragmentation (Janzen, 1988; Dobson *et al*., 1989; Wilson, 1989; Ehrlich and Wilson, 1991; Myers, 1991, 1993; Postel, 1994; Daily, 1995; Pimm *et al*., 1995). The combination of climate change with other pressures on ecosystems produces a particularly significant threat to biodiversity due to the following reasons:

- Climate change, together with other causes of habitat degradation, may locally decrease species diversity (Peters and Darling, 1985; Romme, 1991; Myers, 1992; Peters, 1992; Daily, 1995; Pimm *et al*., 1995; Rind, 1995). Disturbance also may create opportunities for opportunistic or pioneer species, which will become more abundant (Myers, 1993) and, over time, replace many species that are slower growing and require more stable conditions. In some cases, this may lead to a temporary increase in species diversity (e.g., Lugo, 1988; Mooney, 1988; Vitousek, 1988).
- Species may become permanently extinct when local extinction cannot be reversed by reimmigration from

surrounding areas. This problem would be most severe where the climate in a species' reserve changes from being favorable to being completely unsuitable (Peters, 1992), rendering "sanctuaries" into "traps" (Myers, 1993). Thus, an increasing fragmentation of habitats in combination with climate change may cause significant and irreversible species loss, a situation with which many of the current policies on reserves have large difficulties coping adequately (Ehrlich and Wilson, 1991; Botkin and Nisbet, 1992; Franklin *et al.*, 1992; Myers, 1992; Peters, 1992).

Although the effects of climatic change on biodiversity are still poorly understood, many authors anticipate a significant loss of species due to climatic change (e.g., Peters and Lovejoy, 1992; Reid, 1992; Myers, 1993; Vitousek, 1994). Due to its permanency, this must be considered as one of the most important impacts of climate change, not only in economic terms (e.g., Daily, 1995) but also in terms of all other utilitarian and spiritual values that have been attributed to species (e.g., Ehrlich and Wilson, 1991; Sharma *et al.*, 1992; Myers, 1993).

1.3.7. Adaptation

Forests themselves may to some extent acclimate or adapt to new climatic conditions, as evidenced by the ability of some species to thrive outside their natural ranges. Also, elevated CO_2 levels may enable plants to use water and nutrients more efficiently (e.g., Luo *et al.*, 1994). Nevertheless (see Sections 1.3.3 and 1.3.5), the speed and magnitude of climate change are likely to be too great to avoid some forest decline by the time of a CO_2 doubling.

Consideration may therefore be given to human actions that minimize undesirable impacts. Special attention may be given to poor dispersers, specialists, species with small populations, endemic species with a restricted range, peripheral species, those that are genetically impoverished, or those that have important ecosystem functions (Peters and Darling, 1985; Franklin, 1988; Davis and Zabinski, 1992; Franklin *et al.*, 1992). These species may be assisted for a time by providing natural migration corridors (e.g., by erecting reserves of a north–south orientation), but many may eventually require assisted migration to keep up with the speed with which their suitable habitats move with climate change. Some mature forests may be assisted by setting aside reserves at the poleward border of their range, especially if they encompass diverse altitudes, and water and nutrient regimes (Botkin and Nisbet, 1992; Peters, 1992; Myers, 1993), or by lessening pollutant stresses and land-use changes that result in forest degradation (e.g., Vitousek, 1994; Daily, 1995).

1.4. Tropical Forests

1.4.1. Characterization and Key Limitations

Tropical forests cover about 1,900 Mha (FAO, 1993a) and are found between 25°N and 25°S. They are distributed over five continents and are situated mainly in developing countries.

Box 1-5. Tropical Forests and Land-Use Changes

Tropical forests are endangered more by land-use practices than by gradual climatic change. Already at present much of the tropical forest is affected by deforestation due to land conversion and resource use (UNESCO, 1978; FAO, 1982; Brown *et al.*, 1993; Dixon *et al.*, 1994). Such anthropogenic tropical forest disturbances are expected to continue in response to economic development, population growth, and the associated need for agricultural land (DENR-ADB, 1990; Starke, 1994; Zuidema *et al.*, 1994).

Tropical rainforests have been cleared for agriculture since at least 3,000 BP in Africa and 7,000 BP in India and Papua New Guinea (Flenley, 1979). Africa has lost at least 50% of its rainforest, while tropical America and Asia have lost at least 40% (Mabberley, 1992). In addition to deforestation, large areas of previously undisturbed forest are being affected by removal of wood for timber and fuel (Brown *et al.*, 1993; Richards and Flint, 1994). Chapter 24 presents a detailed account of these deforestation trends in tropical forests.

The influence of tropical forests on local and regional climate may be as important as the effects of climate on forests (Lean and Warrilow, 1989). About 20% of the water flux to the atmosphere derives from evapotranspiration from the land, mostly from forested areas with high annual rainfall (Westall and Stumm, 1980; Lean and Warrilow, 1989). Deforestation can significantly reduce global evapotranspiration and increase runoff. This could affect the amount and distribution of precipitation over wide areas (Salati and Jose, 1984). For instance, in the Amazon basin, at least 50% of precipitation originates from evapotranspiration from within the basin (Salati *et al.*, 1979; Salati and Jose, 1984). Deforestation there will reduce evapotranspiration, which could reduce precipitation by about 20%—producing a seasonal dry period and increasing local surface temperatures by 2°C (Gash and Shuttleworth, 1991). This could result in a decline in the area of wet tropical rainforests and their permanent replacement by floristically poorer drought-deciduous or dry tropical forests or woodlands.

The forests consist of rainforests, drought-deciduous forests, and dry forests. In areas with prolonged dry seasons, especially where water limitations are intensified by edaphic conditions (Cole, 1986), there are savannas (Richards, 1966; Odum, 1971; Borota, 1991). Evergreen or partially deciduous forests occur in areas with a mean annual temperature greater than 24°C and with high regular rainfall throughout the year. Most of the closed tropical forests are found in the moist and wet zones, with precipitation to potential evapotranspiration ratios of 1–2 and greater than 2, respectively. The dry zone, with a ratio of precipitation to potential evapotranspiration of less than 1, covers about 40% of the total tropical region. In most of these forests, typical monthly temperatures fall between 24 and 28°C; daily extremes rarely exceed 38°C or fall below 10°C (Longman and Jenik, 1987).

Tropical forests represent about 40% of the world's forested area, containing about 60% of the global forest biomass and one-quarter of total soil carbon (210 Gt C in biomass and 220 Gt C in soils and litter) (FAO, 1982; Longman and Jenik, 1987; Brown *et al.*, 1993; Dixon *et al.*, 1994). Tropical forests cover only 6% of the world's surface but contain about half of all plant and animal species of the world (Bierregaard *et al.*, 1992; Mabberley, 1992; Riede, 1993). Thousands of species in tropical forests are utilized by humans. It is of particular concern that tropical forests are currently being clear-cut, burned, or otherwise degraded by human activity (see Box 1-5).

An important characteristic of tropical forests is that they maintain a tightly closed nutrient cycle and often grow on a mass of very infertile soil, in which only the uppermost few centimeters have substantial amounts of plant-available nutrients. Phosphorus is generally the main limiting nutrient (Jordan, 1985). Therefore, any disturbance that results in loss of nutrients due to leaching, erosion, or timber harvesting can result in decreased growth rates, biomass, and diversity (Whitmore, 1984; Jordan, 1985; Vitousek and Sanford, 1986).

Fire significantly influences the structure, composition, and age diversity of tropical forests. In dry forests, fires tend to be frequent, which excludes fire-sensitive species. In tropical rainforest, fire is usually rare and does not usually spread over wide areas because there is insufficient dry and flammable plant material (Chandler *et al.*, 1983a, 1983b). However, there have been instances in the past when thousands of hectares of tropical rainforest were burned following long dry periods (Goldammer and Seibert, 1990; Goldammer, 1992). Such fires are likely to significantly affect species diversity (Goldammer and Seibert, 1990) and may help prevent forest deterioration by promoting new growth and regrowth (Goldammer and Peñafiel, 1990).

Strong winds associated with tropical cyclones in tropical Asia, Central America, and northern Australia can profoundly influence the structure and floristic composition of forests (Whitmore, 1974; Hartshorn, 1978; Lugo *et al.*, 1983; Longman and Jenik, 1987; DENR-ADB, 1990; Mabberley, 1992; O'Brien *et al.*, 1992). Strong winds frequently damage

tree canopies, create gaps in the forest, and modify the forest structure and micrometeorological environment. This may increase litter quality, allow more radiation to reach the forest floor, increase soil temperature, and make more soil water and nutrients available, which could promote the growth of new vegetation (Waring and Schlesinger, 1985).

1.4.2. Projected Climatic Changes

The climatic changes projected for the regions covered with tropical forest over the period 1990–2050 are increases in temperature of around 0.5–1.0°C, with no general change in seasonal amplitude; an increase in rainfall averaged over the region but with highly uncertain regional shifts in rainfall (differing greatly among GCMs), in the range -40% to +60%; and uncertain increases or decreases in soil water content (Greco *et al.*, 1994). These projections imply the potential for an increased occurrence of droughts in some regions and floods in others.

We also must consider the possibility of changes in the frequency of ENSO (El Niño Southern Oscillation; see Glossary) events, which may increase rainfall seasonality in semi-tropical regions and could lead to a longer dry season in some areas and bring more rains in other places. Fire frequencies may increase in some areas in association with drought (Rind *et al.*, 1990). Fires may further reduce local precipitation because fire-emitted aerosols increase the number of cloud condensation nuclei, producing smaller cloud droplets that are less likely to fall as rain (Andreae and Goldammer, 1992).

1.4.3. Impacts of Climate and Land-Use Changes

1.4.3.1. Forest Area, Distribution, and Productivity

All forests are expected to experience more frequent disturbance, with greater and possibly permanent impacts, such as increased soil erosion, and other forms of degradation and nutrient depletion. A study of 54 countries suggested that, between 1990 and 2050, a further 660 Mha are likely to be deforested, reducing the 1990 area by one-third and releasing 41–77 Gt C (Trexler and Haugen, 1995; see also Chapter 24). Rates of deforestation eventually must decrease as less and less of the original forest remains. There are, however, proposals to slow the loss of tropical forests (e.g., Deutscher Bundestag, 1990; UNCED, 1992), and many nations have large-scale plans for the protection or restoration of their forests (e.g., Brazil, India, and China: Winjum *et al.*, 1993).

Global vegetation models do not agree on whether climatic change (in the absence of land-use change) will increase or decrease the total area of tropical forests (depending on the calculation of transpiration and vegetation properties; see Section 1.3.4), but any major shifts in rainfall pattern due to climate and land-use change are certain to change the present distribution of vegetation types within and among biomes (Neilson, 1993). Henderson-Sellers and McGuffie (1994) show that in an

enhanced-CO_2 climatic regime, tropical evergreen broadleaf forests could readily re-establish after deforestation. In some areas, decreased rainfall may accelerate the loss of dry forests to savanna, while in others, increased rainfall and increased water-use efficiency with elevated CO_2 may favor the expansion of forests and agroforestry. In both cases, the outcome will be strongly influenced by human activities. Overall, shifts in rain-fall patterns in the tropics could increase the rate of conversion of forests to agricultural land by increasing human migration from areas affected by droughts, erosion, or other forms of land degradation to non-degraded and more productive forest land.

The productivities of different areas of tropical forest are likely to increase or decrease in accordance with changes in rainfall, as indicated by simulation studies (Raich *et al*., 1991). The overall effect of predicted changes in climate (excluding elevated CO_2) on the net primary productivity of tropical evergreen forests may be a decrease due to increased temperature and con-sequently increased respiration (in the absence of acclimation) and decreased photosynthesis due to increased cloudiness, but elevated CO_2 levels may cause an increase in productivity (in contrast to boreal regions) unless limited by phosphorus supply (Melillo *et al*., 1993). CO_2 enhancement of photosynthesis and growth, particularly below ground (e.g., Norby *et al*., 1986, 1992; Luxmoore *et al*., 1993), is favored by high temperatures in species with C_3 photosynthesis (i.e., in trees) (Long, 1991; Kirschbaum, 1994) and possibly by vegetation disturbance and consequent fast nutrient cycling (Peterson and Melillo, 1985). This is also consistent with studies of the spatial distribution of CO_2 concentrations across the globe, which also suggest that the tropics constitute a biospheric sink that partially offsets the carbon release due to deforestation (Enting and Mansbridge, 1991; Schimel *et al*., 1995). An alternative view is that elevated CO_2 levels will accelerate carbon and nutrient cycles in tropical ecosystems without increasing growth and biomass (Körner and Arnone, 1992). Researchers are agreed, however, that increased water-use efficiency by plants in response to elevated CO_2 is likely to enhance the productivity of vegetation in the drier trop-ical regions.

Land-use change is obviously the greatest threat to species diversity of tropical forests, but Cramer and Leemans (1993) speculate that climatic change alone could decrease the diver-sity of plant types at the boundaries of biomes, particularly in the tropics. Losses are likely to be greatest where the pres-sures of population and socioeconomic forces are greatest and least controlled (see also Section 1.3.6).

1.4.3.2.   Temperature

In general, temperatures in non-montane tropical regions are already high enough for rapid growth year round, and a 2°–3°C increase in temperature alone will have a marginal effect on rates of photosynthesis, growth, decomposition, and nutrient cycling. However, if plants experience temperatures above 35°–40°C over extended periods, especially in combi-nation with water shortage, tissue damage from desiccation

and sunscald can occur (Fitter and Hay, 1987). In drier areas, the severity and duration of dry spells could be aggravated by increasing temperature. Also, some species sustain damage from temperatures below 10°–12°C or even below 15°–20°C, and there may be some limited future expansion of those species into regions from which they are currently excluded by cool temperatures (e.g., Smith *et al*., 1992b).

1.4.3.3.   Water

In the semi-arid tropical regions, climate-induced desertifica-tion will be a critical issue if precipitation decreases (Mitchell *et al*., 1990; Greco *et al*., 1994). Seasonally dry deciduous forests could burn more frequently and be permanently replaced with thorn scrub or savannah vegetation. It should be noted that changes in forest cover can have effects on ground-water supplies, surface runoff, sedimentation, and river flows (Brooks *et al*., 1991), with potentially serious socioeconomic effects (see also Chapter 5). Also, hydrological changes that include shifts in atmospheric circulation could threaten the survival of cloud forests.

Some evergreen species of the humid forest clearly will be at a disadvantage in those areas that experience more severe and prolonged droughts. Significantly, drought affects the survival of individuals: Those without morphological or physiological adaptations to drought often die. In contrast, an abundance of moisture (in the absence of flooding) more often acts through changed competitive ability. Drought-adapted species are out-competed by those that lack growth-limiting drought-adaptive traits. Species in moist tropical forests, including economically important hardwoods, are the least drought-adapted in the trop-ics, and their survival (with the attendant loss in diversity) in some areas must be considered at risk from climatic change.

1.4.3.4.   Soil Nutrients

Climatic change (including elevated CO_2 levels) could enhance the supply of nutrients to plants in the tropics by, for instance, increasing root and mycorrhizal growth and thereby increasing access to soil phosphorus and enhancing nitrogen fixation by legumes, which are abundant in the tropics. On the other hand, the more important considerations are likely to be nutrient leaching and soil erosion wherever tree cover is lost (because of droughts or fire) or removed (by logging, clearing, or graz-ing)—especially where high-rainfall events occur in hilly areas—and immobilization of nutrients in soil organic matter in response to elevated CO_2.

1.4.3.5.   Pests and Pathogens

Tropical rainforests contain large numbers of insects and pathogens that can cause serious damage to some plant species and may play a role in regulating species diversity (Coley, 1983). Many factors have been associated with the susceptibility of

tropical plants to pests and diseases and with the virility of pests and pathogens. Some of these factors include suboptimal climate, availability of water and nutrients, and the presence of secondary metabolites that act as defensive compounds (Lambert and Turner, 1977; Levitt, 1980a, 1980b; Mattson, 1980; Mattson and Haack, 1987; Jones and Coleman, 1991). Drought stress can sometimes increase host plant suitability due to increases in soluble nitrogen and sucrose (White, 1974), whereas high temperatures and humidities (> 30°C and relative humidity of 50–90%) can decrease the growth rate, survival, and fecundity of some insects (Wilson *et al*., 1982). Consequently, there is still great uncertainty as to whether the impacts of climate change on the relationship between host plants and pests and pathogens will lead to forest loss or gain.

However, the diversity of species in most tropical forests appears to confer some protection against widespread outbreaks of pests and diseases. The low population density of potential hosts prevents the rapid multiplication and spread of pests and pathogens (Longman and Jenik, 1987). Hence, most cases of debilitating outbreaks of pests and diseases—which can, for instance, affect entire stocks of some mahoganies— occur in plantations, agroforests, or stands that are dominated by one species (UNESCO, 1978).

1.4.3.6.   Fire and Wind

It is clear from recent events that wherever there are more droughts, there will be more fires due to the accumulation of more combustible dry organic matter, with major potential economic costs in highly populated areas. In the extreme, recurrent fires will lead to the permanent loss of fire-prone species and the invasion and maintenance of fire-resistant species such as savanna vegetation. Fires, together with the action of wind—especially in regions where storms are frequent—will increase the dominance of pioneer species, including vines and herbs, preventing forests from developing to maturity.

1.5.   Temperate Forests

1.5.1.   Characterization

Temperate forests occur approximately from 25–50° N and S and are found primarily in developed countries in discontinuous blocks on five continents, sharing the landscape with agricultural land and urban areas. Closed forests originally covered about 1,400 Mha but have been reduced to about 700 Mha, 56% of which is in North America and 24% in Europe (see Chapter 15). Humans have had an impact on almost all of these forests; about 20% are managed for wood production or other uses, and many are being affected by pollutants, with both potentially positive and some obvious negative effects on growth (Innes, 1993).

These forests contain broadleaved and needle-leaved species that may be evergreen or deciduous. The most extensive types of temperate forests are the northern deciduous forests, commonly dominated by members of the *Fagaceae*, with leaf-shedding as an adaptation to winter frosts; the temperate coniferous forests of Europe, western and southeastern North America, and eastern Asia; warm evergreen forests in Australia dominated by *Eucalyptus* species; and other forests in the Southern Hemisphere dominated by *Nothofagus* species.

Temperate forests occur within a range of mean annual temperatures of 6–17°C, where average total precipitation exceeds 500 mm, with broad transition zones to boreal and subtropical forests. Within any region there are often steep gradients in forest types along climate gradients of rainfall and temperature, with change in altitude, and from oceanic to continental areas. At the low-rainfall margin, temperate forests change into savanna-type woodlands or Mediterranean shrublands. Temperate forests exist on a wide range of soils and have diverse ecological properties (Ellenberg, 1971; Bormann and Likens, 1979; Reichle, 1981; Edmonds, 1982).

The standing biomass and carbon content of temperate forests is currently increasing (at 0.2–0.5 Gt C yr^{-1}), largely due to reforestation (about 0.6 Mha yr^{-1}), underharvesting and regrowth after wood removal during the 19th and early 20th centuries (Armentano and Ralston, 1980; Heath *et al*., 1993; Kurz and Apps, 1993; Sedjo, 1993; Sundquist, 1993; Dixon *et al*., 1994; Galinski and Küppers, 1994; Kohlmaier *et al*., 1995), and mainly fertilization effects of nitrogen deposition (Kauppi *et al*., 1992). The temperate forests therefore are considered to be a carbon sink (Heath *et al*., 1993). However, if the loss of carbon from decaying forest products and logging debris is taken into account, the net flux of carbon to the atmosphere from northern temperate forests is close to zero (Houghton, 1993) and, in the coming century, increased demand for wood may change the temperate forests to a net carbon source (Heath *et al*., 1993).

Forest fires occur in most seasonally dry forests, despite control measures, and play an important role in ecosystem dynamics in these forests, especially in parts of North America, Australia, and Mediterranean Europe (Kozlowski and Ahlgren, 1974; Gill *et al*., 1981; Goldammer and Jenkins, 1990). Fire affects species distribution by favoring fire-resistant species at the expense of those more sensitive to fire. Fire also creates conditions conducive to the establishment of new seedlings.

1.5.2.   Key Limitations

The ranges and growth of temperate tree species in wetter, maritime, and high-latitude regions often can be related to the length of the growing season, measured in degree-days, and to absolute minimum temperatures in more continental areas. The temperature niches of individual species are often narrow (Figure 1-1) and are commonly determined by critical thermal requirements of the reproductive cycle (e.g., Pigott and Huntley, 1981).

In drier regions closer to the equator, the existence and growth of temperate forests are controlled largely by water availability. Variation in leaf-area indices and ring widths often is related to available water (Gholz, 1982). A minimum ratio of actual to potential evapotranspiration of approximately 0.65 is considered necessary to support the growth and regeneration of temperate-zone trees (Prentice *et al*., 1992). Slight shifts to smaller ratios lead to open woodlands, savannahs, and grasslands. Soil water availability also strongly influences forest density, leaf area, growth, and standing biomass.

Seedling establishment is most vulnerable to shifts in precipitation patterns or amounts. Most temperate-zone seedlings can survive and become established only within narrow limits of soil moisture and sunlight. Slight changes in soil moisture can lead to the loss of a season's seedling crop, although losses in tree establishment cohorts may not lead to changes in forest structure for decades.

Like high-latitude populations experiencing low temperature, mid-latitude populations that are often subject to low soil water availability may be very plastic in their response to environmental variation. This plasticity enables temperate-zone trees to survive most weather variations that may be encountered only once every 200 years (Bugmann, 1994). Reproduction at these locations may be possible if conditions in rare years are favorable for the species' reproductive requirements (Pigott and Huntley, 1981).

1.5.3. *Projected Climatic Changes*

The climatic changes projected for most of the temperate forest region over the period 1990–2050 are increases in both summer and winter temperatures of 1–2°C; regional changes in precipitation in summer and winter, mostly in the ±20% range; and drier soils in summer (mostly with 2–8 mm less water) and, in winter, changes toward drier soils in some regions and wetter soils in others (Greco *et al*., 1994). These projections imply longer and warmer growing seasons, less extreme subzero temperatures in winter, more frost-free winters in maritime areas, and more summer droughts, particularly in mid-continental regions (Manabe and Weatherald, 1987).

Possibly more important to temperate biotic communities than the magnitude of warming or precipitation change is the speed of climatic change (see Section 1.3.5). The projections imply that it will take less than a century for the summers to be warmer than now throughout the current geographic range of many temperate species.

1.5.4. *Impacts of Climatic Change*

1.5.4.1. *Forest Area, Distribution, and Productivity*

As long as the current agricultural surpluses in temperate regions persist, the temperate forest area is likely to be increased by afforestation. In Europe, the potential area for afforestation has been estimated as 44 Mha, and in the United States 100 Mha (Heath *et al*., 1993).

Climatic change will enable the temperate forest to advance poleward, in many northern areas displacing boreal forest, and also potentially to expand in wet, maritime regions (Kellomäki and Kolström, 1992; Leemans, 1992; Morikawa, 1993). Early successional, pioneer species will be favored, and opportunities will exist for foresters to introduce species and ecotypes from warmer regions (Cannell *et al*., 1989). However, in drier, continental regions, repeated summer droughts may lead to the loss of temperate forests. The rate of loss in biomass and carbon in these areas could exceed the rate of carbon gain in newly forested areas (Smith *et al*., 1992a).

The net primary productivity of temperate ecosystems is predicted to increase in response to rising CO_2 concentrations, warming, and increased nitrogen mineralization rates; however, if drier areas, such as those west of the Appalachians, receive just 7% less rainfall, decreased productivity is predicted because of a decrease in the ratio of rainfall to potential evapotranspiration (Running and Nemani, 1991; Melillo *et al*., 1993; Lüdeke *et al*., 1995). Similarly, warming of 2°C and slightly decreased precipitation have been predicted to cause forest decline in Missouri (Bowes and Sedjo, 1993). Many experiments have confirmed that elevated CO_2 enhances the growth of young trees and that the effect is sustained over several years (Wullschleger *et al*., 1995). However, it has proven difficult to detect CO_2-enhanced stem growth of mature trees over the last century (see Section 1.3.1.2 and Chapter A).

Forests that are not in decline may show little change in net carbon storage because, in temperate climates, increases in net primary productivity may be offset by increased soil respiration due to higher temperatures (Thornley *et al*., 1991; Kirschbaum, 1993). That is, the net ecosystem productivity may not change, and may even decrease. Forests suffering from wildfire, pest outbreaks, or decline events will lose carbon and may become a major source of carbon (King and Neilson, 1992; Smith and Shugart, 1993).

1.5.4.2. *Temperature and Water*

Species in the temperate zone differ in their temperature optima for growth, their timing and degree of frost hardening and dehardening, their winter chilling requirements, and the number of degree-days needed to complete different stages in their reproductive development (Cannell, 1990). All of these differences are likely to be involved in driving changes in the distribution and productivities of species. Most studies predict substantial change during the next century, but confidence in our predictions is limited by knowledge of adaptive responses of species and the need to consider interactions among responses to temperature, CO_2, changed water relations, and pests and pathogens. Moderate temperature increases alone often can be beneficial, as evidenced by the faster growth and greater seed

production of some commercial tree species when transferred to slightly warmer climates. But chilling requirements may not be met, and delayed budburst may limit the amount of light intercepted in the growing season while total respiration increases (LeBlanc and Foster, 1992). It also has been shown that frost hardiness can decrease in response to CO_2 enrichment (Barnes *et al.*, 1996), so that winter damage could even increase.

Species that are growing in regions where growth is limited by water shortages for at least part of the year may be adversely affected by intensification of summer soil water deficits (Greco *et al.*, 1994), as a result of decreases in the ratio of rainfall to potential evapotranspiration (e.g., Addison, 1991).

Warm winters will result in less precipitation falling as snow and reduced regional snow packs, resulting in less carry-over of water from the winter to the growing season (Mitchell *et al.*, 1990). Thus, less water will be available for vegetation in the following growing season, which may lead to drought-induced forest decline (King and Neilson, 1992).

1.5.4.3.   *Pests and Pathogens*

Warming in winter may allow destructive insects and pathogenic fungi to survive at higher latitudes than at present, enabling subtropical or warm-temperate pests and pathogens to invade vegetation from which they are now excluded (Dobson and Carper, 1992). Some insects also will be able to complete more generations per year in warmer climates. Increased incidences of pests and diseases may further limit the growth of stands that are already declining from the effects of climate change or pollution. Summer droughts and other climatic stresses have been associated with outbreaks of bark beetles like the southern pine beetle (*Dendroctonus frontalis*) in southern parts of the United States, bark beetles in western Canada (Kimmins and Lavender, 1992), and bronze birch borers on paper birch in northern Michigan (Jones *et al.*, 1993). Elevated CO_2 can change the palatability of leaves and either promote or discourage insect herbivory (Overdieck *et al.*, 1988; Mueller-Dombois, 1992). In areas where forestry practice has led to the establishment of mono-specific stands, forests are particularly vulnerable to outbreaks of pests and diseases, especially where that combines with poor site quality or exposure to industrial pollutants.

1.5.4.4.   *Soil Nutrients*

Nitrogen supply generally limits the productivity of many temperate forests (Tamm, 1991). Climatic warming will increase rates of turnover of soil nitrogen and carbon. In Europe and the United States, nitrogen fertility also may be improving through inputs from industrial and agricultural pollution. While a low level of nitrogen input may have a beneficial effect (Kauppi *et al.*, 1992), further inputs could reverse the initial gains through the development of nutrient imbalances and further acidification of the soil (Heath *et al.*, 1993).

1.5.4.5.   *Fire*

The projected increase in the incidence of summer droughts in much of the temperate zone will increase the risk of forest fires and extend the hazard to areas that are not now affected, particularly where forests are defoliated or killed by drought, pests, or pathogens. Some species that are not adapted to withstand or regenerate after fire may be lost from fire-affected areas. However, large-scale fires may continue to be rare in the temperate zone and confined to drier parts of North America, Australia, and the Mediterranean region because temperate forests mostly occur in dissected landscapes in countries that can afford fire-control measures.

1.6.   **Boreal Forests**

1.6.1.   *Characterization*

The boreal forest covers approximately 17% of the world's land surface area in a circumpolar complex of forested and partially forested ecosystems in northern Eurasia and North America. It contains about 90 Gt C in living biomass and 470 Gt C in soils and detritus (Dixon *et al.*, 1994); the boreal region is estimated currently to be a sink of 0.4–0.6 Gt C yr^{-1} (Apps *et al.*, 1993; Dixon *et al.*, 1994).

The boreal forest consists primarily of evergreen and deciduous coniferous species and is floristically poor, being dominated by only about 15 tree species in both Eurasia and North America (Nikolov and Helmisaari, 1992). Many species have transcontinental distributions and are adapted to withstand extremes of climate and to regenerate after fire or insect attack. Three forest zones are often recognized (from south to north): closed-crown forest, open-crown forest (or lichen woodland), and forest-tundra. The closed-crown forest borders on steppe/prairie in continental areas, whereas in areas under maritime influence the boreal/temperate forest boundary consists of a relatively species-rich community—often in a mosaic of deciduous species on favorable soils and conifers at less favorable or colder sites (Apps *et al.*, 1993). Much of the boreal forest is embedded in a mosaic of wetlands and peatlands that may act as natural fire breaks. Mosses and lichens also play an important role in boreal ecosystem processes.

The northern limit of the boreal forest is largely determined by temperature (Garfinkel and Brubaker, 1980; Larsen, 1980, 1989; Arno, 1984), while both temperature and water supply determine the forest/steppe and forest/prairie boundaries. In general, the length of the vegetative period (related to the length of the frost-free period or July mean temperature) is of great importance in maritime regions. In more continental regions, drought or extreme subzero temperature may be more important—for instance, the apparent -40°C limit of sap supercooling of hardwood species (Arris and Eagleson, 1989) and the winter or drought tolerance of evergreen conifers. This tolerance may be exceeded in Siberia, which supports large areas of deciduous conifers (*Larix*) (Woodward, 1987). Drought is

an important factor in interior Alaska and Siberia, where annual precipitation may be as low as 100–200 mm. Throughout the boreal region, droughts are generally necessary for the onset of fires. Some species, notably *Pinus sylvestris*, are drought-tolerant, whereas others such as *Picea abies* are dominant on wetter soils. A further factor determining the limits of species may be their winter chilling requirements.

The boreal forest consists of a patchwork of small to very large areas that are in various stages of recovery from fire or insect attack (van Cleve *et al*., 1983a). Stands rarely reach maximum biomass or carbon content (Apps and Kurz, 1994), and many areas are dominated by one or a few species in a narrow age-class range. Also, it may be noted that the boreal forest is less than 12,000 years old and still may be expanding in some areas (Tallis, 1990), and even recovering from cool temperatures in the Little Ice Age (AD 1200–1850) (Campbell and McAndrews, 1993).

1.6.2.   Key Limitations

Low air temperatures and small heat sums restrict growth and the production and germination of seed, which is a major factor limiting regeneration in the forest-tundra zone (Henttonen *et al*., 1986). Unseasonal frosts can damage growth and reproductive cycles. Low soil temperature and permafrosts (in non-oceanic regions) have been demonstrated experimentally to limit growth and nutrient availability (van Cleve *et al*., 1981, 1983b). Permafrost can restrict root growth and create an impervious layer that impedes soil drainage but can also be responsible for raised areas that permit drainage, producing islands where trees can grow within wetlands.

Low nutrient availability (except after fire) is characteristic of most boreal forests. Low soil temperatures limit the rate of litter decomposition and mineralization (Shaver *et al*., 1992; Berg *et al*., 1993; Kobak and Kondrasheva, 1993), and the litter of most coniferous boreal tree species is relatively resistant to decomposition because of its high lignin and low nutrient content. Nitrogen availability in boreal coniferous forests is generally in the range of 5–40 kg N ha^{-1} yr^{-1}, compared to 80–120 kg N ha^{-1} yr^{-1} in northern hardwood stands (Pastor and Mladenoff, 1992).

Natural wildfires are ubiquitous throughout the boreal region because of the buildup of large amounts of litter, much of which is not only resistant to decomposition but is also highly flammable. In the absence of fire-suppression measures, the interval between fires (the fire cycle) ranges from 50 to 200 years from south to north but may be over 1,000 years in wet northern ecosystems (Viereck, 1983; Payette *et al*., 1989b; Payette, 1992). There are well-established relationships between fire-cycle length, species composition, age-class distribution, and carbon storage (Johnson and Larson, 1991; Kasischke *et al*., 1995; Kurz *et al*., 1995).

Boreal forests also are characterized by periodic outbreaks of insect pest populations. For many insect species, outbreaks have been clearly associated with climatic conditions and weather events (e.g., Martinat, 1987; Mattson and Haack, 1987; Volney, 1988), and outbreaks are often most common in the southernmost (warmest) part of the tree-host range (Kurz *et al*., 1995). On sites where forests have remained unaffected by fire or insect damage for extended periods, they are characterized by multi-aged stands where tree-fall constitutes the most important disturbance. Tree falls create a variety of microenvironments that enhance diversity and affect regeneration patterns (Jonsson and Esseen, 1990; Liu and Hytteborn, 1991; Hofgaard, 1993).

The net primary productivity of boreal forests tends to be low—commonly 3–8 t (dry matter) ha^{-1} yr^{-1}, compared with 7–12 t ha^{-1} yr^{-1} for northern hardwoods (Cannell, 1982; Melillo *et al*., 1993). Productivity is controlled in a complex way by interactions between various factors as discussed in Section 1.6.4 (Bonan and Shugart, 1989). As a boreal forest stand develops after fire, litter accumulates, more and more nutrients are immobilized in the litter, the depth of thaw is reduced because of the insulating properties of the litter, drainage may then be impaired by permafrost, and moss growth may impair regeneration from seed—some of which may be held within serotinous cones that release their seed only after fire (Bonan, 1992). Fire interrupts this process by burning litter on the forest floor, releasing mineral nutrients, leading to deeper thaw, improving drainage, and often removing the moss layer—all of which improves conditions for seed germination (Landhäusser and Wein, 1993).

1.6.3.   Projected Climatic Changes

The climatic changes projected for most of the boreal region over the period 1900–2050 are increases in temperature of around 1–2°C in summer and 2–3°C in winter; regional changes in precipitation in summer and winter, mostly in the ±20% range; and drier soils in summer (averaging about 2–8 mm less water) (Greco *et al*., 1994). These projections imply longer and warmer growing seasons, appreciably milder winters with the possibility of less extreme minimum temperatures, and less permafrost, which is related to annual mean temperatures.

Most importantly, the changes in temperature, soil water, and vapor pressure deficit may increase the frequency (shorten the return-time) of fires. Flannigan and van Wagner (1991) predict a 40–50% increase in the area burned each year in Canada in a 2 x CO_2 climate scenario, and others have predicted more frequent fires of higher intensity in the forest-tundra (Stocks, 1993; FIRESCAN Science Team, 1995). In Russia, an additional 7–12 million hectares of boreal forest are projected to burn annually within the next 50 years, affecting 30–50% of the land area (Dixon and Krankina, 1993).

1.6.4.   Impacts of Climatic Change

There is a general consensus that climatic change will have greater impact on boreal forests than on tropical and perhaps

temperate forests, and that more frequent or changed patterns of disturbance by fire and insect pests may be more important agents of change than elevated temperatures and CO_2 levels *per se* (Shugart *et al*., 1992; Dixon and Krankina, 1993). Overall, the boreal forest is likely to decrease in area, biomass, and carbon stock, with a move toward younger age-classes and considerable disruption at its southern boundary (Neilson *et al*., 1994; Kurz *et al*., 1995). CO_2 enrichment itself may have less effect than in warmer climates. In Sections 1.6.4.1 through 1.6.4.4, we consider the likely changes in the distribution and composition of the forest and then elaborate on the factors driving change.

1.6.4.1.   *Forest Area, Distribution, and Productivity*

On its southern border, the boreal forest may give way to northern deciduous forest (or agriculture) in areas with a maritime influence and to grassland or xerophytic steppe vegetation in midcontinental areas, and species shifts may occur in the mid-boreal region (Emanuel *et al*., 1985; Kellomäki and Kolström, 1992; Rizzo and Wiken, 1992; Dixon and Krankina, 1993; Monserud *et al*., 1993a; Tchebakova *et al*., 1994; Prentice and Sykes, 1995). Near tree lines in many areas, there is potential for existing populations of suppressed individuals to grow taller and more vigorously, as has apparently happened in response to past climatic changes (Kullman, 1986; Payette *et al*., 1989a; Hofgaard *et al*., 1991).

Over the next century, the potential (or preferred) geographic ranges of species may shift approximately 300–500 km, implying changes in forest-based industries and considerable socioeconomic impacts. In the early Holocene (about 8,000 years ago), when the climate became warmer, fire-adapted hardwood species expanded northward to new sites after fire (Green, 1987). Where northern deciduous species, such as sugar maple, migrate northward, forest productivity may be increased on soils that retain adequate water, whereas productivity may decrease on dry soils where boreal forest may give way to oak-pine savanna (Pastor and Post, 1988).

There is concern that the maximum potential migration rates may be too slow to keep up with the rate of climatic change (see Sections 1.3.3 and 1.3.5)—in which case some researchers consider that there may be areas of transitory forest decline, especially if soils change slowly, are unfavorable for immigrating species, and lack necessary microbes and symbionts (Dixon and Turner, 1991; Davis and Zabinski, 1992; Solomon, 1992; Smith and Shugart, 1993), or where growth by more southern species is limited by photoperiodic constraints. The future of the transitory forest is likely to be determined by increasing occurrence of extended high-intensity wildfires until a new climate-vegetation-fire equilibrium is established (Crutzen and Goldammer, 1993). Other researchers suggest that there may be little forest decline. Intraspecific genetic diversity will buffer change, and species that are no longer in a favorable climate will simply grow and regenerate poorly and be overtaken by invading species either gradually or after disturbance (Malanson *et al*., 1992; see also Section 1.3.3).

Increasing temperatures are likely to stimulate soil organic matter decomposition and increase nutrient (especially nitrogen) availability, leading to an increase in net primary productivity of non-stressed stands, averaging perhaps 10% in the boreal zone in a 2 x CO_2 climate (Melillo *et al*., 1993). However, despite increasing productivity, there may be a net carbon loss from the ecosystem because a small temperature rise will greatly enhance decomposition rates (Jenkinson *et al*., 1991), whereas CO_2 fertilization will be of low effectiveness because of low temperatures (Kirschbaum, 1993). Also, productivity may not increase in dry areas if water limitations were to increase due to increased evaporative demand. Hydrological and landscape changes in the patterns of bogs and forest also may be expected. In the north, melting of permafrost would favor the expansion of wetlands, while drier conditions in the south would lower the water tables (Apps *et al*., 1993).

In the forest-tundra, rising temperatures are likely to enhance the development and germination of seeds of many species, increasing forest cover and enabling a northward migration to occur, probably after fire (Kullman, 1990; Kellomäki and Kolström, 1992; Landhäusser and Wein, 1993)—but again, hampered to some extent by slow changes in soil conditions (Rizzo and Wiken, 1992). There is clear evidence in the fossil pollen and macrofossil record of expansion and recession of boreal forest in both Eurasia and North America in response to temperature changes over the past 10,000 years (Ritchie, 1987). However, it will take more than 100 years for any new forest areas to mature in the forest-tundra, so the northward expansion of mature boreal forest is likely to be slower than the rate at which it is lost to grassland and temperate deciduous forest at its southern boundary (Rizzo and Wiken, 1992). The tundra itself is likely to become a carbon source in response to warming (Billings *et al*., 1984; Oechel *et al*., 1993).

1.6.4.2.   *Temperature*

The productivity of boreal forests—except those at the warmer and drier edge of their species ranges—is likely to respond favorably to increases in temperature, as shown by long-term soil warming experiments and models (van Cleve *et al*., 1990; Melillo *et al*., 1993). It has long been known that trees in the boreal forest exhibit positive relationships between annual growth-ring widths and summer temperatures (Mikola, 1962) and between volume growth and number of degree-days (Kauppi and Posch, 1985; Worrell, 1987). Also, most provenance-transfer studies suggest that some southward movement of ecotypes to warmer climates promotes their volume growth (Beuker, 1994; Matyas, 1994). The magnitude of the growth response will depend on the effect of increased temperatures on nutrient availability, evapotranspiration, and the frequency of fires. Subtle interactions may be important. For instance, Bonan *et al*. (1990) and Bonan (1992) show how increased temperatures combined with increased evapotranspiration could result in a faster build-up of litter and a shallower permafrost zone, but an increased probability of fire. The net effect could be to reduce nutrient availability except after

fires—whereas on the basis of temperature increases alone, nutrient availability would have been expected to increase (Shaver *et al.*, 1992).

Forest simulation models suggest large shifts in species composition in boreal forests (Shugart *et al.*, 1992). Large increases in temperature would cause annual heat sums to exceed the minimum thresholds for seed production, favoring the northward spread of species, especially in the forest-tundra zone. On the other hand, reduced winter chilling may disrupt both vegetative growth and reproductive processes of species at the southern edges of their ranges (Kimmins and Lavender, 1992).

1.6.4.3. Nutrients

Nitrogen is the nutrient that most limits the productivity of boreal forests (e.g., van Cleve *et al.*, 1983a, 1983b; Tamm, 1991). The critical factor is the rate at which nitrogen is recycled through the litter—which, as noted earlier, is a function of both temperature and litter quality (Berg *et al.*, 1993). Species differ in both their response to nitrogen and their litter quality. *Picea* sites in cold locations have forest floors with a high lignin content, little available nitrogen, and slow decomposition rates, whereas *Betula* or *Populus* sites, especially in warmer locations, have forest floors with less lignin. Thus, whereas small increases in temperature will increase rates of decomposition and nitrogen cycling, large or prolonged temperature increases also will lead to a shift from coniferous to deciduous tree species, and—because of the greater decomposability of deciduous litter—this may have a further positive effect on nitrogen availability, leading to increased productivity. On the other hand, increasing CO_2 concentration could increase the C:N ratio of litter, and the reduced litter quality might slow the rate of nutrient cycling (Taylor *et al.*, 1989; van de Geijn and van Veen, 1993).

1.6.4.4. Fire and Insects

In Canada over recent years, about 1 to 2 Mha have burned each year (Kurz and Apps, 1993), and in Russia, between 1.4 and 10 Mha burned each year between 1971 and 1991 (Dixon and Krankina, 1993). If fires occur very frequently, late successional species become unable to outcompete pioneer species, which will thereby become more common. A threefold increase in wildfire frequency in Canada between a high-fire year (1989) and a reference year (1986) resulted in an 86% reduction in the net ecosystem carbon sink (Kurz *et al.*, 1992). However, fires also have a beneficial effect on subsequent ecosystem function and facilitate regeneration (Landhäusser and Wein, 1993). Fires may have most impact in the forest-tundra zone; indeed, Payette and Gagnon (1985) conclude that the modern forest-tundra boundary of northeastern North America is the result of fires during the last 3,000 years, which were followed by lower temperatures that limited forest regeneration. If future fires were followed by higher temperatures, the fires

could be catalysts for a return to coniferous forests that appear to have existed there 7,000–10,000 years ago.

Defoliating insects play an important role in boreal forests, and there are many instances where the proportion of different boreal tree species is related to the intensity of insect pest outbreaks. Pests usually are maintained at a low population equilibrium by a combination of host resistance, natural enemies, and weather conditions. Any one of these factors could be affected by climatic change, particularly tree resistance in response to environmental stress. Once an outbreak exceeds a certain patch size, it can become self-propagating and can spread largely independently of weather conditions. Following climatic warming, it seems very likely that insect outbreaks will expand northward and that new pest and pathogen problems will arise (Kurz and Apps, 1993).

1.7.   Research and Monitoring Needs

Our capability to assess the likely fate of the world's forests under altered climatic conditions has been limited because the conceptual modeling framework for such an assessment is still in an early stage of development. It needs to be refined to improve the understanding of climate change impacts at the following three levels: (1) the ecophysiological responses of trees to changing climate and CO_2 concentrations, (2) the relationship between tree growth and transient forest dynamics, and (3) the influence of changing forest characteristics on the global carbon balance and hence their feedback to the greenhouse effect. The predictive power of current modeling approaches decreases from (1) to (3). A consistent research strategy to overcome these limitations needs to be accompanied by a monitoring program that can provide appropriate databases for initialization, calibration, validation, and application of the models. In particular, future work should address the following:

- *Ecophysiology*, specifically the influence of temperature, water availability, ambient CO_2 concentration, photoperiod, and nitrogen availability on the establishment, growth, water use efficiency, stomatal conductance, biomass allocation, and survival of trees under natural conditions. Urgently required also are studies of belowground plant and soil processes such as the decomposition of organic residues under changing environmental conditions. Most previous studies have been limited to short-term responses of young trees and therefore have ignored longer-term processes influenced by more than one factor, as well as the adaptive potential of plants. There is a need for more long-term studies that investigate simultaneously a well-defined set of key factors. The ecophysiological responses should be measured at experimental sites within a range of forest types, and those experiments should follow protocols that support modeling research.
- *Forest dynamics*. Studies should focus on the stability of natural and managed forests under different types of climatic (temperature, water availability) and

chemical (CO_2, nitrogen) regimes, including the influence of changing disturbance conditions (wind, drought, fire, pest frequencies). Because the direction and magnitude of possible climatic change is not known for all factors relevant to ecosystem dynamics, simulations and experimental studies should focus upon a broad range of such conditions. The potential rate of species migration (either assisted or unassisted) needs to be investigated further using appropriate models. A significant part of this activity should be devoted to further development of monitoring strategies that would allow the collection of data on realistic forest responses through all major forest regions.

- *Monitoring*. The development and application of forest models requires improved global databases on the present conditions of the world's forests, as well as their associated site characteristics. It is crucial that these data-gathering activities are intensified, both through the global network of ground observations that can be made in many research institutes worldwide and through the collection of data from space-borne sensors. For ground-based data collection, standardization and worldwide availability are key issues, as is the continuation of already ongoing observational series. Satellite remote sensing is in a promising stage of development, with respect to both enhanced processing protocols of existing time series of satellite data (such as AVHRR) and the development of sensors with improved capacity to measure ecosystem properties at high spatial and temporal resolution.

To improve the overall modeling framework for the assessment of global forest response to climate change, and to provide an appropriate background for the synthesis of more detailed studies, there is a requirement for process-based terrestrial biosphere models of ecosystem dynamics. These models should build on knowledge from all other levels of model development. Specifically, they should involve a sufficiently high number of plant functional types and forest types to cover the wide range of forests occurring in different climate zones. Various initiatives for the development of such models are currently underway (e.g., Focus 2: Change in Ecosystem Structure, especially activity 2.3. in Steffen *et al*., 1992; Landsberg *et al*., 1995). To succeed, they need to be backed up by the research activities listed above.

CONTENTS

EXECUTIVE SUMMARY

Rangelands (i.e., grasslands, shrublands, savannas, hot and cold deserts, and tundra) occupy 51% of the terrestrial land surface, contain about 36% of the world's total carbon in above and belowground biomass (Solomon *et al*., 1993), include a large number of economically important species and ecotypes, and sustain millions of people. Rangelands support approximately 50% of the world's livestock and provide forage for both domestic and wildlife populations (Briske and Heitschmidt, 1991).

Doubled-CO_2 climate-change scenarios provided for IPCC Working Group II (Greco *et al*., 1994) were used to analyze the regional impacts of altered climate regimes on rangeland resources. Results indicate:

- Rangeland vegetation is found where mean precipitation, temperature, elevation, and latitude interact to provide sites suitable for herbaceous species, shrubs, and/or open stands of trees. However, carbon cycling, productivity, and species composition in any region is directly related to the highly variable amounts and seasonal distribution of precipitation and is only secondarily controlled by other climate variables. Small changes in the frequency of extreme events may have disproportionate effects on what managers must cope with in rangeland systems (High Confidence).
- CO_2 increases are likely to result in reductions of forage quality and palatability because of increasing carbon to nitrogen ratios. These effects will be more common in lower-latitude rangelands where low nutritional value is already a chronic problem (Medium Confidence).

- Boundaries between rangelands and other biomes are likely to change with changes of climate: directly, through climate-driven changes in species composition, and indirectly, through changes in wildfire regimes, opportunistic cultivation, or agricultural release of the less-arid margins of the rangeland territory. These effects will be more common in the temperate rangelands (High Confidence).
- Climatic warming may cause tundra to become a net source of carbon dioxide. Temperature increases in the tundra will reduce species richness, especially of insect-pollinated forbs (Medium Confidence).
- The extensive use of rangelands suggests that strategies to reduce greenhouse gas emissions must focus on maintaining or increasing carbon sequestration through better soil and vegetation management and reducing methane by altering animal production systems (High Confidence).
- Human adaptive strategies for coping with climate-change effects on rangelands include the preservation of an extensive spatial scale in management units and the development of viable marketing systems capable of absorbing opportunistic variations in number and/or kind and class of animals (Medium Confidence).

2.1.   Introduction: Description of the World's Rangeland Resources

Rangelands occupy approximately 51% of the terrestrial surface of the Earth, or 68.5 million km² (Lean *et al*., 1990; Prentice *et al*., 1992). Rangelands include unimproved grasslands, shrublands, savannas, and hot and cold deserts. For the purposes of this assessment, tundra and improved pastures are included here, while hot deserts are described in Chapter 3.

The primary use of rangelands has been and is for grazing by domestic livestock and wildlife. Rangelands support fifty percent of the world's livestock (WRI, 1992) and provide forage for both domestic and wild animal consumption (Briske and Heitschmidt, 1991). Rangeland management systems vary from nomadic pastoralism to subsistence farming to commercial ranching. Markets are largely externally driven, with extensive social systems in contrast to commercial agriculture. Overgrazing (the result of animal consumption exceeding carry capacity) has been and is common to rangelands throughout the world (WRI, 1992).

Most of the forage consumed by domestic livestock (cattle, sheep, goats, buffalo, and camels) is supplied by rangelands in Africa and Asia (Table 2-1). Other regions of the world support many fewer animals from rangeland forage resources. Numbers and kinds of domestic and wild grazing animals vary by region.

The distribution of the world's rangelands falls on continua from wet to dry, fertile to infertile, and hot to cold (Figure 2-1). Holdridge (1947) arrayed the world's vegetation into life zones based on mean annual growing season temperature (°C), average annual precipitation, an index of precipitation divided by potential evapotranspiration (PET), and latitude (Figure 2-2). Rangelands occupy areas where combinations of temperature, precipitation, PET, and latitude prevent occupation by dense stands of trees. Figure 2.2 is a good display of the types of ecosystems covered in this chapter, although the hot deserts

are described in more detail in Chapter 3. Holdridge and others (Walter, 1973; Bailey, 1989; Prentice *et al*., 1992) recognized that seasonality of precipitation, soil factors, herbivory, and fire are additional important factors in determining local vegetation composition and structure. Interactions between plant-available moisture and available nutrients also are crucial to rangeland structure and composition (Walker, 1993).

Rangeland ecosystems are diverse (Table 2-2), and stores of carbon both above and below ground vary by ecosystem type (Solomon *et al*., 1993). Carbon (C) stored in the world's rangeland vegetation has been estimated by the BIOME 1.1 model at 749.7 Gt (Solomon *et al*., 1993), although annual net primary productivity varies widely (Barbour *et al*., 1987). Carbon in the world's rangeland soils has been estimated at 591.6 Gt, or 44% of the world's total soil carbon (Solomon *et al*., 1993). Preindustrial levels of soil C (to 20 cm depth) in grasslands alone have been estimated at approximately 96 Gt (Ojima *et al*., 1993b). Current soil C stocks for these grasslands (based on Ojima *et al*., 1993b) are estimated at 81–164 Gt, based on land-cover estimates of Bailey (1989) minus estimated land under cultivation in these regions provided by Prentice *et al*. (1992).

In rangelands, the amount and timing of precipitation are the major determinants of community structure and function. Other driving forces that determine plant community composition, distribution, and productivity include temperature, fire, soil type, and herbivory. These driving forces prevent species senescence and allow for periodic rejuvenation by eliminating aboveground biomass and organic debris and thereby liberating nutrients. Most rangelands do not exist in a state of equilibrium, nor do they exhibit linear successional trends; rather, they fluctuate from one state to another depending on rain, fire, grazing, and other anthropogenic factors (Westoby *et al*., 1989; Stafford Smith and Pickup, 1993; Hobbs *et al*., 1991; Stafford Smith, 1994). Most rangelands are nonequilibrial within the range of climatic conditions that they currently experience. Underlying trends in climate change may cause some compositional states to become more likely (e.g., the

Table 2-1: *World livestock and their dependence on rangeland resources. Percent of feed from rangeland is an estimate based on figures for the amount of grain fed to livestock; the assumption is that the rest of the feed source supporting the animals is from rangeland [World Resources, 1992–1993 (UNEP/UNDP)].*

| Region | Land Resources (1,000 hectares) | | Animal Units (1,000 animals) | | | |
	Permanent Pasture	Woodland or Other	Cattle	Sheep, Goats	Buffalo, Camel	Feed from Rangeland
Africa	890,889	1,200,565	183,715	372,038	16,877	82%
North, Central America	368,631	779,838	161,050	33,566	9	35%
South America	447,863	237,792	262,254	134,759	1,190	54%
Asia	694,251	1,043,666	389,730	640,938	138,814	84%
Europe	83,177	92,524	124,900	166,023	370	45%
Former Soviet Union	371,500	678,829	118,767	145,588	707	45%
Oceania	436,622	199,523	30,862	223,838	ND	50%

ND = No data.
Figure 2-1. Distribution of rangeland types using the Holdridge classification system (Holdridge, 1947) as modified by Cramer and Leemans (1993). Biotemperature is the mean value of all daily mean temperatures above 0°C, divided by 365. The heavy line between Warm Temperate and Subtropical zones represents the boundary for risk of a killing frost. The demand of plants for moisture is represented by mean annual precipitation and potential evapotranspiration ratio. The shaded areas are rangeland types discussed in this chapter.

shrub invasion process is hypothesized to be linked to climate shifts or to grazing in the United States). However, in managed rangeland systems, management is as likely, at present, to maintain the systems in the desired state. In many areas, however, poor management of rangelands enhances the changes likely to be caused by climatic/atmospheric change—for example, by increasing the ratio of woody to herbaceous vegetation.

2.2. Climate Variables

2.2.1. Precipitation and Temperature

Among climatic variables, those related to water availability and water balance appear most influential in controlling the geographic distributions of rangeland vegetation (Stephenson, 1990) and production (Rosenzweig, 1968; Webb *et al*., 1983; Sala *et al*., 1988). There is a strong linear relationship between aboveground net primary productivity (ANPP) and annual precipitation in rangeland ecosystems (Rutherford, 1980; Webb *et al*., 1983; Le Houerou, 1984; Sala *et al*., 1988; Scholes, 1993), with typically 90% of the variance in primary production accounted for by

annual precipitation (Le Houerou and Hoste, 1977; Webb *et al*., 1978; Walter, 1979; Foran *et al*., 1982; Sala *et al*., 1988).

Temperature does not account for a significant fraction of the ANPP variability among years in a particular region (Sala *et al*., 1988; Lauenroth and Sala, 1992; Sala *et al*., 1992). However, temperature appears to be the major climatic variable controlling the process of decomposition in grasslands and other rangeland types (Jenkinson, 1977; Meentemeyer, 1984; Burke *et al*., 1989). It has been shown experimentally that decomposition rates increase rapidly with temperature, provided that there is enough water (Meentemeyer, 1978, 1984; Schimel, 1988; Holland *et al*., 1992; Ojima *et al*., 1993a; Parton *et al*., 1993; Townsend *et al*., 1992; Burke *et al*., 1995a).

Temperature also affects C_3/C_4 species composition of grasslands (Sims, 1988) because of differences in optimal growing conditions (see Chapter A). The distribution (Terri and Stowe, 1976; Tieszen *et al*., 1979) and seasonal activities of C_3 and C_4 grasses (Kemp and Williams, 1980; Hicks *et al*., 1990) often are highly correlated with temperature. This is not necessarily true for dicotoledenous plants such as legumes, however (Ehleringer and Field, 1993).

2.2.2.   *Effects of Altered Atmospheric CO_2 Concentrations on Rangelands*

Most research on rangeland plant response to elevated CO_2 has focused on responses of individual plants (Bazzaz and McConnaughay, 1992; Idso and Idso, 1994). A wide range of plant parameters have been measured (see Chapter A), and as a rule, studies show that increasing CO_2 levels increase photosynthesis, water-use efficiency (WUE), above- and belowground productivity, and nitrogen-use efficiency (NUE) and decrease stomatal conductance, transpiration, and whole-plant respiration (Wong *et al.*, 1979; Kimball, 1983; Webb *et al.*, 1983; Strain and Cure, 1985; Morison, 1987; Smith *et al.*, 1987; Idso, 1989; Bazzaz, 1990; Kimball *et al.*, 1990; Bazzaz and McConnaughay, 1992; Kimball *et al.*, 1993; Rozema *et al.*, 1993; Zak *et al.*, 1993; Gifford, 1994; Idso and Idso, 1994; Rogers *et al.*, 1994). For example, controlled-environment studies have repeatedly demonstrated that growth and net photosynthesis of C_3 plants, including woody species such as *Prosopsis glandulosa* (Polley *et al.*, 1994), are highly responsive to CO_2 when it is increased over concentrations representative of the recent and prehistoric past (Gifford, 1977; Baker *et al.*, 1990; Allen *et al.*, 1991; Polley *et al.*, 1993a).

Responses to CO_2 increase are not necessarily consistent across species or under all environmental conditions. Two processes—increased photosynthesis and reduced transpiration—typically contribute to the positive influence of CO_2 on plant WUE. Atmospheric CO_2 directly affects the coupling between climatic water balance and vegetation by altering the efficiency with which plants use water. The effect of CO_2 on water use may be more important in water-limited rangelands than in moist grassland systems or irrigated agricultural land. Elevated CO_2 can result in a slower depletion of soil water in drought-stricken rangeland grasses where there is no change in leaf area due to limitations such as nitrogen availability (Owensby *et al.*, 1993; Campbell *et al.*, 1995a).

Plant responses under variable environmental conditions or in competitive settings do not necessarily match responses under steady-state conditions and/or in the absence of competition. That is, results from studies in pots cannot automatically be assumed relevant to plants in native ecosystems (Nie *et al.*, 1992; Campbell and Grime, 1993; Owensby *et al.*, 1993; Campbell *et al.*, 1995b). Competitive outcome in response to elevated CO_2 can be difficult to predict because of the feedback between litter quality, soil, and plant production (Schimel *et al.*, 1991; Bazzaz and McConnaughay, 1992; Ojima *et al.*, 1993b; Newton *et al.*, 1995). In natural ecosystems, nutrient limitation may influence the response of individual species (Billings *et al.*, 1984; Wedin and Tilman, 1990;

Table 2-2: *Major rangeland vegetation types.*

Type	Area (10^6 km^2)	Major Characteristics	General Climate	Current C Stores (Gt) Above Ground	Below Ground
Cool Semi-Desert	4.91	Sparse shrubs dominate	Cold winters with snow, hard frosts; 50–250 mm annual precipitation; meets <28% of demand	3.0	30.7
Cool Grass Shrub	7.17	C_3 grasses dominate, with or without shrubs	Strong summer/winter peaks in precipitation; averages 400–1600 mm; meets 28–65% of demand	5.8	70.9
Warm Grass Shrub	9.84	C_4 grasses dominate	Strong seasonality in precipitation; dry season of ~5 months; rainfall meets 18–28% of demand	13.0	87.2
Hot Desert	20.70	Shrubs less than 100% cover	Mild winters; 50–250 mm precipitation; rainfall meets <18% of demand	6.3	63.1
Tropical Savanna/ Dry Woodland	17.18	C_4 grasses/sedges dominate, with significant discontinuous cover of trees and shrubs	Strong seasonality in precipitation; rainfall meets 45–80% of demand	78.6	124.8
Xerophytic Woods/ Shrubland	10.63	Widely variable woodlands, sclerophyllous shrubs, and annual grasses	Prolonged summer drought of 2–11 months; rainfall meets 28–45% of demand	45.5	80.9
Tundra	11.61	Dominated by herbaceous species	Temperatures generally <10°C; variable precipitation	5.9	134.0

Conroy, 1992; Comins and McMurtrie, 1993), and complex feedbacks between plant and soil microorganisms may arise (Diaz *et al.*, 1993). In some studies, soil microbial respiration rate is greatly enhanced under lower CO_2 conditions and reduced under higher CO_2 conditions in the laboratory (Koizumi *et al.*, 1991) and in the field (Nakadai *et al.*, 1993). Experimental doubling of CO_2 concentration has relatively little effect on plant growth in Arctic tundra, presumably because of constraints of low nutrient supply (Tissue and Oechel, 1987; Grulke *et al.*, 1990). Increased levels of carbon dioxide may increase individual plant production, but the effect on whole-ecosystem production is less clear, as resource augmentation has been shown to decrease species diversity and differentially affect individual species growth (favoring pioneer species) (Wedin and Tilman, 1990; Bazzaz, 1993).

Plants grown in CO_2-enriched environments tend to have reduced mineral concentrations (except phosphorus) relative to those grown at ambient CO_2 levels (Conroy, 1992; Overdieck, 1993; Owensby *et al.*, 1993). Decreases in nitrogen (N) concentration with elevated CO_2 have been demonstrated with a wide array of species (Conroy, 1992; Coleman *et al.*, 1993; Diaz *et al.*, 1993; Overdieck, 1993). These changes in mineral concentration in plants make them less palatable to herbivores and may even influence herbivore health and production (Fajer *et al.*, 1991). Increased concentrations of carbon-based, nonpalatable secondary compounds

could also deter herbivory, although the evidence for this process is weaker (Ayres, 1993; Diaz, 1995). The influence of elevated CO_2 on nutrient cycling must also be considered in light of potential impacts on litter inputs and litter quality. Reduced nitrogen concentrations may reduce the rate of decomposition, thereby slowing nutrient cycling and energy flow (Bazzaz and Fajer, 1992; Schimel *et al.*, 1994). In addition, surplus C may be converted to secondary compounds such as tannins, which decompose slowly.

According to controlled-environment studies, C_3 plants tend to be more responsive to CO_2 than are C_4 ones (see Chapter A). This effect is not always sustained at the community level, however. For example, Owensby *et al.* (1993) report that production of a C_4-dominated tallgrass prairie increased when exposed to elevated CO_2, apparently as a result of higher water-use efficiency, but other studies have detected no effect on production, flowering, or growth rates (Polley *et al.*, 1994; Korner and Miglietta, 1994). Data from grasslands ungrazed for 100 years in Rothamsted, UK, suggest that rising CO_2 does not affect herbage yield (Jenkinson *et al.*, 1994).

Differential species responses to CO_2 could also have implications for species assemblages and plant-community dynamics. Therefore, the outcome of multispecies experiments is not readily predictable from the behavior of individual species (Bazzaz, 1992, 1993; Korner, 1993; Diaz, 1995).

2.2.3.   *Other Important Trace Gases*

The atmospheric concentrations of a number of important trace gases apart from CO_2 have increased (Cicerone and Oremland, 1988; IPCC, 1990, 1992), but their effects on rangeland ecosystems are not clear because they do not directly affect the rates of ecosystem processes or community dynamics (Mooney *et al*., 1987).

A number of factors influence CH_4, NO, and N_2O emissions from rangeland ecosystems: deposition of nitrogen, nitrogen fertilization, changing climate, elevated CO_2, ozone influences on plant production, changing plant community composition, changing animal populations, and changing land use (Schimel *et al*., 1990, 1991; Ojima *et al*., 1993a; Parton *et al*., 1994). Many of these factors are likely to respond non-linearly to climate changes. Changing precipitation and temperature directly affect the production of both NO and N_2O by regulating microbial activity (Firestone and Davidson, 1989). With abundant substrate, increasing temperatures generally increase rates of production, but changing soil moisture could decrease the rates of production. With no change in diet, more animals would result in greater N_2O production (Bouwman *et al*., 1995). However, all of the other factors listed are likely to change emissions through regulation of the nitrogen cycle. The greatest increase in emissions will occur when nitrogen supply exceeds plant demand, because this directly increases the nitrogenous substrates available for volatilization and leaching.

Many of the factors that influence nitrogen gas emissions also influence net methane emissions, but the influences are not necessarily in the same direction. Conversion of forests to pastures, fertilization, and, probably, nitrogen deposition decrease soil methane consumption (Mosier *et al*., 1991; Keller *et al*., 1993; Ojima *et al*., 1993a). Any factor that enhances primary productivity, such as elevated CO_2, N deposition, or fertilization, is likely to increase methane emissions because methane production is limited by substrate availability (Whiting and Chanton, 1993; Dacey *et al*., 1994; Valentine *et al*., 1994; King and Schnell, 1994; Hutsch *et al*., 1995). The possible extent of this enhancement is not yet clear. On the other hand, factors that decrease primary production (and thus CO_2 uptake) or pH, like ozone and acid rain, could have the opposite effect (Yavitt *et al*., 1993).

Increases in animal populations capable of emitting CH_4 via enteric fermentation [currently estimated to be 80 Gt/yr (Cicerone and Oremland, 1988)] are likely to increase methane production, but this could be partially offset if diets are improved through management (Lodman *et al*., 1993; Ward *et al*., 1993). Methane emissions from rangeland ruminants are largely a function of intake (generally about 80% of the variance), with feed quality accounting for about 5%. Hence, increasing intake is likely to dominate the impacts of increased feed quality. However, in rangelands where feed quality is low, there is often an intake restriction (Poppi *et al*., 1981); hence, if CO_2 and temperature reduce feed quality, there is likely to be a tradeoff betweeen reduced intake and increased emissions per unit feed. What will happen is that the energy balance in the animal over the maintenance level will decrease, and the productivity of the animal will decrease as a consequence—and thus there will be increased methane emissions per unit product.

Global estimates of NO emissions from soils range from 4–20 Mt of nitrogen annually, representing between 16 and 20% of the global budget (Davidson, 1991; Yienger and Levy, in press). Tropical and subtropical savannas contribute almost 40% of the NO produced in soils globally, with temperate grasslands contributing another 3% (Davidson, 1991). There are no published estimates of NO production from tundras or deserts. Temperate grasslands and tropical savannas each contribute between 10 and 25% of the global N_2O budget (0.5–2.0 Mt N/yr) (Prather *et al*., 1995).

Tropical areas that have been converted from forests to pastures due to land-use change contribute a variable proportion to both the global NO and N_2O budgets, with elevated emissions for many years following conversion, dropping to below original emissions after 20 years (Keller *et al*., 1993). Emissions of N_2O from cattle and feedlots contribute an additional 0.2 to 0.5 Mt N annually. Assuming that N_2O emissions from pasture conversion represents as much as 50% of the emission from cultivated soils, grasslands and savannas may contribute as much as 42% of the NO emitted globally (Prather *et al*., 1995).

Ammonia (NH_3) is a third nitrogen gas species exchanged with the atmosphere. Ammonia plays an important role in aerosol formation, which in turn influences radiative transfer and contributes substantially to N deposition. Approximately 50% of the NH_3 emitted to the atmosphere is produced by livestock, much of which is raised on rangelands or in feedlots, with an additional contribution by emissions from fertilizers (Dentener and Crutzen, 1994).

2.3.   **Ecosystem Variables**

2.3.1.   *Herbivory*

Grazing and browsing by domestic and wild animals, including invertebrates, alters the appearance, productivity, and composition of rangeland plant communities. Herbivores mediate species abundance and diversity by differential use of plants commonly susceptible to defoliation (Archer and Smeins, 1991). The role of herbivory and subsequent impacts on rangeland structure and function depends in part on the evolutionary history of grazing in an ecosystem (Payne and Bryant, 1994). Herbivory is a disturbance whether the ecosystem has a short (Milchunas *et al*., 1988; Milchunas and Lauenroth, 1993) or long (Hobbs and Huenneke, 1992) evolutionary history of grazing.

Plant species that are well-adapted to the prevailing climate, soils, and topography may be competitive dominants of a plant community when herbivore populations are low (Archer, 1994) but may become subordinates or even face extinction as levels of herbivory increase (Archer, 1992). Grazing establishes a

new set of boundary conditions for dominance. Species with competitive advantage in a moderately grazed system are generally those that are palatable and have a capacity to sprout rapidly after being eaten. Nonpalatability becomes a competitive advantage only when grazing is excessive. For example, excessive herbivory has been shown to favor unpalatable woody species over graminoids (Archer, 1994). Examples are available from North America (Archer, 1994), Africa (van Vegten, 1983; Skarpe, 1990), northern Australia (Lonsdale and Braithwaite, 1988), and South America (Morello *et al.*, 1971; Schofield and Bucher, 1986). Browsing herbivores play a key role in maintaining grasslands, meadows, and savannas, and they can change closed woodland, thickets, or heathland into open, grass-dominated systems (Sinclair and Norton-Griffiths, 1979; Berdowski, 1987).

The extent of influence that herbivory has on the structure and function of a range system depends strongly on interactions with factors such as previous grazing history, nutrient turnover rate, fire frequency and intensity, soil moisture, and soil compaction. Studies of the interactions of vertebrate grazing with these and other factors on rangelands have illustrated the tremendous influence such interactions have on these systems (Milchunas *et al.*, 1988; Holland and Detling, 1990; Hobbs *et al.*, 1991; Holland *et al.*, 1992; Seastedt *et al.*, 1991; Parton *et al.*, 1994; Dyer *et al.*, 1993; Turner *et al.*, 1993). Invertebrate grazing, a potentially more ubiquitous and chronic factor, has received less attention but is equally important to the evolutionary and ecological organization of these systems (Evans and Seastedt, in press).

Climate change and CO_2 may also interact with grazing effects. Drought favors the concentration of herbivores at sites with more reliable water supply and hence leads to overgrazing in these locations (Heitschmidt and Stuth, 1991; Heady and Childs, 1994). Increasing CO_2 will likely result in lower forage quality because of higher C:N ratios and higher concentration of unpalatable and/or toxic compounds in plants (Fajer *et al.* 1989, 1991; Johnson and Lincoln, 1991). Forage consumption may increase up to a point as a result, because herbivores will need to eat more to meet nutritional demands (Fajer *et al.*, 1991)—although the loss of palatability may reduce grazing pressure on certain species. At present, it is possible to say only that the overall carrying capacity for herbivores may increase, decrease, or remain constant, depending on the balance between eventual increases in productivity and decreases in nutritional value.

2.3.2.   *Fire*

Fire has been a factor in the evolution of grasslands and many other rangelands. Annual net primary productivity is strongly influenced by both fire and climate (Hulbert, 1969; Old, 1969; Towne and Owensby, 1984; Abrams *et al.*, 1986; Sala *et al.*, 1988). Fire alters the structure of grassland vegetation (Knapp, 1984, 1985) and affects nutrient cycling (Raison, 1979; Kucera, 1981; Risser and Parton, 1982; Ojima *et al.*, 1990;

Ojima *et al.*, 1994a). Aboveground biomass production in temperate, ungrazed grasslands generally increases following fire during years with normal precipitation (Towne and Owensby, 1984). This increased production has been attributed to release of readily available nitrogen and phosphorus from plant material, increased nitrogen mineralization rates, enhanced nitrogen fixation, and altered microclimatic conditions, including improved light availability (Daubenmire, 1968; Old, 1969; Raison, 1979; Biederbeck *et al.*, 1980; Knapp and Seastedt, 1986; Hulbert, 1988).

By making N and other nutrients more available to soil microorganisms, fire may result in enhanced emissions of N_2O from soil (Anderson *et al.*, 1988). Bouwman (1993, 1994) calculated that from the approximately 12 Mt N/yr remaining on the ground after burning (Crutzen and Andreae, 1990), 20% is volatilized as NH_3, and 1% (0.1 Mt/yr) of the remaining N is emitted to the atmosphere as N_2O (Carras *et al.*, 1994). An estimated 10% of this N is amenable to mitigation. Most of these emissions are short-term effects, which occur directly following fire.

Grasslands subject to annual fires may suffer several long-term effects, such as decreasing soil organic matter, changes in species composition, and long-term loss of nitrogen through volatilization and immobilization (Daubenmire, 1968; Old, 1969; Biederbeck *et al.*, 1980; Kucera, 1981; Risser *et al.*, 1981; Ojima *et al.*, 1990; Ojima, 1994a). Nitrogen limitation is a common characteristic of fire-maintained grassland and rangeland ecosystems (Seastedt *et al.*, 1991).

The influence of climate change on large-scale events, such as wildfire, can only be inferred. However, the predicted increase in climate variability has led several authors to suggest that the frequency and severity of wildfires will increase in grassland/rangeland settings (Graetz *et al.*, 1988; Moore, 1990; Ottichilo *et al.*, 1991; Cherfas, 1992; Torn and Fried, 1992).

2.3.3.   *Land Use and Management*

Land use differs from other factors influencing rangelands because of the inherent involvement of human socioeconomic factors. Human social/economic systems may produce more change in actively managed rangeland ecosystems than any other forces of global change (e.g., Burke *et al.*, 1995b). Model experiments to investigate the feedbacks between land-use change and the climate system suggest strong links (e.g., Dickinson and Henderson-Sellers, 1988).

The most common land-use transformation has been conversion of rangeland to cropland. The pattern of settlement has had important implications for rangeland transformations (Reibsame, 1990). Conventional agriculture has essentially mined many previous rangelands by enhancing decomposition, reducing soil organic matter, and increasing leaching and erosion (e.g., Bauer and Black, 1981; Burke *et al.*, 1989). The net result is that soils must now receive heavy doses of fertilizer

and pH buffers to produce acceptable yields in industrialized countries.

Land use can dramatically alter C storage and fluxes, and modification of land-use practices can greatly influence the net flux of soil C, changing rangelands from a source to a sink for atmospheric C. Although conversion to small-grain cropping is not a large deviation from natural grassland ecosystems relative to albedo (except in periods of bare soil), plant stature, growing season, and energy fluxes, conversion of grasslands to cropland can result in a rapid decline in C stores. Up to 50% of soil C can be lost as a result of conversion from native rangeland to crops (Haas *et al.*, 1957; Cole *et al.*, 1989, 1990; Burke *et al.*, 1989).

For example, the potential influences of changing land management and climate-change effects on C storage of grasslands were assessed using the Century model (Ojima *et al.*, 1993b; Parton *et al.*, 1995). Future soil C pools were calculated for a "regressive management" scenario (i.e., removal of 50% of the aboveground biomass during grazed months) and a "sustainable" scenario [i.e., using moderate grazing and burning regimes as specified by Ojima *et al.* (1993b)]. The impact of "regressive" land management resulted in a loss of soil C in all regions after 50 years, with the largest losses in the warm grasslands. The total net loss relative to current condition was projected at 10.8 Gt. When this regressive management is compared to the sustainable management system (i.e., light grazing), the net difference is 37.6 Gt of soil C.

2.4.   Issues of Scale

Scale is a particularly important issue in rangelands because of the very large size of management units, which is often caused by low productivity. Thus, rangeland management units incorporate spatial heterogeneity, instead of partitioning it as is usually the case in more intensive agricultural systems (Stafford Smith and Pickup, 1993). Most grasslands and rangelands are in climatic regions that are subject to frequent alterations in essential resource availability. The superimposition of management practices such as fire and grazing adds further variation in resource availability over time. Rangelands are characterized by more complex structure and function than other biomes because controlling factors (i.e., precipitation, energy, nutrients) often fluctuate rapidly over short time periods (Seastedt and Knapp, 1993). This variability in ecosystem behavior will lead to complex responses to global change.

The large areas of rangelands and the numbers of livestock they support play significant roles in biogeochemical and climate feedbacks. Response to climate change hinges on the variable scales at which these systems are used, the spatial heterogeneity incorporated in their management units, and the potentially large number of species that may interact in the primary production system (Stafford Smith, 1993). Limitations on production processes occur diurnally to seasonally through water and nutrient availability and management practices (including grazing pressure and distribution, fire, fertilizer use, and water management). Feedback effects on soils and vegetation composition,

---

Box 2-1. Impacts of Climate Change on Pastoral Peoples: The Example of Africa

Major shifts in climate—from relatively wet periods to dry periods or droughts—are common in the rangelands of Africa. Long-term rainfall records and other evidence from Africa's rangeland areas show that shifting climate dynamics have prevailed there for at least the last 10,000 years (Nicholson, 1983; Hulme, 1990). Traditional African livestock husbandry practices have been greatly influenced by the highly variable environment (Ellis and Swift, 1988; Behnke *et al.*, 1993; Ellis and Galvin, 1994). Because the economy depends directly and indirectly on livestock products, pastoralists have developed multiple coping mechanisms. Pastoralists cope with climate variability by keeping diverse species of livestock, by temporary emigration, by maintaining economic diversity, and even by allocating seasonal and drought-induced nutritional stress among stronger community members (Coughenour *et al.*, 1985; Galvin, 1992; Galvin *et al.*, 1994). This system requires extensive land area and external markets.

The pastoralists' stabilizing strategies have become constrained in this century primarily as a result of an increasing human population in conjunction with stable or declining livestock populations and decreasing land area. Although much recent literature suggests that livestock populations are on the increase, abundant data for the arid and semi-arid zones show otherwise. East African pastoralists have been unable to expand livestock holdings due to such factors as disease epidemics, recurring droughts, and intertribal raiding (Sandford, 1983; Homewood and Rodgers, 1984; O'Leary, 1984; Arhem, 1985; Sperling, 1987; McCabe, 1990). In addition, dry-season ranges with more reliable water supply have been lost to colonial and African agriculturalists, to game parks, and to game conservation areas (Campbell, 1984; Bekure *et al.*, 1987; Homewood *et al.*, 1987; Little, 1987). Pastoralists also have taken up agriculture in an effort to meet their increasing food demands. Thus, with increasing population pressure on a declining resource base, there is an expanding reliance on the marketing of animals. However, African livestock market infrastructure and stability is still in an early stage of development.

Persistence of the pastoralists' system in the arid and semi-arid ecosystems of Africa will require a clear understanding of the nonequilibrium dynamics of these systems and development of additional coping strategies.

including carbon and nitrogen sequestration, are thus influenced at seasonal, annual, and decadal temporal scales, but are experienced at landscape spatial scales.

2.5. Extreme Events

Increased frequency and magnitude of extreme events is often mentioned as a potential characteristic of future global climate (Easterling, 1990). Because extremes drive rangeland systems (Griffin and Friedel, 1985; Westoby *et al.*, 1989), small changes in the frequency of extreme events may have a disproportionate effect on what management must cope with in these systems. For example, the structure of long-lived perennial communities may change drastically if the frequency of extremes increases significantly, because seedling establishment and mortality of these plants are highly sensitive to extremes (Graetz *et al.*, 1988). Both the stability of forage supply and the balance between temperate and subtropical species are largely controlled by the frequency of extreme climatic events and thus are subject to change in a CO_2-warmed world (Campbell and Grime, 1993). Individual events (e.g., a major rainfall event that recharges deep moisture stores) and extended periods of above- or below-average temperature or rainfall are both likely to be significant (Stafford Smith and Morton, 1990).

Rangelands are systems adapted to a wide range in climate, fire frequencies, and grazing intensities, but anthropogenic fragmentation has already affected rangeland systems such that many systems may be vulnerable to further pressures (Archer, 1994). With the addition of climate change to existing impacts, rangelands may be more susceptible to extreme events such as drought, 100-year floods, and insect outbreaks.

2.6. Boundary Changes

Boundaries among rangeland vegetation types and between rangeland systems and other biomes are likely to change with changes in climate. Shifting boundaries between plant community types (the ecotone), potentially in response to past changes in climate, are well documented in the fossil record (Solomon and Shugart, 1993). Significant changes in the distribution of grasslands and arid lands worldwide in response to climate change are suggested by biogeographical models (Emanuel *et al.*, 1985; Prentice and Fung, 1990; Prentice *et al.*, 1992; Neilson, 1993; Henderson-Sellers and McGuffie, 1995). Specific changes in rangeland ecosystem boundaries will be determined by the nature of climate change, including the frequency and severity of extreme events. As nonequilibrium systems, rangelands may experience structural reorganization, and individual species may change distribution, but there probably will not be any synchronized movement of entire vegetation belts. Land-use change and human interventions will greatly modify the expressions of climate change and may overwhelm them, particularly in tropical and subtropical areas (Parton *et al.*, 1994).

Semi-arid and arid ecosystems may be among the first to show the effects of climate change (OIES, 1991). Their sensitivity to climate change may be due to the current marginality of soil water and nutrient reserves. The droughts of the 1930s and the 1950s in the United States, for example, changed plant production systems (Weaver and Albertson, 1944; Albertson *et al.*, 1957) and led to modification of land surface characteristics. Weaver and Albertson (1944) showed that the distribution of grasslands changed in the United States, with the shortgrass species moving eastward into the midgrass prairie and midgrass species moving eastward into the tallgrass prairie. In addition, these grasslands were invaded by ruderals (weedy species) and other non-native grasses. In Australia, the distribution of *Heteropogon contortus* shifted west in wet decades and eastward in drier periods (Bisset, 1962).

The balance between herbaceous and woody vegetation is sensitive to climate in most grassland/savanna regions (Parton *et al.*, 1994). Changes such as replacement of grasses with woody plants can occur quite quickly (Griffin and Friedel, 1985; McKeon *et al.*, 1989; Westoby *et al.*, 1989)—within a decade or so in response to a mixture of reduced grazing, fire suppression, and climate variability. Fire and grazing regimes, in conjunction with changes in climate characteristics affecting soil moisture status, relative humidity, or drought stress, will have the greatest influence on grassland-woody species boundaries (Neilson, 1986; Hulbert, 1988; Schlesinger *et al.*, 1990; Hobbs *et al.*, 1991; Archer *et al.*, 1995).

Mayeux *et al.* (1991) discuss evidence that open, mostly C_4 grasslands worldwide are becoming increasingly populated by C_3 woody plants—a process abetted, perhaps, by the 25 to 30% increase in atmospheric CO_2 and correlated rise in plant WUE in the last two centuries. There is ample evidence that C_3 woody species have increased in both mesic and arid C_4 grasslands during the historical period of CO_2 increase. The change from shrubland to grassland that would be predicted from climatic diagrams as plant water-use efficiency rose, however, has not been evident. Here, the opposing influence of a possible change to a warmer, drier climate since industrialization—perhaps in combination with grazing by domestic livestock (Hastings and Turner, 1965; Archer *et al.*, 1995)—may have negated the effects of increased CO_2 on vegetation structure.

In some regions, warmer temperatures and increased summer rainfall, with fewer frost days, may facilitate the encroachment of both annual and perennial subtropical C_4 grasses (e.g., *Digitaria sanguinalis*, *Paspalum dilatatum*) into some temperate C_3 grassland areas. This would likely cause a depression in forage quality and result in a more pronounced warm-season peak in biomass production, with consequent problems for traditional livestock systems. The rate of invasion of these and other weed species is expected to be greatest in more productive grassland and rangeland systems, with high stocking pressures, high utilization, and consequently greater opportunities for seedling establishment and invasion in gaps (Campbell and Hay, 1993; Campbell and Grime, 1993). The invasion rates of C_4 grasses may be offset to some extent by increased atmospheric CO_2 concentration (Campbell and Hay, 1993), but the effects are unclear.

Biogeographical shifts predicted for CO_2 and temperature increases are variable, depending on the vegetation classification used, general circulation model (GCM) assumptions, and assumptions about current vegetation distribution and equilibrium status (Parton *et al*., 1994). Recent analyses using BIOME 1.1 (Prentice *et al*., 1992) and IMAGE 2.0 (Alcamo, 1994) were compared to determine potential rangeland boundary shifts under different model assumptions (Table 2-3; see also Chapter 1, Figures 1-3 through 1-7, and Table 1-2).

The results suggest that rangelands are likely to be vulnerable to biogeographic change and that the areal extent of the changes may be significant (Table 2-3). Warm grass/shrub types will likely expand, while tundra ecosystems will most likely contract. The opposing results occur because of differences in the definitions of vegetation types, regional variation, and model assumptions. However, the analysis is instructive.

The direction of carbon-storage changes projected by three GCM models of climate change do agree quite closely under

Table 2-3: *Potential changes in extent of rangeland cover types from the BIOME 1.1 model (Prentice et al., 1992) and IMAGE 2.0 (Alcamo, 1994). Numbers are in 10^6 km^2 and are rounded, so numbers do not exactly sum.*

[4] See Chapter 3.

climate-change scenarios (Table 2-4). Analyses indicate that carbon stores are expected to increase in warm grass shrub and tropical savanna/dry woodland types, partly because these vegetation types are expected to expand (Solomon *et al*., 1993). Conversely, total carbon stores are likely to decline in the other major rangeland types.

It is important to compare these impacts to those resulting directly from human activity (Parton *et al*., 1994). According to Burke *et al*. (1990), the impact of a 2 x CO_2-driven climate-change scenario on grassland soil C levels in the southern Great Plains would be an order of magnitude smaller than the impact of plowing the grassland for crop production. Mosier *et al*. (1991) have shown that plowing and fertilization of grasslands increases N_2O flux by 50% and decreases soil sink strength for CH_4 by 50%. These impacts, too, are much larger than the potential effects of a 2 x CO_2-driven climate change (Burke *et al*., 1990). While the effects of plowing on soil carbon and trace-gas fluxes may be large on a regional basis, the impact of CO_2 and climate may be similar on a global average. The effects of climate and land-use changes combined could lead to more rapid changes than either would alone.

2.7.   Regional Variation

2.7.1.   *Low-Latitude Regions*

Natural tropical grasslands (Box 2-2) are a close second to tropical forests in extent and may equal them in productivity (Hall and Scurlock, 1991). Tropical grasslands and savannas are important as both a source and a sink of C at the regional and world level. Because of their extent, productivity, and capacity for above- and belowground biomass accumulation, the amount of C sequestered is very high (Fisher *et al*., 1994), (Tables 2-2 and 2-4). On the other hand, they are frequently burned and therefore represent a large efflux of C into the atmosphere. Almost one-fifth of the world's population lives in these ecosystems, many in rural societies that depend on subsistence agriculture (Frost *et al*., 1986).

Extreme events seem to influence the system more strongly than do average climatic parameters. Highly seasonal water availability and chronically low soil-nutrient availability appear to be the most limiting factors (Medina, 1982; Frost *et al*., 1986; Solbrig *et al*., 1992). Natural and anthropogenic fires are a major and apparently very ancient structuring force. In some tropical systems, frequent burning does not lead to major changes or invasion, and the dominants tend to recover fast (Coutinho, 1982; Farinas and San José, 1987; Lewis *et al*., 1990; Medina and Silva, 1990; Silva *et al*., 1991). In others, invasion of exotic species is the norm (D'Antonio and Vitousek, 1993). The effect of climate change on tropical rangelands will depend on the balance between increasing aridity favoring C_4 grasses and increasing CO_2 concentration favoring C_3 photosynthesis (Box 2-3). The already low nutritional value of most tropical grassland plants may decrease as a consequence of increased C:N ratio and because of higher

---

Box 2-2. The Northern South America Savanna

Location: Northern South America (Medina, 1986, 1987; Sarmiento, 1983, 1984; Sarmiento and Monasterio, 1983; Goldstein and Sarmiento, 1987).

Climate: Average daily temperatures ranging from 22°C to more than 35°C; average annual precipitation ranging from 800 to 2000 mm with a strong seasonal distribution, including a dry period of 3–6 months (Medina, 1982; Sarmiento *et al*., 1985).

Vegetation: Continuous cover of perennial grasses with a significant discontinuous cover of perennial woody plants (Medina, 1982; Medina and Silva, 1990).

Probable biological impacts of climate change: An alteration in the amount and pattern of rainfall, the occurrence of extreme events (e.g., hurricanes, drought), and the El Niño–Southern Oscillation (ENSO) may alter actual functioning of savanna ecosystems. The vegetation structure of the ecosystems located at higher altitudes may become similar to those 300–500 m lower in elevation. During ENSO years, precipitation in northern South America is lower (Aceituno, 1988), increasing the likelihood of drought. Because ENSO events could become more frequent and bring more severe weather under a doubled-CO_2 climate, these systems could fail to function as they do now.

---

production of secondary metabolites in C_3 plants (Oechel and Strain, 1985; Fajer *et al*., 1989). Thus, the carrying capacity for herbivores may be reduced in this region.

2.7.2. *Middle-Latitude Regions*

Temperate rangeland systems experience drought stress at some time during the year, but the degree of drought stress and its timing vary among regions. The distribution of different rangeland types is correlated with different climatic patterns, including the seasonal distribution of mean monthly air temperature and precipitation and the ratio of precipitation to potential evapotranspiration (e.g., see Boxes 2-4 and 2-5).

Temperate grasslands and associated savannas and shrublands clearly are vulnerable to climate change. Parton *et al*. (1993) highlight three ways in which changing climate might influence mid-latitude grassland ecosystem function and structure. In some grassland regions, significant reductions in precipitation or increases in temperature may accelerate degradation and lead to the replacement of grassland vegetation by woody species. Second, soil erosion rates may increase as plant cover decreases, leading to a nearly irreversible loss of productive potential. Finally, the above transitions are almost always exacerbated by intense human land use, as occurs in most temperate grassland and savanna regions (OIES, 1991; Archer *et al*., 1995). Degradation can thus occur through both functional (e.g., reduced primary productivity) and structural (e.g., perennial-to-annual vegetation, shrub encroachment) change (see Boxes 2-6 and 2-7).

Nutrient cycling in temperate grasslands is largely driven by climate. Rates of carbon gain, decomposition, and nutrient cycling are all sensitive to temperature and moisture (Parton *et al*., 1987; Schimel *et al*., 1990). Soil organic-matter storage—the primary

Table 2-4: *Rangeland BIOME 1.1 carbon stocks (in Gt) under three 1994 IPCC (Greco et al., 1994) climate scenarios (Max-Planck Institute, Geophysical Fluid Dynamics Laboratory, and UK Meteorological Office). Data are from Solomon et al., 1993; current carbon estimates can be found in Table 2-2.*

Box 2-3. African Savannas

Location: Nearly continuous distribution in the central African continent (see Figure 2-1).

Climate: Distinct wet (600–1500 mm/yr) and dry (400–800 mm/yr) savannas.

Vegetation: Distinct layers of woody and herbaceous vegetation. In the moist savanna, vegetation is dominated by broad-leafed trees of the genera *Brachystegia* and *Julbernadia* as dominants. Herbivory by large mammals consumes a relatively small fraction of total primary production (5–10%) due to high concentrations of secondary compounds (mainly tannins) and low nitrogen concentrations in the foliage of the woody plants; thus, there is a high fire-fuel load and a short (1–3 year) fire interval. Dry savanna is dominated by fine-leafed trees (mainly *Acacia*) and stoloniferous grasses (Scholes and Walker, 1993). Large mammal herbivory is high (10–50% of total primary production), the fuel load is low, and the inter-fire interval is relatively long (5+ years).

Probable biological impacts of climate change: The major predicted impact is an increase in the frequency and severity of drought (McKeon *et al.*, 1993). An increase in the frequency of drought is likely to lead to episodic die-offs of woody vegetation. This will increase the fire-fuel load and thus potentially increase the frequency and intensity of fires. The greatest impacts are likely to be in the semi-arid savannas, where human populations depend mainly on pastoralism (see Box 2-1). Human responses are likely to include increasing the distribution and security of surface water for livestock. This is likely to further weaken the grass layer, with acceleration of desertification. One strategy to bolster the production of animal protein would be to promote the sustainable use and management of indigenous herbivore species, especially preferential browsers (giraffe, eland, kudu, impala, etc.), many of which are independent of surface water and largely do not compete with domestic grazers.

---

reserve for nutrients in grasslands—is sensitive to temperature and generally decreases with increasing temperature. In New Zealand, research using both spatial analogue (Tate, 1992) and modeling approaches (Tate *et al.*, 1995) has shown that soil carbon could decline by about 5% per °C increase in regional temperature. If temperatures increase in grasslands worldwide, soil carbon storage is likely to decline (Parton *et al.*, 1994). Declining soil carbon would likely lead to nutrient loss in the longterm, and could lead to degraded hydrological properties and increased

erosion. Losses of soil carbon and increases in temperature could also lead to higher trace-gas emissions as the soil N-cycle is accelerated. Thus, carbon storage and nutrient cycling in temperate grasslands could change significantly if climate changes; indeed, interannual variability in climate is clearly reflected in observed and modeled production and decomposition. However, Buol *et al.* (1990) showed that, for soils that experience a wide annual temperature fluctuation, there is no correlation of organic carbon content to mean annual temperature.

Box 2-4. Rio de la Plata Grassland in South America

Location: Argentine Pampas, the Campos of Uruguay, and Southern Brazil.

Climate: Temperate humid to semi-arid. Mean annual temperature 13–18°C, mean annual minimum temperature <13°C. Mean annual rainfall 400–1600 mm, evenly distributed over the year in the east, becoming concentrated in spring and fall in the west (Cane, 1975; Cabrera, 1976; Lemcoff, in Soriano, 1992).

Vegetation: Mostly tall tussock grasses, but perennial grazing lawns are the actual physiognomy. C_3 and C_4 grasses, with the growth of C_3 and C_4 grasses segregated temporally (Cabrera, 1976; Arana *et al.*, 1985; Leon, in Soriano, 1992).

Probable biological impacts of climate change: These grasslands are vulnerable to drought. IPCC climate scenarios (Greco *et al.*, 1994) suggest that mean annual winter (JJA) temperatures may increase 0.5 to 1°C, while mean annual summer (DJF) temperatures may increase as much as 2°C. Generally summer (DJF) precipitation is expected to decline from 0–40% by the year 2050, while winter (JJA) precipitation may increase or decrease ±20% in the region (Greco *et al.*, 1994). If these projections are correct, the crop and animal production for the region could drop drastically. During the 1920s and 1930s, extremely dry conditions caused a shift of agriculture to the east, and the abandoned agricultural land eroded, with the loss of 60,000 km² of arable land (Suriano *et al.*, 1992). Unusually dry summers may bring about some long-lasting changes in community structure (Chaneton *et al.*, 1988; Sala, in Soriano, 1992). The projected changes may allow C_4 species to develop earlier in the season, while decreased summer precipitation will likely favor C_3 species.

Box 2-5. Mediterranean-Basin Region

Location: Bordering the Mediterranean Sea, stretching 5000 km eastward from the Atlantic coast between 30 and 45°N.

Climate: Transitional between temperate and dry tropical climates, with a distinct summer drought of variable length. Highly variable annual precipitation.

Vegetation: Evergreen sclerophyllous shrubs that change to heathlands in nutrient-poor soils along an increasing-moisture gradient and into open woodlands and annual grass or dwarf shrub steppes along an increasing-aridity gradient.

Probable biological impacts of climate change: A shift of carbon storage from soil to biomass is likely to occur, with probable negative effects on soil stability and increased erosion (Ojima *et al*., 1993b). Mediterranean rangelands are expected to undergo a 300–500 km poleward extension of grass and dwarf shrub steppes at the expense of the sclerophyllous shrubland. In Euro-Mediterranean countries, extension of shrubland as a result of agricultural release is expected, with a parallel increase in wildfires and evapotranspiration, and a decrease in livestock grazing with increases of game and other wildlife. In Afro-Asian Mediterranean countries, extension of agriculture and overgrazing in marginal areas, combined with overall smaller P:PET ratios, will probably lead to further degradation of plant cover and soil loss.

Finally, the balance between herbaceous and woody vegetation is sensitive to climate in most grassland/savanna regions, and the productivity and human utility of these systems is very sensitive to this balance (see Boxes 2-5 through 2-8).

2.7.3.   High-Latitude Regions

Warming is expected to be most pronounced at the poles (Spicer and Chapman, 1990; Long and Hutching, 1991). In the high southern latitudes of South America, annual mean temperature and low and irregularly distributed precipitation (especially as ice and snow) are the main factors constraining grassland productivity (Mann, 1966; Sala *et al*., 1989; Fernández-A. *et al*., 1991). Most Southern Hemisphere high-latitude grasslands lie to the south of the 13°C isotherm and are composed of C_3 species. By 2050, virtually all Southern Hemisphere grasslands might lie to the north of that isotherm; thus, the area would be more suitable for C_4 species (R. Rodríguez and G. Magrin, pers. comm., on the basis of Deregibus, 1988). This change in species composition would decrease the nutritional value of the grasslands, further decrease their carrying capacity, and eventually aggravate the overgrazing-erosion problem. On the other hand, dominant C_3 grasses and shrubs may be promoted by elevated CO_2, depending on water availability, and the increased growth may eventually lead to increased production and carrying capacity.

Indirect temperature effects associated with changes in thaw depth, nutrient availability, and vegetation will cause substantial

---

Box 2-6. Great Basin of North America

Location: Nevada and rain-shadow parts of Oregon, California, Utah, and Arizona in the United States.

Climate: Continental climate with average annual precipitation averaging 50–250 mm. Snow and hard frost are common in winter.

Vegetation: The Great Basin desert is dominated by big sagebrush (*Artemesia tridentata*), although other shrubs dominate on shallow saline soils (*Atriplex* sp.) or in specific soil complexes. Cover is generally low, varying from 5 to 50%.

Some probable biological impacts of climate change: There are a number of possible vegetation changes that could occur as a result of IPCC climate-change scenarios. An increase in precipitation during the growing season may increase the proportion of grasses and forbs over woody plants, which may increase the potential for more frequent fires, further favoring grasses. Cold conditions with increased precipitation during the winter will likely favor drought-tolerant woody species (e.g., *Artemisia* sp.) over herbaceous species. These conditions would also decrease fire frequency, thereby benefiting woody plants over grasses and forbs. Mild, wet winters and dry summers may enhance the spread and dominance of introduced Eurasian annuals such as cheatgrass (*Bromus tectorum*) and Russian thistle (*Salsola kali*). Cheatgrass is a fire-prone species, and previous work has demonstrated that frequent fire-return intervals occur with cheatgrass dominance (Whisenant, 1990). A decrease in total annual precipitation will likely result in shrub steppe communities shifting toward desert shrub.

Box 2-7. European Steppe and Semi-Natural Grassland

Location: Scattered throughout Europe.

Climate: Steppes occupy sites with a continental climate and annual rainfall between 350–500 mm concentrated in the warm season, but with late-summer drought (Walter, 1968). Semi-natural grasslands occupy a wide range of climates, with annual rainfall between 400 mm and 2300 mm (Titlyanova *et al.*, 1990).

Vegetation: Steppes are multi-layered communities (Lavrenko and Karamysheva, 1992), with tall bunch grasses (*Stipa* sp.), short bunch grasses (*Cleistogenes* sp., *Festuca* sp.), and dwarf bunch species (*Carex* sp., dwarf *Stipa* sp.); moss layers are dominant in the northern zone, and ephemeral plants plus lichen layers are dominant in the southern zone. Semi-natural grasslands are secondary plant communities with a multi-layer structure of grasses and forbs (Rychnovska, 1992). Floristic diversity provides semi-natural grasslands better potential adaptation to climate fluctuations; belowground biomass and soil aggregation are the main stabilizing factors.

Probable biological impacts of climate change: Increases of $3 \pm 1.5°C$ within the next century as projected in current scenarios (Greco *et al.*, 1994), could cause a 250–300 km northern displacement of phytoclimatic boundaries (Anderson, 1991) with a substantial reduction of tundra, mires, and permafrost areas and a parallel expansion of grassland and grain cropping into the southern margin of boreal forest zones in Europe. In addition, changes in the concentration of atmospheric gases may alter the competitive relationships in the plant community. For example, indirect competitive effects have been reported in southern Britain (Evans and Ashmore, 1992), where above-normal ozone concentrations caused a decrease in the biomass of upper-layer dominant grasses with a parallel increase in lower-layer forb biomass by reducing competition for light.

---

changes in Arctic species composition, litter quality, and nutrient availability (Chapin and Shaver, 1985; Oberbauer and Oechel, 1989; Kielland, 1990; Marion *et al.*, 1991; Nadelhoffer *et al.*, 1991; Havstrom *et al.*, 1993; Wookey *et al.*, 1993; Chapin *et al.*, 1995). Increased nutrient availability increases shrub abundance and decreases the abundance of mosses, an important soil insulator (Chapin *et al.*, 1995).

The changes in biotic interactions that will occur with climatic warming are poorly known. Field experiments of ≤10 years duration, simulating a 3°C warming, show an increase in shrub abundance and a decline in species richness (Chapin *et al.*, 1995). Insect-pollinated forbs are expected to decline — suggesting that insect pollinators (Williams and Batzli, 1982) and migrating caribou, which utilize these forbs during lactation, could be adversely affected (White and Trudell, 1980). Warmer summers also increase insect harassment of caribou and cause declines in feeding and summer energy reserves. In contrast, browsing mammals, such as snowshoe hare and moose, may benefit from climatic warming because an increase in shrubs will increase fire frequency and lead to an increase in the proportion of early-successional vegetation.

The presence of trees at high latitudes may be determined more by soil temperature than by air temperature (Murray, 1980), so expected warming of soils and increase in thaw depth could have a strong influence on treeline location. Simulation models suggest that conversion of boreal forest to a treeless landscape would increase winter albedo, reduce energy absorption, and cause a 6°C decrease in regional temperature (Bonan *et al.*, 1992). Conversely, we expect treeline advance to provide a strong positive feedback to regional and global warming.

Regional warming and treeline advance are expected to increase fire frequency, directly releasing CO_2 stored in peat to the atmosphere. Current predictions (Anderson, 1991) indicate that the tundra may change from being a sink to a source of C, with a net flux to the atmosphere of about 100 g $C/m^{-2}/yr$. This study also projected that about 15% of C storages in soils of peats, tundra, and boreal forests could be released over the next 50 years. Recent work suggests soil drying over the past decade (Maxwell, 1992) has already changed the Alaskan tundra from a net sink to a net source of CO_2 (Anderson, 1991; Oechel *et al.*, 1993; Zimov *et al.*, 1993a, 1993b).

2.8.   Modeling Rangeland Ecosystem Response

Several models are currently used to predict rangeland response to climate change and land use. While most global-scale models are correlational — such as those based on the Holdridge Life Zone classification scheme (e.g., Emanuel *et al.*, 1985) — there are many regional-scale models of ecosystem dynamics in rangelands (e.g., Century: Parton *et al.*, 1987, 1988, 1994; GEMS: Hunt *et al.*, 1991; GRASS: Coughenour, 1984; Hurley model: Thornley and Verbene, 1989; Thornley *et al.*, 1991; SPUR: Hanson *et al.*, 1993; STEPPE: Coffin and Lauenroth, 1990; GRASP: McKeon *et al.*, 1990).

These models generally show that when a variety of directional climate change scenarios are imposed on rangeland ecosystems, such as in Century model simulations, effects are detectable but small on a per-unit-area basis relative to changes induced by management activities (Burke *et al.*, 1989) — although climate effects are more substantial globally (Parton

---

Box 2-8. Australian Tussock Grassland and Steppe

Location: Alluvial plains running southwest from the eastern half of the continent.

Climate: There is an enormous climatic gradient across the continent, from 100–200 mm median annual rainfall in the central part of the region—distributed throughout the year at random, without seasonality—to 800–900 mm along the northern and southern borders, the former concentrated in summer and the latter in winter as a Mediterranean-type climate. In the south, there are a significant number of frosts; winter rains are usually gentle and associated with frontal systems passing around the South Pole. In the north, there is no frost, and rains are often monsoonal and very heavy. Occasionally, northern cyclonic incursions may reach the south, bringing the heaviest rainfall events. Rainfall variability is very high—increasing toward the equator and as annual totals decline—and is greatly affected by ENSO and other climatic systems driven by sea surface temperatures in the Pacific and Indian oceans.

Vegetation: A complex range of communities, including monsoon tallgrass (*Schizachyrium* sp.), subtropical and tropical tallgrass (*Heteropogon contortus*), tussock and midgrass (*Astrebla* sp., *Aristida* sp., *Bothriochloa* sp.), hummock grasslands (*Spinifex* sp.), acacia and eucalyptus shrublands and woodlands, temperate grasslands (*Themeda triandra*, *Danthonia* sp.), annual grasslands (*Echinochloa* sp.), and chenopod shrublands (*Atriplex* sp., *Maireana* sp.).

Probable biological impacts of climate change: Scenarios of future climate (Greco *et al*., 1994) suggest increased variability and unpredictability in productivity and community composition in the region (McKeon and Howden, 1991; Stafford Smith *et al*., 1995). A shift toward summer rainfall will have a major effect in southern Australia, where vegetation is currently dominated by winter rainfall (Stafford Smith *et al*., 1995). Although it is unlikely that mean climatic conditions will move outside their envelope of current possible conditions, extreme drought periods, high intensity rainfalls, and water distribution could become more common (Whetton, 1993; Stafford Smith *et al*., 1995).

---

et al., 1995). A recent intercomparison of several of these models showed that the degree to which forests invade grasslands or vice versa depends on the GCM climate scenario used (VEMAP Participants, 1995).

These models, plus recent global-scale mechanistic models, have been used to evaluate the outcome of various management schemes, including fire, grazing, and strip-mine reclamation (e.g., de Ridder *et al*., 1982; Coughenour, 1984, 1991; Coffin and Lauenroth, 1990; Ellis *et al*., 1990; Ågren *et al*., 1991; Hunt *et al*., 1991; Holland *et al*., 1992; Hanson *et al*., 1993; Ojima *et al*., 1994b). They have also been used to assess potential impacts of various climate scenarios on plant productivity and nutrient cycling (e.g., BIOME-BGC: Running and Hunt, 1993; Century: Parton *et al*., 1987, 1992, 1994; SPUR: Hanson *et al*., 1993; TEM: McGuire *et al*., 1992).

Results from tests of rangeland sensitivity to climate and management using these models support previous discussion of the importance of seasonality and distribution of rainfall, and suggest that rangelands are sensitive to changes in environmental conditions associated with fire and grazing as well as their land-use history.

2.9. Human Adaptation

By the time there is a detectable rise in mean temperature of a degree or two, pastoral societies may already have begun to adapt to the change. Adaptation may be more problematic in some pastoral systems where production is very sensitive to

climatic change, technology change is risky (Caceres, 1993), and the rate of adoption of new technology is slow. Decreases in rangeland productivity would result in a decline in overall contribution of the livestock industry to national economies. This would have serious implications for the food policies of many underdeveloped countries and on the lives of thousands of pastoral peoples.

Intervention—in terms of active selection of plant species and controlled animal stocking rates—is the most promising management activity to lessen the negative impact of future climate scenarios on rangelands. Proper rangeland management, including sustainable yield and use of good-condition areas while marginal or poor condition areas are allowed to rest, will become increasingly necessary under climatic conditions projected for the future. A shift in reliance toward more suitable and more intensively managed land areas for food and fiber production could have the dual benefits of greater reliability in food production and lesser detrimental impact of extreme climatic events such as drought on rangeland systems. Improvement and intensification of management of certain areas of rangeland may also have the additional benefit of reducing average methane emissions per head of livestock because of improved feed quality.

One management option for the future is to actively change species composition of selected rangelands. Legume-based grassland systems may become more important in the future because legumes reduce the reliance on fertilizer inputs and improve the nutritive value of forage. The use of leguminous species is important as a means of producing more-sustainable

forage systems (Riveros, 1993). Legume species generally show larger yield responses to elevated CO_2 than do grasses at warm temperatures and also show enhanced nitrogen-fixation rates (Crush *et al*., 1993; Newton *et al*., 1994; Campbell *et al*., 1995a). The benefits of leguminous species could be offset to some extent by future increases in damaging UV-B radiation (Caldwell *et al*., 1989), because legumes may be quite susceptible to UV-B relative to other species (Krupa and Kickert, 1989; Brown, 1994). However, the effects are uncertain at present because there are only limited experimental data available on the effects of future UV-B radiation levels on forage and rangeland legumes.

In some grass-dominated rangeland systems, improved pastures may help people to adapt livestock grazing strategies. In these systems, there is significant intervention—including selection of forage type, selective animal breeding, pasture renewal, irrigation, and other practices (Campbell and Stafford Smith, 1993). This intervention provides opportunities for graziers to adapt systems so they are protected against negative effects of global change and so that any potential benefits are realized. McKeon *et al*. (1993) developed a scheme for adapting rangelands to climate change by linking management decisions to climate variability.

2.10.   Mitigation

Opportunities for reducing greenhouse gas (GHG) emissions on rangelands (Table 2-5) include maintaining or increasing carbon sequestration through better soil management (Ojima *et al*., 1994b), reducing methane production by altering animal-management practices (Cicerone and Oremland, 1988; Howden *et al*., 1994), and using sustainable agriculture practices on rangelands capable of sustaining agriculture (Mosier *et al*., 1991).

Productivity and carbon cycling in rangeland ecosystems are directly related to the amounts and seasonal distribution of precipitation and are only secondarily controlled by other climate variables and atmospheric chemistry (Sampson *et al*., 1993). In fact, rangeland productivity may vary as much as fivefold because of timing and amounts of precipitation (Walker, 1993).

Carbon storage in grasslands, savannas, and deserts is primarily below ground (Table 2-2). Estimates using the BIOME model (Solomon *et al*., 1993) suggest that in the world's rangelands approximately 595 Gt C is stored in belowground biomass (44% of the world's total), while only about 158 Gt is stored in rangeland aboveground biomass. Thus, good soil management is the key to keeping or increasing C storage and protecting rangeland health (condition). Improving rangeland health, and thus the amount and kind of vegetation, will also reduce methane emission from ruminant animals per unit product by improving the quality of their diet. Total methane emissions from the grazing system will decrease only if there are commensurate reductions in animal numbers in the less-resilient parts of the grazing landscape however (Howden *et al*., 1994).

Nonsustainable land-use practices such as inappropriate plowing, overgrazing by domestic animals, and excessive fuelwood use are root causes of degradation of rangeland ecosystems (Ojima *et al*., 1993b; Sampson *et al*., 1993). Some systems may already be degraded to such an extent that the ability of the ecosystem to recover under better management practices will be greatly hampered. Practices listed in Table 2-5 may prove to be useful in GHG mitigation. None of the practices is relevant for every country, social system, or rangeland type. Unfortunately, because of the high dependence of rangeland function on adequate amounts and timing of rainfall, none of these practices is likely to significantly improve rangeland function and carbon sequestration without adequate rainfall (Heady, 1988; McKeon *et al*., 1989).

Reduction of animal numbers. Reduction of animal numbers can increase carbon storage through better plant cover (e.g., Ash *et al*., 1995) and decrease methane emissions. This practice can have a positive ecosystem effect if there is sufficient rainfall, but reduction in animal numbers on rangelands may require alternative sources of food for humans, and thus changes in national and/or regional food-production policies.

Changing the mix of animals. Changing the mix of animals on a given rangeland area can increase carbon storage and decrease methane emissions, but the benefit derived depends on the kind of rangeland and the proposed mix of animals. If a country is considering only cattle and small stock (sheep, goats, etc.), the mix may not be ecologically efficient; rather, it may reflect an economic risk aversion—in bad times, cattle die but goats survive. In this kind of grazing mix, the ecosystem may deteriorate. In contrast, a mix of cattle and wildlife ruminants may be both ecologically and economically efficient.

Changing animal distribution. Changing animal distribution through salt placement, development of water sources, or fencing can increase carbon sequestration through small increases in plant cover overall and improved status of the root system (due to less intense grazing). None of the changes in animal distribution, however, is expected to affect methane production. Animal-management practices will be specific to local and regional production systems; for example, fencing and/or placement of salt may not be useful in herding systems and may potentially interfere with wildlife migration. Costs and practices will vary widely by region.

Agroforestry. In regions where woody species and grasses coexist (Boxes 2-2, 2-3, 2-5, and 2-8), management practices to enhance both woody and herbaceous productivity may increase carbon storage and reduce methane emissions per unit product from domestic and wild ruminants, by improving the quality of the diet.

Watershed-scale projects. Practices involving the development of dams with large-scale water-storage capacity may improve long-term carbon storage and reduce animal methane production per unit product, by improving the quality of the diet through improved animal-management options and improved

Table 2-5: *Practices (mitigation options) to improve rangeland condition or health, and to reduce GHG emissions on rangelands. Possible effects of implementing each practice are listed for two greenhouse gases, and qualitative cost/benefits estimates are provided. Unhealthy, poor-condition rangelands are those lands where soil loss, plant species and cover loss, species invasions, and interrupted and poorly functioning nutrient cycling are the norm. Good condition, healthy rangelands, on the other hand, have nutrient cycling and energy flows intact; soils are not eroding; and plant species composition and productivity is indicative of a functioning ecosystem (NRC, 1994).*

Practice	Healthy	Not Healthy	Carbon	Methane	Biophysical Benefit/Cost	Soc./Cultural Benefit/Cost	Economic Benefit/Cost	General Comments
Reduce animal numbers	No	Yes	Increases carbon sink because of increasing vegetation cover and better root growth	Reduces animal methane production through reduction in total number	Increases plant cover, increases soil organic matter, and improves productivity	Depends on country and value of animals as a social resource	Depends on the value of livestock products to national and/or local economy	May require changes in national and/or regional food production policies
Change mix of animals	Yes	Yes	Possible increase in carbon sink with change in plant species	Change to native herbivores reduces emissions in some cases	Potential changes in plant species composition	Depends on country and cultural value of specific animal type	Depends on the value of livestock products	Positive effect in general; improves efficiency of utilization
Alter animal distribution by placing salt licks or feed supplements	Yes	Yes	Increases carbon sink because of increasing vegetation cover overall	Feed supplements may decrease methane production	Useless in rangeland areas already high in salt, but very useful in rangelands low in N,P	Appropriate in countries where animals graze extensively, rather than herded	Cost and distribution of salt and supplements	Positive; not applicable for herding systems
Alter animal distribution by placing water resources	Yes	Yes	Potentially increases carbon sink by increasing total vegetation cover	No effect	Developed water resources may not be sustainable	May affect territorial and property boundaries	Motorized water sources often too costly to purchase or maintain	Negative impacts if used to increase numbers of animals
Alter animal distribution by placing fences	No	Yes	Increases carbon sink because of vegetation cover overall	No effect	Benefit is to control domestic animal number and distribution	Depends on country and livestock/ wildlife system	Varies, depending on country and source and kind of materials	Potentially interferes with wildlife migration
Provide livestock protein and phosphorus supplement	Yes	Yes	If supplement increases intake (usual case) and stocking rate is not reduced, soil carbon may decline	Decrease in methane production, especially CH_4 per unit product	May reduce extensive grazing to some degree	Possible where animals are herded	Cost of protein blocks or similar supplement, but often large increases in productivity	Potentially difficult to distribute to local areas

Table 2-5 continued

Practice	Healthy	Not Healthy	Carbon	Methane	Biophysical Benefit/Cost	Soc./Cultural Benefit/Cost	Economic Benefit/Cost	General Comments
Increase native grasses and/or plant-adapted species	No	Yes	Increases carbon sink because of increasing vegetation cover overall	Possible methane reduction if quality of diet increases, but animals eat more	Benefit in retention of native species for gene conservation	Local people rely on native species for medicine and other health-related goods	Depends on the value of livestock and wildlife products, and the value of herbal medicine	Potential unknown benefits from native species; adapted species survive over the long term
Selective application of herbicides	No	Possibly	Potentially increases carbon sink, although not if woody species removed	Potential increase if animal numbers expand	Cost if non-target species affected: water pollution, damage to food chain	Cost if non-target species affected: water pollution, damage to food chain, removal of firewood source	Varies, depending on country and source of herbicide	Costs or benefits depend on meeting of management goals
Mechanical treatment or restoration	No	Possibly	Potentially increases carbon sink	Potential increase if animal numbers expand	Potential for large-scale alteration of soil and vegetation	May not fit pastoral system	Varies with country, depending on availability of equipment	Benefits depend on success of treatment relative to disruption of ecosystem
Plant halophytes (salt-tolerant species)	If appropriate		Increases carbon sink and increases productivity	No known effect	Benefit with increased plant cover and productivity	Benefit with increasing forage production for livestock and wildlife	Cost of planting and maintaining with irrigation	Brings into production otherwise non-productive land
Apply prescribed fire	Yes	Yes	Increases carbon sink and increases productivity in the long term on appropriate rangeland types	Possible methane reduction per unit product by increasing quality of diet	In systems adapted to fire, can increase productivity and maintain nutrient cycling	Use of fire can be part of social system; uses local knowledge	Threat of wildfire and destruction of human resources	Short-term increase in CO_2 to atmosphere; long-term benefits in adapted systems
Implement agroforestry systems	Yes	Yes	Increases carbon sink and increases productivity in the long term on appropriate rangeland types	Possible methane reduction per unit product by increasing quality of diet	Possible benefit with increased plant cover, diversity, and productivity	Potential benefit with change in grass/browse forage mix for livestock and wildlife	Cost of planting and maintaining	Increases carbon storage in trees; benefit in diversity and productivity if adapted species are used

Table 2-5 continued

Practice	Healthy	Not Healthy	Carbon	Methane	Biophysical Benefit/Cost	Soc./Cultural Benefit/Cost	Economic Benefit/Cost	General Comments
Develop large-scale watershed projects	Possibly	Possibly	Increases carbon sink and increases productivity	Methane reduction by increasing quality of diet	Potential for large land disturbance, with benefit to human and animal populations because of regulated and regular water supply	Potential for improved food production, both plant and animal	Cost of dams, etc.; benefit of hydroelectric power	Potential for increased human and animal populations because of increase in water availability

food-production systems. However, such projects are expensive and can result in social and cultural dislocation, local extinction of wildlife, and may result in increases in both human and animal population density.

Although rangelands have been used historically for livestock production for meat, wool, hides, milk, blood, and/or pharmaceuticals, policymakers must realize that an equally important objective for maintaining rangelands may be to maximize the number of domestic animals as a social resource (e.g., in some tribal cultures, wives are bought with livestock). Rangelands also are increasingly affected by human activities for mineral production, construction materials, fuel, and chemicals. Additionally, rangelands provide habitat for wildlife, threatened and endangered species, anthropological sites, ecotourism, and recreational activities. As the human population grows, rangelands also incur increased demand for marginal agriculture production. All of these activities and uses potentially affect rangeland condition—and thus the potential of the ecosystem to sequester carbon.

Using the practices in Table 2-5 requires the recognition that productivity on rangelands is variable and that vegetation and animal response to changes in livestock numbers is not linear. Futhermore, there are system lags, and management activities may result in largely irreversible changes in the rangeland system. Risk-management strategies include long-term low stocking or changing animal numbers annually to track variation in precipitation (McKeon *et al.*, 1993). Either approach requires flexible management response to different events, opportunities, and hazards and whole-system analyses in which the interactions of climate, land management, fire, and plant and animal species and communities will determine the outcome.

2.11.   Research Needs

We need to know more about the C and N storage capacity of soils under different conditions of degradation and under different land uses and land management, as well as the potential for increased sequestration of C, especially in whole-system analyses. More information is needed regarding the actual release rates of various greenhouse gases in real environments, across the spectrum of climates, soils, and land uses (rather than the current measurements just from a few points) and land management. Our lack of ability to track plant responses within growing season also affects our ability to accurately estimate rapid changes in greenhouse gas fluxes and remains a major gap in our ability to link management practices with global climate-change issues.

Rangeland research on climate-change effects should emphasize multispecies field experiments. The concept of functional groups might be a way to cope with the overwhelming species diversity of most rangelands, especially grasslands. Models that incorporate nonequilibrium theory in grassland and rangeland ecosystem response would be most useful.

Rangeland research emphasis should be on multidisciplinary projects in which different components (e.g., vegetation, soil, herbivores) and various approaches (e.g., conservation, economic sustainability) are simultaneously considered. Maintenance of long-term monitoring sites is essential for understanding boundary changes (especially C_3/C_4, shrub/grass boundaries), as well as fire, herbivory, and land-use affects on rangeland productivity and diversity. Along with monitoring, there needs to be an ongoing analysis of the results and review of monitoring methods and criteria.

Information on various aspects of climate, community structure and function, and land use needs to be standardized.

At a national level, scientists and policymakers must better understand the implications of land use for global-change issues, because land use and management feeds into global change as well as being influenced by it. The interaction between human population growth and rangeland use must also be better understood. Land use will change in the future as a result of altered climatic extremes (especially those in rainfall and temperature), decreased productivity and soil fertility,

and possibly socioeconomic changes spurred by adaptation and mitigation requirements.

Interfacing research on global change effects on agroecosystems with those on rangeland systems would be helpful in that it would promote access to a greater range of databases and models. The International Geosphere Biosphere Programme (IGBP)—Global Change and Terrestrial Ecosystems (GCTE) Project Task 3.1.3 (Pastures and Rangelands) (Campbell and Stafford Smith, 1993; Stafford Smith *et al.*, 1995) is combining the research efforts of grassland scientists in improved pastures and rangeland systems to predict global-change effects on the whole spectrum of different grassland types, taking into account future land-use change.

Finally, detailed analyses of the potential biological effects of climate change in terms of rangeland boundaries, coupled with an economic assessment of potential effects on pastoral peoples and national economies, will improve future assessments of impact, adaptation, and mitigation potentials on rangelands.

CONTENTS

EXECUTIVE SUMMARY

Deserts are an environmental extreme. The biota in deserts are at the limit of conditions that allow growth and survival and show very specialized adaptations to aridity and heat. The biomass of plants and animals is low; nevertheless, deserts have a significant species richness and a high endemism. The following statements regarding climate change can be made with certainty:

- Most deserts are likely to become even more extreme if climate changes as projected by current scenarios; most desert regions are expected to become hotter and most will probably not become significantly wetter (Medium Confidence).
- If changes in the frequency or intensity of the rainfall events occur, they are likely to cause changes in the flora and fauna. Higher atmospheric CO_2 concentrations and more intense rainfall events may lead to the opportunity for greater invasion of desert systems, particularly by C_3 plants. More frequent large pulses of rain will allow ephemeral organisms to reproduce more often. Any reduction in the intensity of the rainfall, however, could also be detrimental to this set of organisms due to false starts in their life cycles (Medium Confidence).

- In a few places (e.g., central Australia) conditions may improve, but any net change in rainfall—thus the vegetation—will depend largely on the human management of these regions (Low Confidence).
- Opportunities to mitigate greenhouse gas emissions in desert regions are few (High Confidence).

Human-induced desertification has the potential to counteract any ameliorating effect of climate change on most deserts unless appropriate management actions are taken.

3.1.   Introduction

This chapter describes deserts and the main processes that dominate extreme desert environments. It then discusses how these processes might be affected by climate change. Variability in different deserts is described, and the likely impacts on specific areas are explored. The chapter concentrates on the hottest and driest land types and excludes extreme-cold deserts of polar regions.

3.2.   Climate and Biology

3.2.1.   *Definition and Extent*

Deserts are characterized by low rainfall that is highly variable both intra- and interannually. Desert air is very dry, and incoming solar and outgoing terrestrial radiation are intense. Large daily temperature fluctuations occur (ca. 30°C), and potential evapotranspiration is high. There is high spatial and temporal variability in desert biota, driven largely by water availability (Noy Meir, 1985).

There are many definitions of deserts, but the common point is that water (or the lack of it) is the dominant factor controlling ecosystem processes. A common definition classifies ecosystems with an annual rainfall of <250 mm as arid and <100 mm as extremely arid (Noy Meir, 1973; Walter, 1985). Both are commonly referred to as deserts, but this chapter concentrates on the extremely arid regions; Chapter 2 deals with most aspects of arid and semi-arid regions. The permanent biota in extremely arid regions have specialized adaptations to cope with the harsh environment—sometimes obtaining their moisture from fog or dew. There also are ephemeral biota that migrate into desert regions or become active from drought-resistant seeds or dormant life stages, to take advantage of the rare rainfall events. Thus, extreme deserts have very distinctive characteristics.

Desert environments arise in several circumstances. Most deserts occur between 20° and 40° latitude, where persistent high-pressure cells bring dry air to the Earth's surface (see Figure 2-2 in Chapter 2). However, the climate depends on the precise balance between this air mass and topography, continentality, and sea currents (Evenari, 1985a). Some deserts are in the rain shadows of major mountain ranges (e.g., the Atacama desert of South America; see also Chapter 5). Others are a great distance from a source of oceanic moisture or are more-or-less continuously swept by winds that have traveled a great distance over land (e.g., the central Asian deserts).

Approximately 30% of the globe's land surface is desert or semi-desert, with almost 5% receiving less than 70 mm annual rainfall, 11% less than 100 mm, and 18% less than 120 mm (Shmida, 1985; Le Houerou, 1992). Some of the extremely arid deserts are shown in Figure 3-1. Human population estimates for the extremely arid regions are not available; however, for regions classified as drylands (i.e., <75 growth days per year)

it is over 800 million people (World Resources Institute, 1988–89). Many of these people will be affected by phenomena described in this chapter.

3.2.2.   Biological Productivity

Average aboveground net primary productivity in areas with annual precipitation of <250 mm varies from almost 0 to about 2000 kg/ha/yr (Evenari *et al.*, 1971; Noy Meir, 1973; Hadley and Szarek, 1981; Webb *et al.,* 1983; Le Houerou, 1984). Most productivity estimates are for aboveground vegetation only; there is very little information on belowground plant productivity. Root to shoot ratios differ greatly among desert life forms (Noy Meir, 1973). Ephemeral species often have relatively small root systems (root:shoot < 0.5), whereas some perennials have large belowground storage systems with root:shoot ratios as high as 20. Productivity is directly related to rainfall, often by a simple linear function. Alternatively, it can be expressed as a close relationship with actual evapotranspiration because actual evapotranspiration is closely related to rainfall (Branson *et al.,* 1981). Estimates of water-use efficiency by desert plants vary from 0.3 to 2.0 mg dry matter produced per gram of water transpired, with a threshold of 25 to 170 mm of annual rainfall to sustain any vegetation at all (Noy Meir, 1973; Webb *et al.*, 1978).

3.2.3.   Desert Biodiversity

Although deserts are not as diverse as some biomes, they have significant diversity—with many groups of organisms and often a high degree of endemism (Le Houerou, 1992). Taxa that are diverse relative to other biomes include predatory arthropods, ants, termites, snakes, lizards, migratory birds, succulents, and annual plants (McGinnies *et al.,* 1968; Huenneke and Noble, 1995). There is substantial variation in the richness of particular taxa among the deserts of different continental areas (Evenari, 1985b; Huenneke and Noble, 1995). Desert biota are unusual in the frequency with which particular morphological or physiological adaptations have evolved independently in different taxonomic groups (Cloudsley-Thompson, 1993). For example, many animals and plants have thick skins or cuticles to reduce water loss; other have hairs or spines to reflect radiation.

Biodiversity—measured as the number of species (i.e., species richness)—is moderately high in semi-arid regions and declines with increasing aridity for most taxa (Shmida, 1985; Pianka and Schall, 1981; Currie, 1991; O'Brien, 1993). For example, Aronson and Shmida (1992) found that plant species richness fell linearly from 116 species at a site with 280 mm mean annual rainfall to 15 species at a site with about 30 mm mean annual rainfall. The number of life forms (e.g., annual grasses, small shrubs) declined with increasing aridity, and only chamaephytes (low-growing perennial plants with buds just above the soil surface; e.g., *Salsola tetrandra*) persisted at the driest sites in all years. In addition, they found very little fluctuation of species richness with variability in annual rainfall at the driest site.

Correlative studies show that the diversity and density of some animal groups are related to vegetation productivity gradients, precipitation, and potential and actual evapotranspiration (Clark, 1980; Maurer, 1985; Owen, 1988; Currie, 1991; Hoffman *et al.,* 1994; Specht and Specht, 1994). However, the links are complex—depending on the taxonomic group, seasonality of precipitation, frequency of droughts, and the scale at which diversity and density are measured. Thus, changes in animal populations in response to changes in climate are very difficult to predict.

3.3.   Ecosystem Variables

3.3.1.   Temperature

The hottest deserts of the world (e.g., central Sahara, Namib) have average monthly temperatures above 30°C during the warmest months, with extremes above 50°C. The diurnal range often is very high, with nights as cold as 10°C. High insolation loads mean that soil surface temperatures often rise to more than 80°C (Cloudsley-Thompson, 1977).

Some high continental deserts have extremely cold winters; e.g., the Chihuahuan Desert in North America has average monthly minimum temperatures below freezing (MacMahon and Wagner, 1985). Cold conditions prevent effective growth of plants in winter; however, snow or moisture often accumulates and can contribute to growth in the warmer months.

3.3.2.   Rain and Soil Moisture

3.3.2.1.   Factors in Moisture Budget

Precipitation, soils, and temperature all contribute to the nature of desert ecosystems. Vegetation is largely a function of rainfall modified by soil type (in particular, the coarseness of the soil; Bertiller *et al.,* 1995) because these two factors determine potential soil moisture and water-holding capacity. Higher temperatures usually imply higher vapor-pressure deficits (evaporative demands) and thus higher evaporation and transpiration losses.

The availability of moisture at and near the soil surface is critical for the activity of desert organisms. The water available to plants is dependent on the balance between input from precipitation and losses from direct evaporation from the soil surface, transpiration through the leaf-root systems of plants, and drainage below the root zone. Thus, the effectiveness of a given amount of rain is dependent on how far it infiltrates below the surface; greater penetration reduces evaporative losses. More-intense rainfall events tend to penetrate less and create more runoff than less-intense events. In contrast to most other arid ecosystems, the sandy soils of extreme deserts

support higher plant biomass than do clay soils (Walter, 1985) because water penetrates deeper in coarser soils.

To a large degree, water loss due to transpiration is an unavoidable byproduct of the necessity for plants to take up CO_2 from the atmosphere through stomata. Various adaptations have developed to limit this loss (Ehleringer and Monson, 1993). Most C_3 species have a common metabolism but can vary enormously in leaf structure, leaf protection, stomatal density, and control over stomatal activity. For example, many species close their stomata during the hottest part of the day to avoid the highest rates of water loss. Some C_4 species have a special leaf anatomy and metabolism that allows them to concentrate CO_2 within the leaf and thus reduce water loss. Several major groups of plants (mostly succulents) have CAM species, in which most gas exchange is limited to the cooler nighttime hours.

These mechanisms are all of particular importance in desert communities, where water is usually limiting while light and CO_2 are usually in excess. Increased concentrations of atmospheric CO_2 will alter the relative effectiveness of these mechanisms and thus the balance of plant communities. It is expected that this will favor C_3 species over C_4 and CAM species (Skiles and Hanson, 1994), which could make desert communities more subject to invasion and increased dominance by C_3 species.

3.3.2.2.   *Pulse System*

Biological activity in most ecosystems is controlled by the availability of light, water, and nutrients. Complex interactions and feedbacks have developed that govern the growth and development of organisms in these systems. In contrast, desert ecosystems are dominated by rainfall events. Rainfall is infrequent, usually highly unpredictable, and often provides moist conditions for only a short period. Deserts have been described as pulse-driven ecosystems (Noy Meir, 1973). This means that the response of desert ecosystems to climate change may be different than that of other systems, where more complex feedbacks and interactions have developed.

Most desert organisms are adapted to one of two survival mechanisms (see Noy Meir, 1973). Some survive in a dormant state between rainfall pulses and take quick advantage of the brief respites. Typical examples are the ephemeral plants, but certain species of crustacea, molluscs, and frogs use similar strategies (Williams and Calaby, 1985). Other organisms—such as perennial plants, reptiles, and some mammals—persist through the dry conditions because they have extremely efficient water and energy conservation strategies (Williams and Calaby, 1985). Some smaller plants and animals are able to persist on the moisture settling as dew or fog (Louw and Seely, 1982).

Climatic changes that increase the frequency of pulses will favor the pulse-adapted (i.e., ephemeral) species if the duration of favorable conditions is not shortened. In the long term, more-frequent pulses of ephemerals could affect the long-lived perennial species either by directly competing for resources or

indirectly affecting local fire frequency and grazing intensity (Skarpe, 1992).

If, under climate change, the duration of periods of moist conditions becomes shorter or more variable, the pulse-adapted species may be disadvantaged. They will be triggered into responding more frequently but will often fail to complete their life cycle in the shorter moist periods (Frasier *et al.*, 1985, 1987). For example, ephemeral plants could be triggered into germinating but not have time to set seeds before drying out, thus depleting their seed bank.

3.3.3.   *Wind*

Windiness varies from desert to desert, but in general windiness is not significantly different than in nondeserts except that there is little vegetation to moderate the wind near the ground surface. This creates soil instability and is the major factor creating and shaping dune systems and extending desert boundaries (Alwelaie *et al.*, 1993). Some organisms are adapted to feed on the accumulation of organic matter on the slip faces of dunes (Louw and Seely, 1982).

3.3.4.   *Fogs*

Fog and dew can each contribute 30 mm or more of moisture per year. Dew can form on more than half the nights of a year in some deserts (Seely, 1979). Thus, fog and dew are an important and relatively reliable source of water for plants and animals alike (e.g., Namib beetles and lizards; Louw and Seely, 1982). In some of the driest coastal deserts (e.g., Atacama or Peruvian deserts), fogs are particularly frequent and provide the majority if not all of the moisture in most years (Rauh, 1985). Alwelaie *et al.* (1993) have suggested that the shrub-dominated vegetation in a desert island in the Red Sea depends on fog for its water supply.

3.3.5.   *Nutrient Cycles*

The main sources of nitrogen in deserts are N-fixing organisms on the soil surface such as lichens, cyanobacteria, moss, and fungi. Atmospheric deposition is an important source in some areas. Nitrogen fixation inputs in arid regions of the United States are 25 to 40 kg N/ha/yr (West and Skujins, 1977; Rundel *et al.*, 1982), whereas atmospheric deposition is estimated to be 3 kg N/ha/yr (Peterjohn and Schlesinger, 1990). Assimilation of nitrogen from fog is sometimes considered to be a significant source of N, but Evans and Ehleringer (1994) found that this is not the case in the fog zones of the Atacama Desert.

Rates of decomposition in deserts are slow because warm and moist conditions that favor decomposition are rare and volatilization of N can be high due to low vegetation cover and high evaporation. Thus, many desert systems are N-limited. Some studies have shown that decomposition rates are correlated with rainfall

in arid regions (Santos *et al.*, 1984), but others (Whitford *et al.*, 1986) have failed to find a correlation. Steinberger and Shmida (1984) conclude that along a rainfall gradient of 300 mm to 25 mm there is no correlation between decomposition and rainfall and that most decomposition in very dry regions arises from mechanical rather than biotic processes.

Soil nitrogen is unevenly distributed in arid environments and is usually higher in surface soil and beneath larger plants or shrubs than in bare areas (Charley and West, 1977). Most nitrogen fixation occurs near the soil surface, and species that take up most of their water from the surface zone might be at an advantage over deeper-rooted species. However, Evans and Ehleringer (1994) found that this is not the case for deep-rooted *Chrysothamnus nauseosus* individuals compared with neighboring shallow-rooted species. They conclude that water deep in the soil profile also provides an adequate nitrogen source.

3.4.   Impacts of Climate Change

3.4.1.   Higher Temperature

For most desert regions, the temperature increases predicted in the Greco *et al*. (1994) scenarios are typically in the range of 0.5 to 2.0°C, with greater increases in summer. A rise of 2°C without an increase in precipitation will increase potential evapotranspiration by 0.2 to 2 mm per day (Mabbutt, 1989; Chapter 4). Evapotranspiration may increase due to higher leaf temperatures and higher surface and soil evaporation rates, although the direct effects of higher CO_2 concentrations may partly compensate the tendency for increased transpiration.

Nasrallah and Balling (1993) found an average 0.07°C increase per decade in temperature records for the Middle East from 1945–90 with the greatest increases in spring and the smallest in winter. This increase appears to have been slowed by sulfate emissions and increased by human-induced desertification. Mühlenbruch-Tegen (1992) found no evidence of changes in mean daily temperatures during the past 50 years in South Africa but did find changes in daily minimum and maximum temperatures. These could be accounted for by changes in cloudiness. For example, increased cloud cover may decrease maximum temperatures and increase minimum temperatures by reducing insolation during the day and long-wave reradiation at night. Lane *et al.* (1994) found that from 1901–87, mean annual temperatures increased by 0.12°C per decade in the desert southwest region of the United States, but they could not separate an anthropogenic component from natural variability. Changes in land-use practices can affect surface temperatures. Balling (1988) has suggested that an observed 2.5°C temperature difference across the Mexican/U.S. boundary in the Sonoran desert may be due largely to heavier grazing on the Mexican side, which has led to lower vegetation cover and higher albedo.

Many organisms are already near their tolerance limits, and some may not be able to persist under hotter conditions. Higher temperatures in arid regions with cold winters are likely to allow spring growth to begin earlier. In some cases this may result in earlier depletion of water reserves accumulated over the cooler winter, leading to an even longer period of potential drought (Skiles and Hanson, 1994).

3.4.2.   Rainfall

The Greco *et al*. (1994) scenarios indicate that while some desert regions will receive more rainfall than at present, most will remain extremely arid. In most deserts the predicted additional rainfall is at most only a few centimeters per year, with some models predicting a decrease in many areas. Decreased rainfall is predicted for large parts of the Sahara, northern Arabian, Sonoran, and central and western Asian deserts. Rainfall in the Chihuahuan, southern Arabian, and Atacama deserts is predicted to increase slightly or remain the same, while some of the arid regions of central Australia are predicted to have significant increases in precipitation. The prediction of increased rainfall in Australian desert regions based on the Greco *et al*. (1994) scenarios is contradicted, however, by a general circulation model (GCM) developed by CSIRO in Australia (Whetton *et al.*, 1994). In an alternative approach, Wigley *et al*. (1980) used past warm-weather periods as an indicator of changes in precipitation under global warming. They conclude that precipitation in the arid and desert portions of the United States would decrease under a warmer climate scenario.

The coefficient of annual variation (standard deviation/mean) increases rapidly as mean annual rainfall falls from 300 to 100 mm per year; for sites with 100 mm annual rainfall, the standard deviation can be 0.65 or higher (MacMahon and Wagner, 1985; Fisher, 1994). This means that at sites with 100 mm/yr average rainfall, one year in six will have less than 35 mm of rain. Thus, extreme desert systems already experience wide fluctuations in rainfall and are adapted to coping with sequences of extreme conditions. Initial changes associated with climate change are less likely to create conditions significantly outside the present range of variation.

As CO_2 concentrations increase, plant transpiration is expected to decrease and water-use efficiency to rise (Mooney *et al.*, 1991). Simulation studies for semi-arid and arid sites indicate that water-use efficiency (i.e., carbon fixed per unit water transpired) might increase by up to 50% under a doubled-CO_2 scenario. Even in simulations in which precipitation was assumed to decrease by 10%, standing biomass increased by 15 to 30% (Skiles and Hanson, 1994).

All predictions of changes in precipitation should be treated with caution. None of the current GCMs can reliably predict the distribution of rainfall throughout the year, nor the distribution of rainfall per event. These characteristics are as important as absolute rainfall amounts in the initiation and maintenance of plant growth. Pittock (1988) suggests that in Australian arid areas there may be an increase in the amount of rainfall for a given event. This suggests that pulse species

could benefit in these areas because more of the events may result in moisture sufficient for the completion of their life cycles.

3.4.3.   *Runoff and Ephemeral Waters*

The impact of changes in temperature and precipitation regimes on runoff and groundwater recharge are complex and depend greatly on the precise timing of events and assumptions about surface conditions. Increases in rainfall intensity, amount per event, and storm clustering will tend to increase runoff in arid and semi-arid ecosystems (Wang and Mayer, 1994; Weltz and Blackburn, 1995). Vegetative cover tends to reduce runoff (Walker, 1991; Weltz and Blackburn, 1995).

A landscape mosaic of runoff and run-on areas is an important component of desert systems. In some deserts with gently sloping surfaces (<0.6°), narrow bands of vegetation ("stripes") develop. These bands trap the runoff from wider bands of almost-bare surface upslope of them (White, 1971). At a larger scale, arid lands often are a mosaic of erosion cells, each consisting of erosional, transfer, and sink areas (Pickup, 1985). The sink areas receive the benefits of most of the precipitation falling on the entire cell and accumulate many of the surface nutrients. Both of these situations will amplify any change in runoff patterns (Noble and Burke, 1995).

Lapenis and Shabalova (1994) have suggested that soil structural change may be an important component of climate change because increased precipitation will lead to more organic matter being accumulated in the soil, improved soil field capacity, enhanced moisture availability, and changed runoff patterns. However, their model shows that this process is slow (ca. 400 yr) in desert regions. Fossil aquifers are important water sources in many deserts but will not be affected in the time scales relevant to humans.

Catchment-scale runoff is difficult to predict. An empirical study that predicted catchment-scale runoff from precipitation and temperature suggests that runoff will decrease in arid watersheds in the western United States (Revelle and Waggoner, 1983). However, Idso and Brazel (1984) show that the effect could be reversed if changes in water-use efficiency under increased CO_2 concentrations were taken into account. Skiles and Hanson (1994) used a more detailed ecosystem model to take into account the seasonal responses of vegetation and found that there was little change, or a decrease, in runoff in simulated semi-arid watersheds. Morassutti (1992) concludes that runoff from three major drainage basins in Australia, including the arid Lake Eyre drainage basin, would increase under scenarios based on the GISS GCM. However, he warns that there are a number of shortcomings in the model and that no trends in precipitation and runoff are discernible from the historical record.

Neilson and Marks (1994) used five GCMs to look at the effect of climate change at the global scale. Their maps suggest that average annual runoff (in the five GCMs) under doubled-CO_2 scenarios for most of the desert areas of the world will remain the same or increase by 0–25 mm at the most. However, this lack of response may be due to their inclusion of Leaf Area Index (LAI) as a major component in the runoff calculations. In all their desert biomes, LAI is <0.1 or not calculable.

Scattered permanent and ephemeral waters are important for migrating and breeding birds. More than 300,000 birds can reproduce on the ephemeral Lake Eyre in central Australia after a major rainfall event that floods the lake— an event that has occurred only four times in the last 100 years. A population of thousands of egrets has been recorded in ephemeral waters following torrential rainfall in the Peruvian coastal deserts (Caviedes, 1984). Ephemeral water bodies can thus be very important to wetland birds (Kingsford and Porter, 1992) in different desert systems. However, very little is known about the effect of ephemeral events on the overall population dynamics of birds.

3.4.4.   *Desert Locusts*

The desert locust has a wide distribution in Africa and southwestern Asia, extending over areas with a mean annual precipitation of <50 to 500 mm (Uvarov, 1977). There have been various widely distributed plagues recorded this century (Uvarov, 1977; Pedgley, 1989) that have caused enormous damage. For successful breeding, locusts need warm and moist conditions (Pedgley, 1989); warmer temperatures also hasten their life cycle. Locusts favor ephemeral systems with silty or clayey soil that allows the eggs to survive and provides enough vegetation for the later life stages. However, to reach plague levels they also require meteorological and vegetation conditions that bring previously scattered populations together, allowing them to continue breeding while avoiding natural enemies. Scattered pockets of ephemeral, green vegetation appear to be most suitable.

In the gregarious phase, adult swarms can fly for many days and cover several hundred kilometers, especially in favorable wind conditions (Uvarov, 1977; Pedgley, 1989). Gentle winds allow locusts to take advantage of moist conditions in widely dispersed areas. The most common breeding sites have been recorded during the hot season in the Sahel-Sahara region (Uvarov, 1977). This area has an average annual precipitation of 50–200 mm, and the lush ephemeral vegetation supported by run-on in the wadi systems provides a suitable food source as well as areas suitable for egg-laying.

Other locust species (e.g., the red locust; Walker, 1991) have different behaviors, but in most cases they are best able to take advantage of pulses of moisture availability spread in both space and time. Changes in the frequency of future rainfall events that favor ephemeral or pulse systems could lead to more plagues of locust species. Conversely, in areas that become more continuously wetter or drier, they may be disadvantaged.

3.4.5.   ENSO and Related Issues

It has been shown that the El Niño Southern Oscillation (ENSO) phenomenon has a wide-ranging effect on regional climates that varies with latitude (Caviedes, 1984). Because major desert areas are driven by anticyclone systems, changes in sea surface temperature have repercussions for the moisture budgets of deserts. For example, El Niño has been associated with droughts in Australia (Nicholls, 1985) and north central Africa (Caviedes, 1984). However, it can also lead to higher precipitation and air temperatures, as in the coastal deserts of Peru and Chile. In these deserts, Caviedes (1984) recorded about a three- to tenfold increase in precipitation and up to a 4°C increase in air temperature during the 1982–83 El Niño. However, the central areas of Peru and the higher elevation areas suffered from drought during the El Niño period. Sea surface temperatures also affect humidity, and some coastal deserts may have more dew and fog associated with ENSO events.

Meehl *et al*. (1993) simulated the effect of ENSO events using a coupled ocean-atmosphere model in combination with a 2 x CO_2 scenario. Their general conclusion is that under doubled CO_2 the ENSO will intensify, and anomalously dry areas will become drier and wet areas will become wetter during ENSO events.

3.5.   Biogeographical Shifts

Desert regions are known to have undergone significant changes in the past. For example, the northern Sahara changed from Mediterranean flora at about 10,000 yr BP to its present aridity over several thousand years (Evenari, 1985a). Historical records show little shift in desert climates more recently, although vegetation at the margins of desert regions responds dramatically to variations in seasonal rainfall (Tucker *et al*., 1991). There has also been massive change in some areas due to human activity (see Chapter 4). Long-term studies of desert communities show that they are highly responsive to small changes in the climate regime in which they grow, and in particular to rare events such as unusually moist or dry periods (Hall *et al*., 1964; Noble, 1977; Noble and Crisp, 1980; Goldberg and Turner, 1986; Turner, 1990).

Monserud *et al*.'s (1993) projection of global vegetation changes in response to a doubled CO_2-driven climate indicates relatively little change in their desert category (by their definition, about 25% of land surface and thus close to the generally accepted desert and semi-deserts). They found that 82–92% of existing deserts remain so classified under any of the four GCM climates they used. For all vegetation types combined, only 59–66% remain in the same category; deserts were the most stable of the 16 vegetation types they considered.

The Greco *et al*. (1994) scenarios predict moister conditions along the boundaries of only a few deserts. Even if wetter conditions were to prevail, the "greening" of the deserts would often be negated by pressure from the expanding human population and the associated desertification problems (see Chapter 4).

Climate amelioration may lead to increased invasion by species able to disperse widely and possibly to increased fire frequency if the occurrence of ephemeral flora becomes more common. Long-range dispersal mechanisms tend to be rare in plants of the extreme deserts (Ellner and Shmida, 1981; Chambers and MacMahon, 1994). Thus, even if deserts with little plant cover (e.g., the central Sahara) were to become more moist, vegetation may take a long time to respond. In some cases, as in Australia, species (especially birds) that are dependent on ephemeral water bodies may show a population increase.

3.6.   Mitigation

Despite their extent, extreme deserts store only a small portion of the global C and N pools (much less than 1%); thus, deserts are not a likely sink for excess CO_2. Some small gains may arise through modified land-use and grazing management practices (see Chapter 2).

3.7.   Future Needs

There is a lack of information on many aspects of the extreme deserts. The highly pulsed availability of resources and the ephemeral nature of much of the biological activity make them difficult to study. Predictions of the impacts of climate change will depend critically on the precise changes in the seasonality and distribution of rainfall events as much as on the absolute amounts of rainfall.

CONTENTS

EXECUTIVE SUMMARY

The impact of climate change on soils needs to be considered in parallel with impacts caused by unsustainable land-management practices. In many cases, it is impossible to separate the effects of these impacts; often they interact, leading to a greater cumulative effect on soils than would be predicted from a simple summation of their effects. Findings follow:

- Fundamental soil properties and processes—including organic-matter decomposition, leaching and acidification, salinization, soil water regimes, soil stability, and soil erosion—will be influenced by changes in climate (High Confidence).
- Desertification arises both from human abuse of the land and from adverse climate conditions. Climate-related factors such as increased drought can lead to an increase in the vulnerability of land to desertification and to the escalation of the desertification process (High Confidence).
- Reversing the effects of desertification is not always possible and is more difficult for drier environments with shallower soils (High Confidence).
- Changes in the frequency and intensity of precipitation will have the greatest direct effect on soils via erosion by water. However, future erosion risk is likely to be related more to increases in population density, intensive cultivation of marginal lands, and the use of resource-based and subsistence farming techniques than to changes in precipitation regimes (High Confidence).
- In structurally stable soils, greater precipitation will increase the rate of leaching of basic cations. In the long term, after buffering pools have become exhausted, accelerated leaching could lead to soil acidification (High Confidence).

- Higher temperatures are likely to increase the decomposition rate of organic matter and organic-matter loss (High Confidence). However, too little is known about the influence of increased atmospheric carbon dioxide (CO_2) levels on the amount of organic matter returning to the soil to judge the extent to which soil organic-matter levels will decline.
- Where conditions become more arid, salinization and alkalization are likely to increase because evapotranspiration and capillary rise will be enhanced (High Confidence). Areas with a shallow water table may experience increased salinization if rainfall increases (Medium Confidence).
- Predicted warming may give rise to higher evaporation rates, leading to drier soils and more frequent episodes of severe wind erosion (Medium Confidence).
- Because arid and semi-arid land ecosystems have little ability to buffer the effects of climate variability relative to most other terrestrial ecosystems, they are particularly vulnerable to climate change and may be among the first ecosystems to be affected by global environmental change (Medium Confidence).
- Adaptation to desertification will rely on conventional strategies, such as the use of agroforestry, animals that are better adapted to dry conditions, diverse and multiple production systems, and water- and energy-saving techniques (Medium Confidence).
- Climate change could be beneficial to some semi-arid and sub-humid tropical highlands because of temperature increases and CO_2 fertilization (Medium Confidence).

4.1.   Introduction

Land degradation, defined here as "a reduction in the capability of the land to support a particular use" (Blaikie and Brookfield, 1987), is considered to be one of the major problems facing the world (UNEP, 1992). In this chapter, we examine the likely impact of climate change on this global problem. Will degradation of land be exacerbated or reduced? There are many recognized forms of land degradation, including soil erosion, salinization, soil contamination, loss of soil organic matter, decline in nutrient levels, acidification, and loss of soil structure. Desertification currently affects about one-sixth of the world's population and one-quarter of the world's land: 6 to 7 million hectares (Mha) are lost annually due to soil erosion, and up to 20 Mha of irrigated land are affected by salinization (World Resources Institute, 1992). Much of this degradation is undermining economic development and is already irreversible.

With the forecast world population increase, there will be increased pressure on the soil to produce more food; thus, future trends in the potential of land to produce food will be of particular interest. The impact of climate change on the health of the land should be considered in parallel with the effects of existing pressures caused by unsustainable land management—because it is often impossible to separate the effects of these impacts and because their cumulative impact on soils often is greater than a simple summation.

Emphasis in this chapter is given to the effects of climate change on soil erosion, salinization, and desertification, but impacts on other degradation processes capable of being accelerated by climate change also are reviewed. Additional processes of importance include organic-matter loss, nutrient loss, acidification, and soil structural deterioration (Rogasik *et al*., 1994). In some instances, changes in such processes will lead to the formation of new soil types requiring new types of management and having different use potentials.

4.2.   Soil Erosion: Causes, Processes, and Predictions

Soil erosion is the movement and transport of soil by various agents—particularly water, wind, and mass movement—that leads to a loss of soil. Erosion has been recognized by many scientists and some governments as a major problem since the U.S. Dust Bowl of the 1930s (Jacks and Whyte, 1939); the causes and processes involved have been well-researched over the last 60 years, providing voluminous literature.

Clearing soils of their natural vegetation cover and subsequently using them for arable agriculture has been the primary cause of soil erosion onset. Historically, this has resulted in disastrous soil losses, particularly in conjunction with climate variations and extreme weather events (Bork, 1983, 1989). More recently, population pressure in developing countries, as well as changes in land use and management in other parts of the world, have increased erosion susceptibility even further.

The annual rates of new soil formation are crudely estimated to be between 2 and 11 t/ha (Wischmeier and Smith, 1978), although experimentally derived rates often are less than this (Lal, 1994a). Globally, rates of soil erosion can exceed these estimated values by 10- to 20-fold, thereby reducing productivity (Crosson and Stout, 1983; Sehgal and Abrol, 1994a, 1994b) and causing sediment and nutrient loading of rivers (Clark *et al*., 1985).

The main factors influencing soil erosion are rainfall (amount, frequency, duration, and intensity), windspeed (direction, strength, and frequency of high-intensity events), land use and management, topography, and soils and their properties (Morgan, 1986; Hallsworth, 1987). Since the 1950s, significant advances have been made in predicting erosion risk, particularly through model development. Several models that are commonly used include the Wind Erosion Equation (Woodruff and Siddoway, 1965), the Universal Soil Loss Equation (USLE) (Wischmeier and Smith, 1978), EPIC (Williams *et al*., 1990; Skidmore and Williams, 1991), WEPP (Flanagan *et al*., 1991), and EUROSEM (Morgan *et al*., 1992). All of these models have weather/climate components and are capable of being manipulated to predict erosion risk under different climate-change scenarios (e.g., Favis-Mortlock, 1994). Generally, increased rainfall intensity and amount, increased windspeed, and increased frequencies of high-wind events—especially if coupled with increasing droughtiness—are likely to lead to an increase in erosion. However, erosion is site-specific, and different permutations of conditions can increase or decrease it. Research has predicted erosion risk as a function of land use and environmental conditions (Nearing *et al*., 1994; Skidmore *et al*., 1994), agronomic quality (Williams *et al*., 1984), and environmental quality (Knisel, 1980; Lal, 1994a).

Despite scientific advances, the problem of accelerated soil erosion is more serious now than ever before (Lal, 1994c), and erosion hazards are being exacerbated particularly in the tropics and subtropics (Lal, 1994d). Reliable estimates of the current amounts of erosion and future areas at risk are difficult to obtain (Table 4-1; Lal, 1994b), although erosion has been suggested as affecting about 33% of the land currently used for global crop production (Brown and Young, 1990).

4.2.1.   Erosion by Water

Climate change is likely to affect soil erosion by water through its effects on rainfall intensity, soil erodibility, vegetative cover, and patterns of land use. Estimates of changes in erosion risk can be made from a knowledge of projected changes in these factors. General circulation models (GCMs) can provide a range of climate scenarios, but these alone are not sufficient to predict future erosion risk, particularly because GCMs are currently poor predictors of changes in rainfall intensity and surface windspeed. In addition to more regionally reliable GCMs, accurate and reliable databases of parameters such as vegetation cover, soil properties, land use, and management

Table 4-1: *Estimates of current global rates of soil erosion and likely future trends.*

Region	Soil Erosion by Water				Soil Erosion by Wind	
	Area[1] (10⁶ ha)	Denudation Rate[2] (mm/yr)	Dissolved Load[3] (10⁶ t/yr)	Future Trends	Area[1] (10⁶ ha)	Future Trends

systems are needed. These databases are important for the assessment of biophysical processes and biomass productivity (Rosenzweig *et al*., 1993) and are needed at scales appropriate to regional and global degradation processes (Bliss, 1990; Bouwman, 1990; Batjes *et al*., 1994). Such databases have not yet been developed.

GCMs indicate a marked change in soil moisture regime and, therefore, attendant changes in soil erodibility, land use, and vegetative cover. Regions likely to experience an increase in soil moisture include southern Asia (50 to 100%), South America (10 to 20%), and Oceania (10 to 20%). Regions likely to experience decreases in soil moisture include North America (10 to 50%), sub-Saharan Africa (10 to 70%), and Europe (10 to 60%) (Schneider, 1989). However, with respect to erosion, much will depend on the pattern, intensity, and seasonality of rainfall events.

A potential change in the climate might have positive effects that lead to a decrease in soil erosion risk (Sombroek, 1991–92; Brinkman and Sombroek, 1993) as a result of negative feedback mechanisms. Examples include increased biomass production, increased vegetation cover, and enhanced soil organic-matter content resulting from elevated CO_2 concentrations. However, predicted changes in temperature, rainfall, and soil moisture (IPCC, 1994) suggest that few areas will receive benefits from negative feedback effects. Instead, projected declines in levels of soil organic matter and the weakening of soil structure will make soils increasingly prone to erosion.

Modeled estimates of the effect of climate change on soil erosion depend on assumptions regarding the frequency and intensity of precipitation (Phillips *et al*., 1993). However, some estimates of future erosion have been made. For example, changes

in the U.S. national average for sheet and rill erosion have been modeled under a number of different climate change scenarios. For cropped land, modeled erosion increased by 2 to 16%; in pastureland, predicted changes were -2 to +10%; and in rangeland, modeled erosion changed by -5 to +22% (Phillips *et al*., 1993). EPIC was used in the UK to show that, although an increase in temperature has little effect on erosion rate, a 15% increase in rainfall leads to a 27% increase in mean annual erosion (Favis-Mortlock *et al*., 1991; Boardman and Favis-Mortlock, 1993; Favis-Mortlock, 1994).

4.2.2. Erosion by Wind

Soil erosion occurs when wind transports soil particles by suspension, surface creep, or saltation over distances ranging from a few centimeters to many kilometers. Wind erosion not only transports soil particles around arid and semi-arid landscapes but provides inputs into ecosystems around the world and may even alter global climatic patterns. Wind erosion is particularly problematic on sandy and organic soils subject to low soil moisture, patchy vegetation, sporadic rainfall, and periodic winds. Even soils resistant to wind erosion can be blown away if the soil is damaged by trampling of animals, loosening by ploughing and tillage, pulverization by traffic (human and animal), and denudation of natural vegetation by the expansion of agriculture, excessive grazing, or fire.

Wind erosion is mainly a feature of arid and semi-arid conditions but may occur in moister zones where soil damage occurs during or just prior to periods of high wind velocity. In some areas, climate change is expected to lead to more droughty soils and less vegetation, both of which make soils more vulnerable to wind erosion (Middleton, 1985;

Hennessy *et al*., 1986). The predicted warmer climate may give rise to higher evaporation rates, leading to more frequent soil drying whether precipitation increases or not. Consequently, wind erosion may become more frequent. Although the influence of climate and human activities on wind erosion is well-documented, the feedback effect of windblown dust in the atmosphere on the warming of the upper atmospheric layers has not been thoroughly investigated (Nicholson, 1994). Desertification—an advanced result of wind erosion—is considered in Section 4.4.

4.2.3.   *Mass Movement and Subterranean Erosion*

The occurrence of mass movement depends upon the interaction of various factors, including land form, lithology, soil type, rainfall intensity and duration, drainage characteristics, vegetal cover, and human intervention (Rosewell *et al*., 1991). Where sloping land is subjected to increasing rainfall of high intensity, it will become increasingly subject to mass movement.

There are various forms of subterranean erosion (Dunne, 1990), including piping (Kirkby and Morgan, 1980), intrasoil erosion, and tunnel erosion (Barrow, 1991). As with mass movement, increasing rainfall amounts and intensities will lead to increases in this form of erosion.

4.2.4.   *Coastal Erosion*

The main factors affecting coastal erosion and sediment redistribution are winds, currents, tides, and floods. Rising sea level could increase coastal erosion and the loss of highly productive wetlands—and thus intensify pressure on the remaining land (see Chapter 9).

4.2.5.   *Adaptive Strategies for Mitigating the Impact of Climate Change on Soil Erosion*

More than 60 years of experience are available in the development of conservation techniques and soil protection, following the U.S. Dust Bowl and similar phenomena elsewhere in the world (Kirkby and Morgan, 1980; FAO, 1983; Morgan, 1986; Schwertmann *et al*., 1989; Lal, 1990). A serious problem, however, is that many of these conservation techniques have not been adopted. Nevertheless, they are available and could be used for or adapted to changing climatic conditions. The most important requirement is that governments recognize the problem of soil erosion and set in motion the appropriate conservation mechanisms.

Future erosion risk is more likely to be influenced by increases in population density, intensive cultivation of marginal lands, and the use of resource-based and subsistence farming techniques than by changes in climate. One can anticipate that erosion, mass movement, and landslides are most likely to increase in and near regions of high population density.

4.3.   **Salt-Affected Soils**

4.3.1.   *Coastal Salinity*

Coastal salinity depends primarily on sea level and its tidal, seasonal, and long-term fluctuations; the temperature, concentration, and chemical composition of seawater; the geology, geomorphology, and relief of the coastal area, including river deltas and estuaries; and climate (temperature, precipitation, rate of evaporation, and spatial and temporal variability in them) (Jelgersma, 1988; Day and Templet, 1989; Pirazzoli, 1989; Szabolcs and Rédly, 1989; Fisher, 1990; Várallyay, 1994). The assessment and prediction of coastal salinity and salt accumulation requires comprehensive information on the hydrological, chemical, and ecological consequences of a potential rise in the eustatic sea level. Consequences include inundation of coastal lowland plains, deltas, and estuaries of big rivers; intrusion of saline seawater or brackish tidal water; rapid erosion of coastlines; a rising water table; and impeded drainage in coastal plains. In general, any rise in the eustatic sea level will result in the territorial extension of coastal salinity under the direct and indirect influences of saline seawater (Titus, 1987; Jelgersma, 1988; Szabolcs and Rédly, 1989; Hekstra, 1989; Pirazzoli, 1989; Scharpenseel *et al*., 1990; Szabolcs, 1991).

4.3.2.   *Continental Salt Transport and Salt Accumulation Processes*

Impact analysis of climatic scenarios on continental salt transport and salt accumulation processes requires a much more complex approach. There are three principal mechanisms of salinization: salt accumulation, seepage, and wind deposition. Salinization by salt accumulation occurs when leaching is reduced and salt accumulates at the surface or at some depth in the soil profile—where, following erosion, it may become exposed (West *et al*., 1994). Salinization also can occur when salt is leached into a perched water table and then seeps to a lower point in the landscape (Ballantyne, 1963). Salinization by wind deposition relies on a suitable source of salt deposits. All three of these salinization processes are likely to be affected by climate change. The effects of two possible future climate scenarios—warm and dry versus warm and wet—are considered in Sections 4.3.2.1 and 4.3.2.2. Such climates are likely to show high spatial and temporal variability; various combinations of temperature and precipitation changes are likely in nature (Manabe and Holloway, 1975; Solomon *et al.,* 1987; Szabolcs and Rédly, 1989). Further variations may be caused by the physiographic variability of specific regions (agroecological unit, water catchment area, etc.) (Jelgersma, 1988; Brammer and Brinkman, 1990; Fisher, 1990; Szabolcs, 1990) and by human activities (e.g., agricultural water-management practices and water-conservation practices) (Hekstra, 1989; Szabolcs, 1989; Várallyay, 1990a, 1990b, 1990c).

4.3.2.1.   *Warm and Dry Climate*

Rising temperatures during the summer will lead to higher evapotranspiration and aridity and thus higher concentration of

salts in the soil solution. Where the water table is shallow, drying usually is associated with enhanced capillary rise from groundwater to overlying soil horizons. The consequences are increasing salinity in the solid and liquid phases of the soil, salt efforescence or salt crust on the soil surface, higher salt content in the soil profile, and higher salt concentration in the soil solution. If the lowering of the groundwater table is prevented by horizontal inflow, capillary transport leads to increasing salt accumulation in the overlying soil layers. Seepage from unlined canals and reservoirs and/or filtration losses from over-irrigated or imperfectly irrigated fields will lead to horizontal groundwater inflow and/or saline seep from the surroundings to low-lying areas. These processes result in a rise of the water table due to increased capillary transport and thus to increasing salinity (Várallyay, 1968, 1994).

Higher winter temperatures have much less impact on salinity. For example, changing the ratio of rain to snow and/or having a shorter period of freezing leads to better infiltration concurrent with leaching. If the water table does rise during the temperate-zone winter, there is negligible (or no) capillary transport (because few plants are active), thus no salt accumulation (Várallyay, 1994).

4.3.2.2. Warm and Wet Climate

If the temperature increase is accompanied by a significant increase in rainfall, aridity and the concentration of salts in the soil solution will be reduced. This climatic scenario results in a net downward flow of water in the soil profile, at least for most of the year, associated with leaching, as well as a salinity reduction. However, where there is periodic drying (e.g., in a dry summer), capillary transport of salts can occur from shallow groundwater to overlying soil horizons. Thus, increased climate variability that includes periods of severe drying can lead to temporally sporadic or seasonal salt accumulation.

The accumulation of salts in soils often negatively affects soil properties and processes, including nutrient-holding capacity, nutrient dynamics, bulk density, soil structure, and porosity (see Box 4-1). Salt accumulations create extreme ecological soil environments and reduce the potential of the land for agricultural and many other uses (Kovda and Szabolcs, 1979; Szabolcs, 1990, 1991; Várallyay, 1994).

4.4.   Desertification

Desertification is the process of ecological degradation by which economically productive land becomes less productive and, in extreme cases, develops a desert-like landscape incapable of sustaining the communities that once depended on it (Kassas, 1988; Westing, 1994). Desertification has aroused much emotive and scientific interest, and there are many different definitions of the term (Verstraete, 1986). The definition used in this chapter is the one adopted at the United Nations Conference on Environment and Development (UNCED) in June 1992: "...land degradation in arid, semi-arid, and dry sub-humid areas resulting from various factors including climatic variations and human activities" (UNEP, 1992; Hulme and Kelly, 1993). Desertification occurs most frequently in ecosystems that have low rainfall, long dry seasons, recurrent droughts, mobile surface deposits, skeletal soils, and sparse vegetation cover (Le Houérou, 1968; Dregne, 1983; Kassas, 1988).

Box 4-1. The Impact of Salinization on Crop Productivity in India

Soil salinity is an important chemical degradation problem for Indian agriculture, affecting 10 Mha of land—of which 2.5 Mha lie in the Indo-Gangetic Plateau. Saline soils are dominantly observed in coastal areas and in some irrigated areas inland. Sea-level rise would adversely affect the 7,000-km coastal belt of India, comprising 20 Mha of coastal ecosystem. A rise of 70 cm per century (IPCC, 1990) would inundate 25% of the coastal areas of Kerala, parts of Pondicherry, Karaikal, Tamil Nadu, and vast deltaic areas of Sundarbans (West Bengal), increasing coastal salinity and reducing crop productivity. Increased tidal ingression through creeks along the east and west coasts may further aggravate coastal salinity and damage fragile wetland ecosystems. Expected losses of soil productivity will depend on the level of sodicity but would be expected to approximate those listed in Table 4-2.

Table 4-2: *Percent loss in soil productivity.*

Exchangeable Sodium Percentage	Loss of Productivity in Alluvium-Derived Soils (Fluvisols)	Loss of Productivity in Black Soils (Vertisols)
Up to 5	nil	Up to 10
5–15	<10	10–25
15–40	10–25	25–50
>40	25–50	>50

Source: Sehgal and Abrol, 1994b.

Climate-related factors such as increased drought can lead to an increase in the vulnerability of land to desertification and to the escalation of the desertification process. In essence, desertification results from a combination of drought and mismanagement of land—in particular, the disharmony between land use and management on the one hand and the soil and prevailing climate on the other. Desertification may, in turn, affect local and global climate and thus should be viewed in a cause-effect context, as outlined by Hulme and Kelly (1993) and shown in Figure 4-1.

4.4.1.   The Climatic Background of Desertification

We use the term "desert" in the sense of "true" or "climatic" desert, which is associated only with the hyper-arid zone. Desertification is a process that occurs mainly in arid to sub-humid climates that have precipitation:potential evapotranspiration (P:PET) ratios shown in Table 4-3.

The area of land occupied by these four zones in which true or induced deserts can occur is 47% of the land mass of the planet (Table 4-4).

The hyper-arid to dry sub-humid zones are subject to strong fluctuations in climate. Data from dendrochronological studies,

Table 4-3: *Precipitation-to-potential evapotranspiration (P:PET) ratios of hyper-arid to sub-humid lands.*

P:PET	Regions
< 0.05	Hyper-arid (true climatic desert)
0.05–0.20	Arid (subject to desertification)
0.20–0.45	Semi-arid (subject to desertification)
0.45–0.70	Sub-humid (subject to desertification)

pollen analyses, lake level surveys, glacier advances and retreats, crop distribution surveys, and grape harvesting dates confirm the occurrence of many fluctuations in the last 2,000 years.

Regional, short-term trends or fluctuations in rainfall are a feature of semi-arid and arid lands. There has been a clear decline in rainfall in parts of Chile, where the influence of the El Niño–Southern Oscillation (ENSO) has been evident since the beginning of the century (Burgos *et al.*, 1991; Santibanez and Uribe, 1994). Rainfall in the African Sahel has failed to reach 1931–1960 mean levels in virtually all of the last 25 years. Although similar dry periods have occurred in the historical and recent geological past, there is evidence that the recent dry period in the Sahel shows more of a tendency to continental-scale dryness (Nicholson, 1994). Increasing rainfall variability

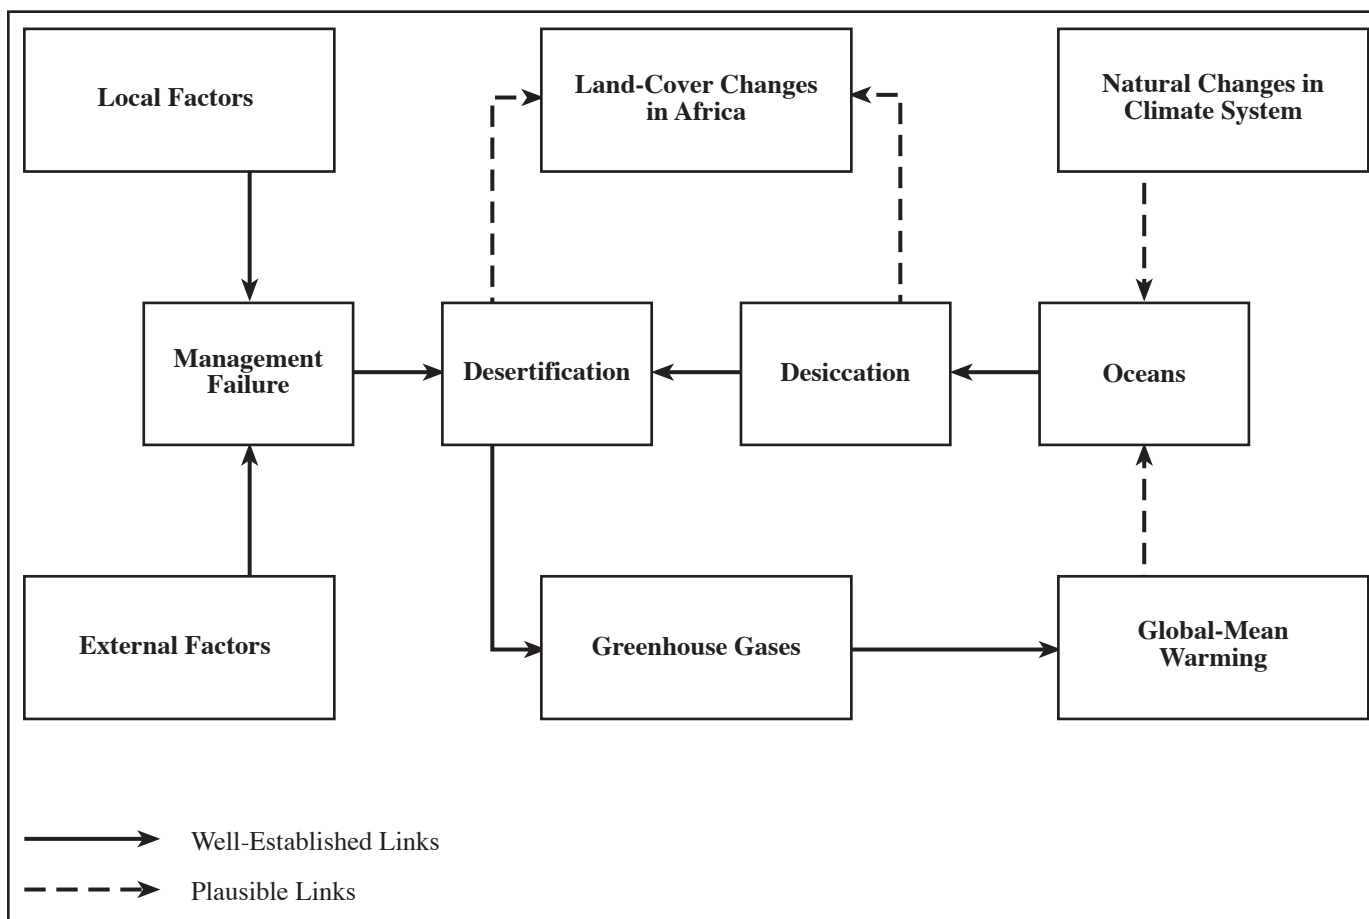

Figure 4-1: A matrix of cause and effect surrounding desertification and the role of climate change (Hulme and Kelly, 1993).

Table 4-4: *Regional distribution of world drylands (10^3 km²) (after Oldeman et al., 1990; UNEP, 1992).*

Zone	Africa	Asia	Australasia	Europe	North America	South America	Total
Cold	0.0	1082.5	0.0	27.9	616.9	37.7	1765.0
Humid	1007.6	1224.3	218.9	622.9	838.5	1188.1	5100.4
Dry Sub-Humid	268.7	352.7	51.3	183.5	231.5	207.0	1294.7
Semi-Arid	513.8	693.4	309.0	105.2	419.4	264.5	2305.3
Arid	503.5	625.7	303.0	11.0	81.5	44.5	1569.2
Hyper-Arid	672.0	277.3	0.0	0.0	3.1	25.7	978.1
Total	2965.6	4256.0	882.2	950.5	2190.9	1767.5	13012.7

appears to be associated with this; Hulme (1992) found that there were more areas of increased variability than those of reduced variability. Highly variable conditions can trigger desertification. However, other than those areas under the influence of the ENSO and the few areas with longer-term droughts such as the Sahel, there is little evidence for recent changes in drought frequency or intensity in arid and semi-arid lands (see Chapter 3, *Observed Climate Variability and Change*, of the IPCC Working Group I volume).

Analysis of temperature data for semi-arid and arid lands by various groups presents a more confused picture than that for rainfall. For example, in Kenya there was a mean annual temperature rise of 0.4°C over the period 1942–91, perhaps tied to urbanization (Kinuthia *et al*., 1993). In South Africa, there was no temperature trend over the 1940–90 period (Mühlenbruch-Tegen, 1992). Central Asia did not see a consistent trend over 1900–1980 (Kharin, 1994); there was no trend in southern France, either (Daget, 1992). Over the last 100 years, temperature in North America increased by 0.8°C (Balling, 1994). Chapter 3 of the IPCC Working Group I volume summarizes the global surface temperature trends for the period 1920–93. The future magnitude of increases in temperature in arid and semi-arid lands is likely to be similar to or lower than the global estimate of 0.005°C per annum. The greatest increase in such lands is likely to be experienced above latitudes north and south of 40°.

Whereas most terrestrial ecosystems have some built-in ability to buffer the effects of climate variability, this is not so true of those in arid and semi-arid lands—where even small changes in climate can intensify the already high natural variability and lead to permanent degradation of the productive potential of such lands (OIES, 1991). Arid and semi-arid lands may thus be among the first regions in which ecosystem dynamics become altered by global environmental change (West *et al*., 1994).

There also is the question of the extent to which desertification itself can exacerbate climate change. It has been suggested that surface air temperature has increased significantly in desertified areas because of changes in land cover, thereby affecting global mean temperature (Balling, 1991). A reduction in surface soil moisture results in more available energy for warming

the air because less is used to evaporate water. Hulme and Kelly (1993) consider this effect to be very weak but identify a better-established, though less-direct, link through the effects of changes in carbon sequestration potential and possible changes in soil conditions on emissions of nitrous oxide and methane. Hulme and Kelly (1993) point to the difficulty of quantifying the precise effect of desertification on global warming. Arid-region temperatures and rainfall should be monitored to develop a stronger information base.

4.4.2. The Nature, Causes, and Severity of Desertification

Desertification arises both from human abuse of the land and from adverse climatic conditions such as extended drought (UNEP, 1992)—which may trigger, maintain, or even accelerate the process of dryland degradation. Currently there is disagreement as to whether human impacts or climatic factors are the primary agents responsible for the desertification of the world's arid and semi-arid lands.

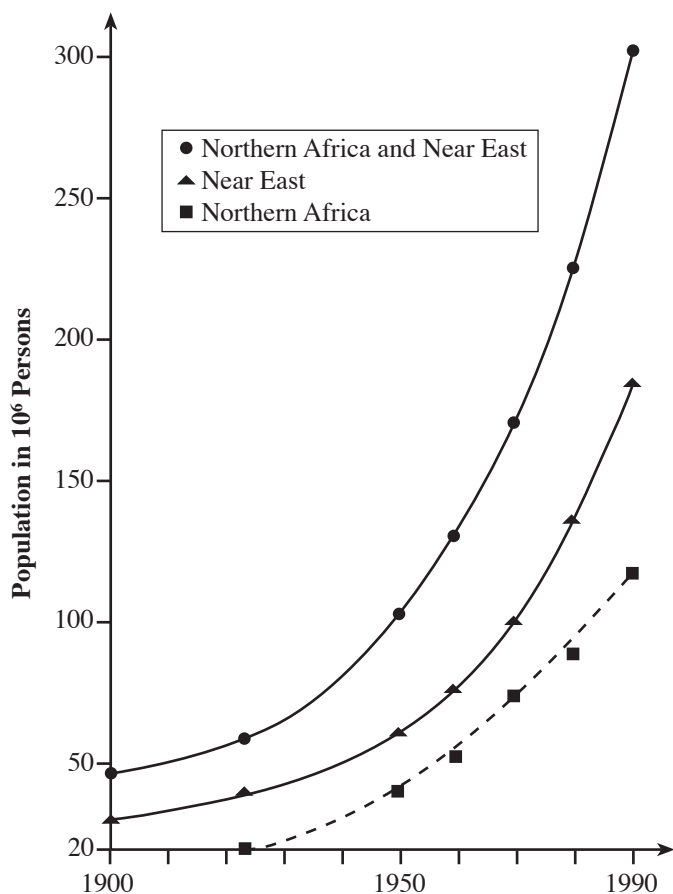
Some evidence suggests that human impacts arising from overstocking, overcultivation, and deforestation are primarily responsible for the process. Such conclusions have been reached by scientists working in northwest China (Chao Sung Chiao, 1984a, 1984b); Australia (Perry, 1977; Mabbut, 1978); South America (Soriano, 1983); North America (Dregne, 1983; Schlesinger *et al*., 1990); Europe (Lopez-Bermudez *et al*., 1984; Rubio, 1987; Katsoulis and Tsangaris, 1994; Puigdefabregas and Aguilera, 1994; Quine *et al*., 1994); North and West Africa and the Sahel (Pabot, 1962; Le Houérou, 1968, 1976, 1979; Depierre and Gillet, 1971; Boudet, 1972; Lamprey, 1988; Nickling and Wolfe, 1994; Westing, 1994); East Africa (Lusigi, 1981; Muturi, 1994); and South Africa (Acocks, 1952; Hoffman and Cowling, 1990a; Bond *et al*., 1994; Dean and McDonald, 1994). Many of these studies suggest that, although desertification is the result of a complex interaction of a number of factors, the direct causes are human actions—which themselves are a function of population density (see Figure 4-2), cultural traditions, land tenure, and other socioeconomic and political factors. Although climate and soil type are important in determining the severity and rate of desertification, it is ignorance or the force of circumstance in


Figure 4-2: Evolution of the human population in northern Africa and the Near East from 1900 to 1990. Sources are various, including FAO yearbooks (Le Houérou, 1992).

extended droughts over the last several decades in the desertification process or suggests that desertification has been overstated due to a lack of adequate information (Hellden, 1988, 1991; De Waal, 1989; Forse, 1989; Mortimore, 1989; Binns, 1990; Hoffman and Cowling, 1990b; Tucker *et al.*, 1991; Grainger, 1992; Thomas, 1993; Dodd, 1994; Pearce, 1994; Thomas and Middleton, 1994). Proponents of this view argue that domestic livestock populations seldom build up to numbers that are damaging for these environments because the periodic droughts that characterize these regions frequently result in high animal mortality (see Behnke *et al.*, 1993; Dodd, 1994; Scoones, 1995).

There also is a great deal of variation in assessments of the nature and severity of the desertification problem, due mainly to the lack of adequate data. Some researchers suggest that almost 20 million km² (15% of the land surface of the Earth) are subject to various degrees of desertification; they provide estimates of the extent and severity of the problem for different regions (Dregne, 1983, 1986; Le Houérou, 1992; Table 4-6). In addition, there have been a number of attempts to calculate the rate of expansion of the more arid regions into the more mesic areas. Most of these studies have employed remote sensing, notably with air photos and large-scale satellite images (e.g., SPOT) taken decades apart, combined with detailed maps of ground-control and older vegetation, forest, or range resources. Many of these large-scale studies have suggested that the annual rate of expansion of desertified lands in central Asia, northwest China, northern Africa, and the Sahel ranges from 0.5 to 0.7% of the arid zone (Le Houérou, 1968, 1979, 1989, 1992; Depierre and Gillet, 1971; Boudet, 1972; De Wispelaere, 1980; Gaston, 1981; Haywood, 1981; Floret and Pontainier, 1982; Chao Sung Chiao, 1984b; Peyre de Fabrègues, 1985; Vinogradov and Kulin, 1987; Grouzis, 1988; Rozanov, 1990). Assuming a conservative rate of expansion of 0.5% per annum, this information has been used to suggest an annual increment of desertified land of 80,000 km² (see also Hulme and Kelly, 1993). Because 25% of the arid zone already is desertified, this estimate would mean that almost all of the world's arid and semi-arid lands will become desertified within the next century if rates of desert expansion are similar to those that have prevailed over the past 50 years. Complete arid-land desertification could occur earlier if human and livestock populations continue to increase and particularly if the resilience of arid regions is negatively affected by climate change (Hulme and Kelly, 1993).

failing to match the use and management of the land to the soil and prevailing climate that leads to the removal of soil. Overstocking, deforestation, wood collection, and overcultivation usually are cited as the principal direct causes of the problem; estimates of the percentage of desertified land attributed to each of these factors are available (Table 4-5).

However, a somewhat different view of the causes of desertification also exists. For some Asian environments (e.g., Singh *et al.*, 1994) and particularly in African environments, there is a growing body of literature that emphasizes the impact of

Table 4-5: *Causes of desertification, in percent of desertified land (after Le Houérou, 1992).*

Regions or Countries	Overcultivation	Overstocking	Fuel and Wood Collection	Salinization	Urbanization	Other
Northwest China	45	16	18	2	3	16
North Africa and Near East	50	26	21	2	1	–
Sahel and East Africa	25	65	10	–	–	–
Middle Asia	10	62	–	9	10	9
United States	22	73	–	5	–	–
Australia	20	75	–	2	1	2

Table 4-6: *Extent and severity of desertification (after Oldeman et al., 1990; Le Houérou, 1992; Le Houérou et al., 1993; UNEP, 1992).*

Region	Light Area	%	Moderate Area	%	Strong Area	%	Severe Area	%
Africa	1180	9	1272	10	707	5.0	35	0.2
Asia	1567	9	1701	10	430	3.0	5	0.1
Australasia	836	13	24	4	11	0.2	4	0.1
North America	134	2	588	8	73	0.1	0	0.0
South America	418	8	311	6	62	1.2	0	0.0
Total	4273	8	4703	9	1301	2.5	75	0.1

Notes: Area desertified in 10^3 km^2; % = area desertified in percent of total drylands; drylands = arid + semi-arid + dry sub-humid.

Some recent research, however, has not supported the expanding-desert hypothesis. First, a number of researchers question the data upon which the severity estimates (see Table 4-6) are based (Hellden, 1988; Thomas, 1993; Dodd, 1994). Second, some argue that the process cannot be accurately described as a degradation front that grows incrementally larger each year. Arid and semi-arid systems are characterized by variable climates subject to large fluctuations in annual rainfall. During favorable or "wet" years there is little evidence to suggest that the desertification front expands (Thomas, 1993). On the contrary, a number of recent studies suggest that vegetation cover at the margins of arid and semi-arid regions both increases and decreases, depending largely on seasonal and annual rainfall totals (Hoffman and Cowling, 1990b; Tucker *et al.*, 1991). The different views regarding the importance of human abuse versus adverse climatic conditions in causing desertification, and the lack of agreement on the scale of the problem, point to the need for a better understanding of the problem and, in particular, better and more comprehensive data on its nature and extent. There is little doubt that desertification is an important environmental problem that needs to be addressed urgently—and that climate change will have an impact on it.

4.4.3. The Impact of Drought and Desertification on Natural Ecosystems and Rain-Fed Crops

The impact of drought on natural ecosystems is measured by plant cover and biomass production and by the disruption of food production systems (De Waal, 1989; Mortimore, 1989). Drought reduces the number, phytomass, and ground cover of plants and hence reduces the protection of the soil against erosion (Grainger, 1992). Desertification has much more profound and lasting effects. Desertified soils are subject to extensive water and wind erosion and therefore lose much of their depth and ability to store water and nutrients (Mainguet, 1986; Grainger, 1992). In the worst cases, all perennials are removed, and the soil surface is subjected to large-scale wind and water erosion. Without permanent vegetation protection, the soil surface is eroded by running water, sealed and crusted by raindrop splash, and made increasingly impervious and

hence prone to more erosion. Soil surface sealing and encrustation reduces water intake, resulting in a drier environment. Thus, a whole spiral of self-perpetuating edaphic aridity is triggered (Le Houérou, 1969; Floret and Pontainier, 1984). Eventually, all of the soft soil layers are removed, and the situation becomes irreversible.

Schlesinger *et al*. (1990) propose that not only does drought and the loss of vegetation cover lead to desertification, but a mere shift in plant growth form dominance, as a consequence of overgrazing, may drastically reduce productivity. In their model of dryland degradation in the southwestern United States, they suggest that overgrazing results in the redistribution of organic matter and nutrients and is the primary agent responsible for the current conversion of previously productive grasslands to unproductive mesquite (*Prosopis glandulosa*) shrublands. Where resources within semi-arid grasslands previously were homogeneously distributed, overgrazing results in their concentration beneath shrub islands. Not only is the productivity of the land reduced, but positive feedback processes render the changes irreversible (Schlesinger *et al*., 1990).

Rangelands are likely to be prone to desertification because of their inherent fragility (see Chapter 2). Hanson *et al*. (1993) use three GCMs to assess the effect of climate change on plant and animal production in the Great Plains of North America. Their scenarios predict decreases in plant nitrogen content during summer grazing and decreases in animal production because of increased ambient temperature and decreased forage quality. Using a 1-year time-step livestock-production model, they show for the simulations used that carrying capacities would need to drop from above 6.5/ha to 9/ha to maintain 90% confidence of not overstocking.

Desertification causes soil to lose its ability to support rain-fed crops (El-Karouri, 1986). It inevitably results in emigration as the land cannot sustain the original inhabitants (Westing, 1994). There are indications that as much as 3% of the African population has been permanently displaced, largely as a result of environmental degradation.

4.4.4.   Adaptive Strategies for Mitigating the Impacts of Climate Change on Desertification

As we have noted, some desertification already is irreversible. Many other examples of desertification are reversible given appropriate legislation, technology, conservation techniques, education, and, most importantly, the will to act. There are various measures to combat the aridity that might lead to desertification. The impact of increased aridity on natural ecosystems and crops would be moderate and in most cases manageable if improved agricultural and management practices—such as the selection of more drought-tolerant species and cultivars, shorter-cycle annual crops, better tillage practices, soil conservation practices, more timely agricultural operations, and more water-conserving crop rotations—were adopted. In natural ecosystems such as rangelands, increased aridity could be mitigated through the use of more appropriate stocking rates and more balanced grazing systems such as deferred grazing, the concurrent utilization of various kinds of stock species and breeds, game ranching, mixed stock and game ranching, commercial hunting, and so forth.

4.4.4.1.   Water Use and Management

One of the primary factors affecting water availability is the annual distribution of precipitation. There are large differences in water availability in soils within a given land system or landscape, depending on topography, geomorphology, and the nature of the soil and its depth. Many surveys show that water availability in contiguous soils may vary by a factor of one to ten or more (Le Houérou, 1962; Floret and Pontainier, 1982, 1984). The actual distribution of water in soils may be modified considerably by tillage and mulching practices, soil and water conservation techniques, runoff farming, water harvesting, and wadi diversion. Most of these techniques have been known for nearly 3,000 years in the Near and Middle East.

The techniques of runoff farming—which probably date to nearly 3,000 years ago in western China, Iran, Saudi Arabia, Yemen, Jordan, northern Africa, and Spain—have hardly been used outside their own regions but are capable of development elsewhere. Unfortunately, some of these techniques are being abandoned in countries in which they have been in use for centuries, such as southern Tunisia, Libya, northern Egypt, Yemen, and Iran. The techniques of water harvesting—well-developed in the Near East and North Africa during Roman and Byzantine periods (200 BC to 650 AD)—could be developed again within and outside these regions taking care to ensure that the new conditions are suitable for them.

Irrigated farming may not suffer from increased aridity even if water availability becomes more difficult. Improved irrigation practices (e.g., generalized drip irrigation, underground irrigation) can save up to 50% water compared with conventional irrigation systems. Under more-arid future conditions, one could expect a very large increase in the use of irrigation, in addition to the expansion of controlled farming, crop genetic improvement, and the expansion of winter-growing crops that are much less demanding on water.

In most arid and semi-arid countries, wasted water is common, particularly in agriculture (due to inefficient irrigation systems). The amount of waste commonly reaches 50% in many countries, but such waste often is easy to prevent with appropriate techniques. In many countries, water from aquifers (both shallow and deep) is being used at rates that exceed recharge. Increased pumping of water from these aquifers for irrigation will hasten their depletion and threaten the availability of this water for even more vital needs. Future development in many countries will require water savings.

Two ways to save water besides improved irrigation and drainage systems are to utilize water-efficient plants and to develop winter-growing crops. Alfalfa, for instance (a very popular fodder crop), is extremely water-demanding—requiring about 700–1000 kg of water to produce 1 kg of fodder dry matter—whereas some other fodder crops are less water-demanding for the same yield. Winter-growing crops consume much less water than summer crops because PET during winter is only a small fraction of the summer amount.

Drainage water, which has a rather high concentration of salts, can be re-used to grow salt-tolerant crops, including cashcrops such as asparagus or industrial crops such as sugar beet; it also may be used to grow timber and fodder. Some timber and fuelwood species can produce high yields with water having half the salt concentration of seawater, as can a number of fodder crops such as saltbushes, fleshy sainfoin, tall fescue, and strawberry clover (Le Houérou, 1986). There is, however, a potentially detrimental effect of re-using salt-enriched drainage waters—namely, the accelerating salinization of soil, as occurred adjacent to the Nile in Egypt.

There are many techniques that could be used to counteract a moderate increase in climatic aridity, such as those outlined above, but these techniques tend to increase the costs of production and thus alter the conditions of commercial competition of products on the markets.

4.4.4.2.   Land-Use Systems

Adaptation to drought and desertification has challenged pastoralists, ranchers, and farmers for centuries. Pastoralists and ranchers have drought-evading strategies and farmers have drought-enduring strategies. Drought-enduring strategies include the adoption of a light stocking rate that preserves the dynamics of the ecosystems and their ability to recover after drought, and the utilization of agroforestry techniques whereby fodder shrubs and trees that can store large amounts of feed over long periods of time are planted in strategic locations in order to provide an extra source of feed when drought occurs. Among the species used are saltbush plantation, spineless fodder cacti (*Agave americana*), wattles (*Racosperma* spp), mesquites (*Prosopis* spp), and acacias (*Acacia* spp). These provide and

thus encourage a more permanent rather than nomadic existence even when the range is dry and parched.

Another drought-enduring strategy utilized in the United States and South Africa is game ranching of animals that are better adapted to dry conditions than are livestock—including several species of Cervidae, various antelopes, and ostriches. There are at present more than 20 Mha of game ranching in South Africa, Namibia, Botswana, and Zimbabwe (Le Houérou, 1994). The utilization of stock species and breeds that are better adapted to dry conditions is a further possible adaptation. Many East African pastoralists (Somali, Rendille, Gabra, Samburu) have shifted recently from cattle-husbandry to camel-rearing as a response to the deterioration of their environment; others have increased the proportion of goats compared to sheep (e.g., Turkana).

A drought-evading approach to coping with drought and desertification is the application of soil-conservation techniques, including zero or minimum tillage, contour furrowing, pitting, banking, terracing, and benching. Most of these techniques have been known to some ethnic groups and to some regions for a long time, yet they have rarely been extended outside their region of origin.

The overall strategy should be the development of diversified and multiple production systems—including wildlife, combined with livestock and game ranching; commercial hunting; various tourism activities, including so-called green-tourism; runoff farming; poultry production; and nonagricultural activities such as handicraft. Such activities are developed to various levels in a number of countries, such as the drylands of the United States (west of 100° longitude), Australia, South Africa, Namibia, Botswana, Zimbabwe, Kenya, and Tanzania. There is no reason why these practices could not be developed elsewhere.

4.4.4.3.   Agroforestry

Agroforestry may play an extremely important role in the development of semi-arid and arid lands and in the struggle against desertification (Le Houérou, 1980; Baumer, 1987; Le Houérou and Pontainier, 1987). Agroforestry techniques have been developed for centuries in some rural civilizations—such as Kejri [*Prosopis cineraria* (L) Druce] in northwest India (Rajasthan); *Faidherbia albida* (Del.) Chev. in various parts of intertropical Africa; saltbushes in various arid zones of the world; *Argania spinosa* (L.) Sk in southwest Morocco; *Quercus ilex* L. and *Q. suber* L. in Spain and Portugal; and Espino (*Acacia caven* Mol.) and Algarrobo (*Prosopis spp*) in Latin America. Such techniques permit high rural population densities in arid zones (e.g., 60–80 people/km^2) with *Faidherbia* in southern Sahel, and similar densities in Rajasthan with *Prosopis cineraria* and in southern Morocco with *Argania* (the latter region receives <150–300 mm/yr rainfall).

Agroforestry therefore should be an integral part of any dryland development strategy for sustainable agriculture. This development should include village woodlots, which—when located in strategic situations on deep soils, and benefiting from some runoff—may produce very high yields as long as the right species of tree are selected and then rationally managed. Such woodlots could and should be an important part of the fight against desertification because fuelwood collection is a major cause of land degradation in many developing countries.

4.4.4.4.   Conservation and Biodiversity

The world's semi-arid and arid lands contain a large number of species of plants and animals that are important to humankind as a whole. Due to recent desertification of several regions of the world, many species are endangered or will soon be. The only way to preserve this biological capital for the benefit of humankind is *in situ* conservation projects. However, conservation is expensive, particularly in areas where the demand on the land is acute because of high human population growth.

4.5.   Other Forms of Soil Degradation

There are a number of other soil processes that can lead to land degradation under a changing climate. For example, organic-matter levels may decline; leaching may increase, giving rise to loss of nutrients and accelerated acidification; and, in some instances, soil structure may deteriorate. Some of these changes already are taking place as a result of land-use changes, poor farming practices, and industrial emissions. To date, the changes are fairly subtle, and increasing slowly—unlike some forms of erosion and salinization which can occur more quickly.

4.5.1.   Declining Organic-Matter Levels

Organic matter probably is the most important component of soils. It influences soil stability, susceptibility to erosion, soil structure, water-holding capacity, oxygen-holding capacity, and nutrient storage and turnover, and it provides a habitat for extremely large numbers of soil fauna and microflora. With the expansion of agriculture and its intensification, soil organic-matter levels have declined. In the United States, for example, many prairie soils have lost more than one-third of their initial organic-matter contents after 100 years or more of cultivation (Papendick, 1994).

A decline of 55–58% in organic matter (equivalent to a loss of 29–32 t/ha) has been noted in the top 10 cm of two alluvial soils in New Zealand after just 2 years of continuous cropping (Shepherd, 1992). Much of this organic matter was lost to the atmosphere as CO_2; this demonstrates the point that some intensively cropped land can potentially release a significant amount of greenhouse gases (Tate, 1992).

Organic matter is susceptible to change with changing climate. Higher temperatures increase rates of decomposition. Whether

enhanced atmospheric CO_2 concentrations will give rise to sufficient increases in plant growth to return organic matter to soils and compensate for this loss is still not established (see Chapter A). If CO_2 levels do not lead to compensation, it will be important to implement programs of organic-matter management to maintain adequate soil organic-carbon contents to prevent degradation. This also will benefit carbon sequestration (see Chapters 23 and 24).

4.5.2.   Declining Nutrient Levels

Loss of nutrients is a common phenomenon in countries with low-input agriculture and also occurs under soils with a high leaching potential and a low buffering capacity.

In soils in which the movement of water is predominantly downward, there will be a tendency for nutrients to be lost. In intensive, high-input agriculture, such losses are compensated by fertilizer additions, but under low-input agriculture, loss of nutrients is a common occurrence—one that is recognized as an increasing problem, particularly in subtropical and tropical countries (Smaling, 1990; Pereira, 1993).

Temperature and precipitation changes could affect soil nutrient levels in several ways. Rising temperatures could act to maintain nutrients within the soil because of increased evaporative forces, and thus reduce leaching. An increase in rainfall generally will give rise to increased nutrient loss. Conversely, a decrease in rainfall may lead to upward movement of nutrients—which, in some cases, can lead to salinization (see Section 4.3). Nutrient loss can be compensated by the use of inorganic and organic fertilizers, but the cost can be prohibitive for subsistence farmers.

4.5.3.   Acidification

Most countries contain large areas of acidified soils (Wild, 1993). The extent to which acidification will increase with climate change depends on both rainfall and temperature. Significant increases in rainfall would be accompanied by increased leaching and thus acidification (Rounsevell and Loveland, 1992). A decline in rainfall could reduce the extent and intensity of acidification. In the sub-arid and sub-humid zones, soils are subject to seasonal changes—from leaching conditions to evaporative conditions. An altered climate could shift conditions to a dominantly leaching regime involving increased acidification, or to a dominantly evaporative regime involving less acidification but possible salinization. The direction of change will depend on the extent to which rainfall and temperature change.

One of the soil types most affected by acidification is termed acid sulfate soils. These soils suffer from extreme acidity as a result of the oxidation of pyrite when pyrite-rich parent materials are drained (Dent, 1986). Pyrite accumulates in waterlogged soils that are rich in organic matter and contain dissolved sulfates, usually from seawater. When these previously waterlogged soils are drained, oxygen enters the soil system and oxidizes pyrite to sulfuric acid, causing the pH to drop to less than 4.

Several areas of the world contain potential acid sulfate soils, which would be converted to acid sulfate soils if climate change were to lead to the lowering of water tables and increased oxidation (in total over 20 Mha; Beek *et al*., 1980). The principal areas affected would be coastal areas of West Africa, South America, India, and the Far East.

4.5.4.   Deterioration of Soil Structure

Soil structure regulates water retention and movement, nutrient transformations and movement, faunal activity and species diversity, and the strength and penetrability of the rooting media (Lal, 1994a). Soil structure affects the ability of the soil to be cultivated, and the quality and durability of seedbeds—and thus plant growth and vigor, grain yield, and grain quality (Shepherd, 1992). The potential for deterioration of soil structure as a result of climate change, in conjunction with poor soil management, has received little attention from the scientific community even though soil structure controls water and air movement and transport processes in the soil profile. Changes to soil structure are notoriously difficult to quantify, partly because of the influence of land use and management; research needs to be directed toward a better understanding of this. However, some potential consequences of climate change can be identified.

A decline in soil organic-matter contents as a result of climate change has important implications for soil quality in general and specifically for soil structural development because there is a strong relationship between organic-matter levels and soil structure quality (see Chapter A). A decline in soil organic-matter levels would cause a decrease in soil aggregate stability, an increase in susceptibility to compaction, lower infiltration rates, increased runoff, and, hence, enhanced likelihood of erosion.

A second important function of soil structure—in relation to clay soils particularly—is their influence on water quality and seepage. Soils with high clay contents, especially those with expanding type clays (smectitic mineralogy), tend to shrink when they are dry and swell as they wet-up again. This behavior results in the formation of large cracks and fissures. Drier climatic conditions would be expected to increase the frequency and size of crack formation in soils, especially those in temperate regions that currently do not reach their full shrinkage potential (Climate Change Impacts Review Group, 1991). One consequence would be more rapid and direct movement of water and dissolved solutes from soil to surface waters or aquifers through so-called "bypass" flow via cracks (Armstrong *et al*., 1994). The more direct movement of water in this way would decrease the filtering capacity of soil and increase the possibility of nutrient losses and pollution of ground and surface waters. Where animal manures or sewage sludge are applied to land, there would be a greater risk of organic contaminants and microorganisms reaching aquifers.

In the case of acid soils, increased cracking could lead to an increase in the quantity of metals (e.g., aluminum, manganese, iron, heavy metals) entering aquifers. In these situations, the combined effects of changes in soil chemical and biological cycles and increased cracking need to be assessed (Rounsevell and Loveland, 1992). An additional consequence is that the soil profile would not re-wet as before, and the rooting zone could be deprived of valuable water. Such changes also would have important implications for the stability of the foundations of buildings and roads—which would have been designed on the basis that such soils did not reach their shrink-swell capacity (Boden and Driscoll, 1987).

4.6. Monitoring and Research Needs

4.6.1. Monitoring

Global estimates of land degradation generally are very crude; as a result, it is difficult to present a meaningful picture of its extent and severity. The most recent attempt by Oldeman *et al.* (1990) helps to indicate the types and severity of land degradation, but because of a lack of adequately established national surveys or a global network of monitoring sites, the results can only be a broad approximation. Compared with air and water, soil has received little attention in terms of monitoring; very few countries have sound data on the quality of their soils, and there often are few or no trend data to indicate whether or how soil quality is changing. There is a need to establish a comprehensive monitoring system for soil quality at a national level that will contribute to the creation of a global picture. In the absence of such a program, there will be general ignorance of changes in soil quality with time, leading to an inability to address strategically any deleterious changes. The limited information that is available suggests that land degradation is a major global problem that urgently needs to be addressed.

4.6.2. Research

To date, most research on the impacts of climate change on soils has involved taking knowledge of soil processes and properties gained over some 50 years and predicting what effect a new climatic scenario might have on them. Other research has examined the impacts of climate change on soils in terms of their ability to support current and future crops and natural ecosystems. Both of these approaches, although justifiable on the basis of the need for early predictions of the effects of climate change, often lack rigor.

There are three areas in which research now needs to focus:

- Determining the impact of increased atmospheric CO_2 concentrations, temperature, and changes in other climatic parameters on soil properties and processes, including those involved in land degradation under different land uses in different climatic zones

- Identifying the impact of these climate-induced changes on soil processes and properties and on the ability of the soil to perform its functions (e.g., as a habitat for microflora and fauna, nutrient storage and turnover, water storage and movement)

- Understanding how such changes will affect terrestrial ecosystems, what the response times of such systems to soil changes will be, and what the suitability of changed soils will be for crops and more natural habitats.

A successful outcome to this research requires continuing improvements to terrestrial nutrient-cycle models and GCMs. In particular, much better information is required for rainfall—including amount, frequency, duration, and intensity—and for surface wind, including direction, speed, and frequency of high-wind events. Given improved model output that is more reliable at the regional scale and the research outlined above, governments and land managers will receive increasingly valuable indicators of future conditions.

CONTENTS

EXECUTIVE SUMMARY

This chapter focuses on the impacts of climate change on physical, ecological, and socioeconomic systems in mountain regions; this topic was not addressed in the form of an explicit chapter in the 1990 Assessment Report.

Scenarios of climate change in mountain regions are highly uncertain; they are poorly resolved even in the highest-resolution general circulation models (GCMs). Furthermore, mountains perturb atmospheric dynamic and thermal characteristics, thereby establishing locally distinct, topographical microclimates that influence a wide range of environmental factors. With these facts in mind, we can summarize the effects of climate change on mountains as follows.

Mountain Physical Systems

If climate changes as projected in most climate scenarios, we have a high degree of confidence that the length of time that snow packs remain will be reduced, altering the timing and amplitude of runoff from snow, and increasing evaporation. These changes would affect water storage and delivery infrastructure around the world (see also Chapters 10 and 14). Alterations in precipitation regimes will modify these responses. Changes in extreme events (floods and droughts) could affect the frequency of natural hazards such as avalanches and mudslides. Downstream consequences of altered mountain hydrology are likely to be highly significant to economies dependent on this water.

Mountain Ecological Systems

We have a medium degree of confidence as to current understanding related to responses of mountain vegetation to changes in temperature and precipitation, based on paleoenvironmental studies, observations, and experiments. However, predictions of vegetation shifts are complicated by uncertainties in species-specific responses to increased CO_2 as well as uncertainties in projected regional temperature, precipitation, and soil moisture changes. All of these factors influence competitive interactions between species, particularly near ecotones such as timberline where species migrating upslope in response to warming are likely to encounter more slowly responding current inhabitants.

Human land use has contributed to diminished biological diversity in many mountain regions around the world. We have a medium degree of confidence as to the probability that climate change will exacerbate fragmentation and reduce key habitats. There is cause for concern that mountaintop-endemic species may disappear.

Mountain Socioeconomic Systems

In many developing countries, mountains provide food and fuel needed for human survival. We have a high degree of confidence that disruption of mountain resources needed for subsistence would have major consequences, but we have a medium degree of confidence as to the response of mountain populations to such changes.

In areas where people do not depend on mountain environments for subsistence, mountain lands are primarily used for cash crops, mining, timber harvest, and recreational activities. While not critical to human survival, these mountain areas are of increasing local and regional economic significance.

Mountains can be used effectively as conservation reserves in a changing climate because they support a relatively broad distribution of possible climates and a high diversity of habitats within a small physical area. Such reserves are most effective if they include a significant elevation range.

We are confident that competition between alternative mountain land uses is likely to increase under climate-change and population-rise scenarios.

5.1. Mountain Characteristics

5.1.1. Introduction

Mountain systems account for roughly 20% of the terrestrial surface area of the globe and are found on all continents. They are usually characterized by sensitive ecosystems and enhanced occurrences of extreme weather events and natural catastrophes; they are also regions of conflicting interests between economic development and environmental conservation. Once regarded as hostile and economically nonviable regions, mountains have attracted major economic investments for industry, agriculture, tourism, hydropower, and communication routes. Most mountain regions except in Antarctica are inhabited; Ives (1992) has pointed out that mountains provide the direct life-support base for about a tenth of humankind and indirectly affect the lives of more than half.

Despite their relatively small surface area, mountains are an integral part of the climate system. As a physical barrier to atmospheric flows, they perturb synoptic patterns and are considered to be one of the trigger mechanisms of cyclogenesis in mid-latitudes. Because of significant altitudinal differences, mountains such as the Himalayas, the Rockies, the Andes, and the Alps exhibit within short horizontal distances climatic regimes similar to those of widely separated latitudinal belts; they also feature increased diversity of species, communities, and habitats over lowland environments. Mountains are also a key element of the hydrological cycle, being the source of many of the world's major river systems. Abrupt changes in existing temperature and precipitation patterns that have led to the present distribution of vegetation, ice, snow and permafrost zones would impact heavily on the unique features of mountain environments. This, in turn, would lead to significant perturbations to the existing socioeconomic structures for populations living within the mountains themselves and indirectly to populations living outside these zones but dependent on them.

Mountains around the world are also significant to local and global economies because of the mineral and timber resources they contain, as well as their hydropower potential. Regional climate change could directly affect the viability and health of commercial timber production and, in an indirect manner, add cost to mining and other mineral extraction and processing activities in mountainous areas.

5.1.2. Climate Characteristics

A precise understanding of the climatic characteristics of mountain regions is limited by a lack of observations adequately distributed in time and space and insufficient theoretical attention given to the complex interaction of spatial scales in weather and climate phenomena in mountains (Beniston *et al.*, 1994). Meteorological research has tended to focus on the upstream and downstream influences of barriers to flow and on orographic effects on weather systems (Smith, 1979) rather than on microclimates within the mountain environments themselves. Climatic features relevant to mountain environments include microscale features of the atmosphere that are superimposed on larger scales of motion and the influence of elements of the surface, such as vegetation and geomorphologic features, which can create microclimatic contrasts in surface heating, soil moisture, or snow-cover duration (Geiger, 1965). Isolating macro- and microscale processes in order to determine their relative importance is complicated by inadequate databases for most mountain areas of the world (Barry, 1994).

Four principal factors influence mountain climates—namely, altitude, continentality, latitude, and topography. The role of these factors is summarized schematically in Table 5-1 (from Barry, 1992); the effects refer to responses to an increase in the factor listed. These climatic differences, in turn, influence vegetation type and cover, hydrology, and sometimes geomorphic features. In particular, vegetation distribution in mountain regions is so closely linked to climatic parameters that vegetation belt typology has been widely used to delineate climate influences (Troll, 1968; Lauer, 1979; Monasterio, 1980; Quezel and Schevok, 1981; Klötzli, 1984, 1991, 1994;

Table 5-1: *Climatic effects of the basic controls of mountain climate.*

Factors	Primary Effects	Secondary Effects
Altitude	Reduced air density, vapor pressure; increased solar radiation receipts; lower temperatures	Increased wind velocity and precipitation (mid-latitudes); reduced evaporation; physiological stress
Continentality	Annual/diurnal temperature range increased; cloud and precipitation regimes modified	Snow line altitude increases
Latitude	Daylength and solar radiation totals vary seasonally	Snowfall proportion increases; annual temperatures decrease
Topography	Spatial contrasts in solar radiation and temperature regimes; precipitation as a result of slope and aspect	Diurnal wind regimes; snow cover related to topography

Ozenda, 1985; Quezel and Barbero, 1990; Rameau *et al*., 1993). Although it would appear simple to discuss how these typologies might be modified as a result of changing global climate, the climate system and its interaction with such landscape components as vegetation, geology, topography, and soil are highly nonlinear (Beniston, 1993, 1994).

5.1.3. Physical Characteristics

The various components of the hydrologic cycle are critical links between climate and the life of mountain communities and also influence areas downstream. The timing and volume of rainfall and snowmelt are critical constraints on hydrological systems. Sediment loadings can be exceptionally high in many rivers originating in mountains and reflect geomorphologic processes. Unless slowed down by major lakes within mountains themselves or in adjacent lowlands, or by engineering works designed to control torrent flows, rivers will carry their heavy loads unimpeded into the plains. This can be beneficial for agriculture because these sediments create rich and fertile soils, but excessive loads can have adverse consequences, such as flooding of populated lowland areas.

Influencing the hydrological system are elements of the mountain cryosphere, particularly glaciers and seasonal snow packs. These are of major significance in some of the more elevated mountain chains of the world in terms of water availability in the source region of many of the world's rivers (Steinhauser, 1970). Snow cover in mountains is affected by the following factors, which are all linked to climate:

- Snow cover duration, which has been shown to vary linearly with altitude and is a function of slope orientation (Slatyer *et al*., 1984)
- Snow depth, which also varies with altitude, orientation, and topography (Witmer *et al*., 1986; Föhn, 1991)
- Snowmelt runoff, which feeds into the hydrologic system of mountains; this is determined by temperatures and surface energy balance in spring (Collins, 1989; Chen and Ohmura, 1990).

Changes in glacier and permafrost ice are linked to changes in the energy balance at the Earth's surface. Rates of such glacier

and permafrost changes can be determined quantitatively over various time intervals, allowing direct comparison with estimated effects of anthropogenic greenhouse forcing (Haeberli, 1994). As a consequence, they are among the clearest signals evident in nature of ongoing warming trends related to the enhanced greenhouse effect (Haeberli, 1990; Wood, 1990; WGMS, 1993). Evidence from borehole profiles in permafrost also helps to determine the rate and magnitude of temperature changes (Mackay, 1990, 1992; Vonder Muehll and Holub, 1995).

A major problem in many mountain regions related to climate change is increased erosion and reduced slope stability. The combination of complex orography with steep slopes, intense rainstorms, and, in some regions, frequent earthquakes, causes a high proportion of mass movement, which eventually finds its way into rivers as heavy sediment load. Any changes to an already fragile environment would impact heavily on geomorphologic processes, resulting in indirect impacts to natural and socioeconomic systems (Innes, 1985). For example, higher precipitation, particularly during extreme events, can augment the risk of erosion. However, the potential for increased erosion depends on a number of other factors linked to topography, geology, soil types, and farming and conservation practices associated with a particular region. Enhanced precipitation can sometimes favor the development of denser vegetation, which in turn prevents soils from being eroded. Precipitation is not only a water source in mountain terrain but also the trigger factor for the occurrence of debris flow, landslide, and slope failure. No general study of the relationship between rainfall and landslides exists at a global scale, but in many specific cases a clear relation has been established between rain duration and induced movements (Noverraz and Bonnard, 1992). Relations between rainfall and induced movements can be direct and immediate or more long-term; in many cases, a long period of rainfall prior to the event has to be taken into account to explain a particular landslide (Bonnard, 1994).

5.1.4. Ecological Characteristics

Altitudinal vegetation distribution has traditionally been used to characterize mountain environments. This distribution is

---

**Box 5-1. Climate Variabilty as Reflected in Glacier Regimes
in the Former Soviet Union (FSU)**

Solomina (1995) presents case studies of glacier fluctuations in the FSU. Major conclusions include:

- The length of many mountain glaciers in the FSU has decreased by up to 4 km during the last two centuries. The maximum degradation has occurred in regions with strong glaciation (the Caucasus, Pamirs, Tien Shan, and Altay).
- Changes in the equilibrium line altitude (ELA: the altitude of a glacier at which snow accumulation is equal to snow ablation) have also been more pronounced in regions with large glaciers, namely the Caucasus, Altay, and the periphery of the Central Asian mountains, and less in other mountain zones of the FSU. The mean ELA is estimated as being 50–80 m lower today than during the Little Ice Age.

strongly influenced by climatic parameters, but not exclusively. Topography, edaphic factors, and, in many areas, human activities and the disturbances they generate strongly interfere with the potential distributions suggested by large-scale climatic parameters alone.

The zonation patterns of vegetation differ according to the location of the mountains along a latitudinal gradient, as shown in Figure 5-1. Tropical mountains typically experience relatively uniform mean temperatures throughout the year, with significant diurnal temperature variation. Mountains in temperate and boreal zones, on the other hand, are characterized by seasonal climates with a well-defined growing season, whereby plants can exploit the short, warm summers. Many plant species at high altitudes are capable of surviving harsh conditions as a result of the onset of a hardening process.

The amount and duration of snow cover influences high mountain vegetation by determining growing season and moisture conditions. In the alpine zones, exposed, windy ridges are generally covered with xeric dwarf shrubs and wind-hardy lichens. Depending on nutrition and soil moisture, more mesic dwarf shrub heaths and mesic low herb meadows are found on lee slopes of intermediate snow cover. The late-exposed snow patches have hygrophilous herb communities. Vascular plants may be completely lacking due to the very short growing season.

Both altitude and latitude contribute to high diversity in species composition in mountain forests: Coniferous trees are common in boreal and temperate mountains, sclerophylous types in Mediterranean zones, deciduous species in oceanic boundaries of continents (e.g., Norway, British Columbia), and ericaceous (East Africa; Hedberg, 1951) or podocarp (Equatorial Andes) species in tropical zones. Furthermore, a unique feature of

tropical mountains are cloud forests, which exhibit a high degree of biodiversity.

5.1.5. *Human Characteristics*

Mountains having a history of relatively dense settlement, such as those in Europe, Japan, and the eastern United States, are facing a decline of traditional agriculture and forestry, which have been economically viable only because of government subsidies. Mountains with a history of less dense settlement, such as the western United States, Canada, South America, Africa, Australia, and New Zealand, have over the past three centuries faced pressure from colonization and immigration, which have introduced scattered but growing settlements. In relatively recent decades, tourism has emerged as a significant income source in mountain regions, as well as a major source of environmental stress (Grötzbach, 1988). While in some regions (e.g., western Europe and Japan) mountains are experiencing depopulation (Yoshino *et al*., 1980; Price, 1994), in general, land-use pressures are increasing because of competition between refuge use, mineral extraction and processing, recreation development, and market-oriented agriculture, forestry, and livestock grazing (Ives and Messerli, 1989; Messerli, 1989).

Mountain habitats in developing nations, where traditional subsistence agriculture continues, face stress from increasing human population, ameliorated to some extent by short-term or seasonal migration. In many of these regions, pressures exist to develop market-based agricultural systems, changing from a largely local economy to a national and international one. In Africa, most of the mid-elevation ranges, plateaus, and slopes of high mountains are under considerable pressure from commercial and subsistence farming activities (Rongers, 1993). In

Figure 5-1: Schematic illustration of vegetation zonations in tropical, temperate, and boreal mountains.

Box 5-2. Socioeconomic Characteristics of North American Mountain Regions

The major mountains of North America are the Rockies, the eastern Appalachian chain, and various coastal ranges along the west coast of the continent. Primarily in the United States and in Mexico, the mountains border on semi-arid, highly populated urban areas (Mexico City, Los Angeles, Denver); most North American mountains are sparsely populated, however. Traditional economies have been in the mining and pastoral fields, with limited agriculture where the climate allows it. Forest harvest and replanting has been practiced in many areas. Much of the remaining area, especially in the Western United States and Canada, is set aside for wilderness, where human influence is minimized, and for parks, which are managed (Peine and Martinka, 1992). Because of this rather significant wilderness designation (over 16 million hectares, about 6% of all forested lands in the United States alone), adaptation to the potential impact of global climate change on natural ecosystems and biological diversity is more an administrative management issue than a scientific one (OTA, 1993). One problem is that wilderness areas tend to occupy only the tops of mountains, not the entire mountain, limiting the availability of diverse habitats and hence migration opportunities.

---

unprotected areas, mountain forests are cleared for cultivation of high-altitude adapted cash crops like tea, pyrethrum, and coffee. Population growth rates in East Africa, among the highest in the world (Goliber, 1985), are concentrated in agriculturally fertile and productive mountain districts (Government of Tanzania, 1979). This is quite evident near Mt. Kenya, Mt. Kilimanjaro, and in the Usambara Mountains (Lundgren, 1980). Tourism is becoming economically important in small, well-defined portions of these regions (Price, 1993).

Particularly in tropical and semi-arid climates, mountain areas are usually wet, cool, and hospitable for human dwelling and commercial cultivation. Human encroachment on mountain regions has reduced vegetation cover, thus increasing soil-moisture evaporation, erosion, and siltation, and thereby adversely affecting water quality and other resources. Impact analyses need to seriously consider not only climate but also the direct anthropogenic influence on mountain regions.

5.2. Impacts of Climate Change

Mountain environments are potentially vulnerable to the impacts of global warming because the combination of enhanced sensitivity to climatic change and limited possibilities for species migration to favorable locations make mountains "islands" in a "sea" of surrounding ecosystems (Busby, 1988). This vulnerability has important ramifications for a wide variety of human uses and natural systems, such as nature conservation, land management, water use, agriculture, and tourism. It also has implications for a wide range of natural systems (hydrology, glaciers and permafrost, ecosystems, and so forth).

Few assessments of the impacts of climate change have been conducted in mountain regions, in contrast to other biomes such as tropical rainforests, coastal zones, and high-latitude or arid areas. There are a number of reasons to explain this, some of which are listed below:

- The dominant feature of mountains (i.e., topography) is so poorly resolved in most general circulation climate models (GCMs) that it is difficult to use

GCM-based scenarios to investigate the potential impacts of climate change. There also is a significant lack of comprehensive multidisciplinary data for impact studies, which is one of the prerequisites for case studies of impacts on natural or socioeconomic systems (Kates *et al.*, 1985; Riebsame, 1989; Parry *et al.*, 1992).

- The complexity of mountain systems presents major problems for assessing the potential impacts of climate change. This applies to assessments of changes in both biophysical systems (e.g., Rizzo and Wiken, 1992; Halpin, 1994) and societal systems, the latter in particular because it is difficult to quantify the value of mountain regions in monetary terms (Price, 1990).

- Tourism, which is an increasingly important component of mountain economies, is not an easily defined economic sector and is highly influenced by factors other than climate change.

5.2.1. Scenarios and Methodologies

Mitigation and adaptation strategies to counteract possible consequences of abrupt climate change in mountain regions require climatological information at high spatial and temporal resolution. Unfortunately, present-day simulation techniques for predicting climate change on a regional scale are by no means satisfactory. This is because GCMs generally operate with a rather low spatial resolution over the globe (~300 km) in order to simulate climate trends over a statistically significant period of time. As a result, entire regions of sub-continental scale have been overlooked in terms of their climatological specificities, making it difficult to predict the consequences of climate change on mountain hydrology, glaciers, or ecosystems in a specific mountain region (Giorgi and Mearns, 1991; Beniston, 1994). The situation is currently improving with the advent of high-resolution climate simulations in which the spatial scale of GCMs is on the order of 100 km (Beniston *et al.*, 1995; Marinucci *et al.*, 1995). However, even this resolution is generally insufficient for most impact studies.

A number of solutions exist to help improve the quality of climate data used in impact assessments and economic decisionmaking.

Options include statistical techniques of downscaling from synoptic to local atmospheric scales (Gyalistras *et al*., 1994); coupling of mesoscale, or limited area, models (LAMs) to GCMs (Giorgi *et al*., 1990, 1992; Marinucci and Giorgi, 1992; Marinucci *et al*., 1995); and use of paleoclimatic and geographical analogs (e.g., LaMarche, 1973; Webb *et al*., 1985; Davis, 1986; Schweingruber, 1988; Graumlich, 1993; Luckman, 1994).

Any meaningful climate projection for mountain regions—and, indeed, for any area of less than continental scale—needs to consider processes acting on a range of scales, from the very local to the global. The necessity of coupling scales makes projections of mountain climates difficult.

5.2.2. *Impacts on Physical Systems*

5.2.2.1. *Impacts on Hydrology*

In spite of limitations in the quality of historical data sets and inconsistencies in projections between GCMs, particularly for precipitation (Houghton *et al*., 1990), assessments of the potential impacts of climate change on water resources, including snowfall and storage, have been conducted at a variety of spatial scales for most mountain regions (Oerlemans, 1989; Rupke and Boer, 1989; Lins *et al*., 1990; Slaymaker, 1990; Street and Melnikov, 1990; Nash and Gleick, 1991; Aguado *et al*., 1992; Bultot *et al*., 1992; Martin, 1992; Leavesley, 1994). For example, high-resolution calculations for the Alps (Beniston *et al*., 1995) using a nested modeling approach (GCM at 1° latitude/longitude resolution coupled to a LAM at 20-km resolution) indicate that in a doubled-CO_2 atmosphere wintertime precipitation will increase by about 15% in the Western Alps; this is accompanied by temperature increases of up to 4°C. Summertime precipitation generally decreases over the alpine domain, with July temperatures on average 6°C warmer than under current climatic conditions. Such numerical experiments, while fraught with uncertainty, nevertheless provide estimates

of possible future regional climatic conditions in mountains and thereby allow more detailed impact assessments.

Climate change may be characterized by changes in seasonal or annual precipitation, proportions of solid to liquid precipitation, or frequencies of extreme events. Whatever the directions and magnitudes of change, mountain communities and those downstream need to be prepared to implement flexible water management strategies that do not assume that recent patterns will continue. Events in recent history may provide useful guidelines for developing such strategies (Glantz, 1988).

Climate-driven hydrology in mountain regions is determined to a large extent by orography itself; mountain belts produce regional-scale concentration of precipitation on upwind slopes and rain-shadow effects in the lee of mountains and in deep intermontane valley systems, often giving rise to high mountain deserts. Many of the more elevated mountain chains of the world intercept large atmospheric moisture fluxes and produce belts of intense precipitation. Along the southern slopes of the Himalayas, enhancement of monsoonal conditions results in some of the highest annual average precipitation in the world, such as at Cherrapunji, India. The spectrum of variability of hydrological regimes ranges from the predominantly rainforested slopes of Papua-New Guinea to the ice fields of the Patagonian Andes. Climate change will affect the relative importance of these two extreme regimes, as well as the total moisture flux and how it is delivered temporally. Mountains such as the Andes and the Himalayas are source regions for some of the world's largest rivers, such as the Amazon, the Ganges, Irrawady, and Yangtse, and the discharge characteristics of these rivers and their shifts under changed climatic conditions will be largely governed by modified precipitation regimes.

5.2.2.2. *Impacts on Mountain Cryosphere*

The effects of temperature and precipitation changes on glaciers are complex and vary by location. In polar latitudes and at

---

**Box 5-3. Estimates of Cryosphere Response to Climate Change
in Asian, Latin American, and African Mountain Chains**

Wang (1993) estimates that about 21% of the glacial area will disappear in Northwest China if temperature increases by 1–1.3°C and precipitation decreases by 60–80 mm. Glaciers with areas of less than 0.5 km^2 in the Tianshan and Qilian ranges and permafrost areas in Northeast China and Qing-Zang plateau are expected to disappear if temperature increases by 2°C or more (Zhang, 1992; Wang, 1993).

In the Venezuelan Andes, photographs from 1885 show that the present-day snowline has risen from 4,100 m to more than 4,700 m (Schubert, 1992). These changes in ice extent and in snowline altitude have had important geoecological effects, leading to shifts in vegetation belts and to the fragmentation of previously continuous forest formations. Enhancement of the warming signal in these regions would lead to the disappearance of significant snow and ice surfaces.

On Mount Kenya, the Lewis and Gregory glaciers have shown recession since the late 19th century. Calculations of area and volume loss of the Lewis Glacier for 1978–90 show similar rates to those of the preceding decades. Nevertheless, Hastenrath and Rostom (1990) propose that the retreat in the late 19th century was triggered by a decrease in cloudiness and precipitation, whereas the retreat since the 1920s may be due to an observed warming trend.

very high altitudes of mid-latitudes, atmospheric warming does not directly lead to mass loss through melting/runoff but to ice warming (Robin, 1983). In areas of temperate ice, which predominate at lower latitudes or altitudes, atmospheric warming can directly impact the mass and geometry of glaciers (Haeberli, 1994).

Haeberli (1994) indicates that alpine glacier and permafrost signals of warming trends constitute some of the clearest evidence available concerning past and ongoing changes in the climate system. The glacier fluctuations, in particular, indicate that the secular changes in surface energy balance may well be in accordance with the estimated anthropogenic greenhouse forcing. In fact, the evidence strongly indicates that the situation is now evolving at a high and accelerating rate beyond the range of Holocene (natural) variability. Temperature profiles from permafrost boreholes also confirm the nature of recent warming trends (Vonder Muehll and Holub, 1992; Mackay, 1990, 1992).

In terms of climate-change impacts on snow, Föhn (1991) suggests that one potential effect of global warming in the European Alps might be a delay in the first snowfall and a reduction in the length of snow cover. Analysis of satellite data from the 1980s and early 1990s has shown that lowlands around the Alps experience about 3–4 weeks less snow cover than they historically have had (Baumgartner and Apfl, 1994); this tendency will likely accelerate in a warmer climate. Additionally, snow accumulation and ablation exhibit different temporal patterns than in the past and could be even more irregular in a changed climate. For higher elevations, the total annual snow volume accumulated during the winter has not changed significantly this century, despite the observed global temperature rise.

Investigations concerning the impact of climate change on snow conditions in the French Alps were undertaken with a physically based snow model (CROCUS) coupled to a meteorological analysis system (SAFRAN). The two systems have been validated by comparing measured and simulated snow depth at 37 sites of the area for the period 1981/1991. Sensitivity studies show that lower elevations (i.e., below 1500 m) are extremely sensitive to small changes in temperature, especially in the southern part of the French Alps. Variations of precipitation amount influence the maximum snow depth (or snow water equivalent) much more than snow cover duration (Martin, 1995).

Reduced snow cover will have a number of implications; it will increase early seasonal runoff, leading to drier soil and vegetation in summer and greater fire risk. Further details on impacts on mountain cryosphere are provided in Chapter 7.

5.2.2.3.   Impacts on Extreme Events

It is uncertain whether a warmer global climate will be accompanied by more numerous and severe episodes of extreme events because current GCM capability to simulate extremes and their altered frequency of occurrence in a changed climate is extremely limited. Enhanced occurrences of intense storms,

accompanied by high precipitation and/or winds, would inevitably have significant repercussions on a number of sensitive environmental and socioeconomic systems. If the severity of storms such as "Vivian" (European Alps, 1990, which destroyed vast areas of forested slopes) or the intense precipitation of August 1987 in central Switzerland (which disrupted rail and road traffic in the Gotthard Region, one of the major communication routes across the Alps) were to increase in frequency in a changed climate, populations living in mountains would be faced with significant social and economic hardships.

Other impacts associated with extreme events include fire. Forest fires are likely to increase in places where summers become warmer and drier, as has been projected for the Alps, for example (Beniston *et al*., 1995). Prolonged periods of summer drought would transform areas already sensitive to fire into regions of sustained fire hazard. The coastal ranges of California, the Blue Mountains of New South Wales (Australia), Mt. Kenya, and mountains on the fringes of the Mediterranean Sea, already subject to frequent fire episodes, would be severely affected. There would be major socioeconomic impacts as well, because many sensitive regions are located close to major population centers (e.g., Los Angeles and the Bay Area in California; the Sydney conurbation in Australia; coastal resorts close to the mountains in Spain, Italy, and southern France).

5.2.2.4.   Impacts on Geomorphologic Processes

The latitude and altitude of different mountain systems determine the relative amount of snow and ice at high elevations and intense rainfall at lower elevations. Because of the amount of precipitation and relief, and the fact that many of these mountains are located in seismically active regions, the added effect of intense rainfall in low- to middle-altitude regions is to produce some of the highest global rates of slope erosion. Climate change could alter the magnitude and/or frequency of a wide range of geomorphologic processes (Eybergen and Imeson, 1989). The following examples provide an indication of the nature of the changes that might occur with specific changes in climate.

Large rockfalls in high mountainous areas often are caused by groundwater seeping through joints in the rocks. If average and extreme precipitation were to increase, groundwater pressure would rise, providing conditions favorable to increased triggering of rockfalls and landslides. Large landslides are propagated by increasing long-term rainfall, whereas small slides are triggered by high intensity rainfall (Govi, 1990). In a future climate in which both the mean and the extremes of precipitation may increase in certain areas, the number of small and large slides would correspondingly rise. This would contribute to additional transport of sediments in the river systems originating in mountain regions. Other trigger mechanisms for rockfalls are linked to pressure-release joints following deglaciation (Bjerrum and Jfrstad, 1968); such rockfalls may be observed decades after the deglaciation itself, emphasizing the long time-lags involved. Freeze–thaw processes also are very

---

Box 5-4. Long-Term Records of Climate and Vegetation Dynamics: A Key to Understanding the Future

Paleoenvironmental records represent the only available source of information on the long-term natural variability within the biosphere-atmosphere system. The spatial and temporal resolution of paleoenvironmental data sets has increased in recent decades on annual to millenium scales, and data reflecting vegetation dynamics are now available for many parts of the world (Bradley and Jones, 1992; Wright *et al*., 1993; Graumlich, 1994). In addition, comparisons of records of past vegetation dynamics to paleoclimatic simulations by GCMs have improved the understanding of the role of climate in governing past vegetation change (Webb *et al*., 1993). Several major findings of paleoresearch have guided investigations of the effects of future climate change on the Earth's biota. These include changing seasonality, which may result in unexpected vegetation patterns (Prentice *et al*., 1991); rapid changes in both climate and vegetation with ecosystem-wide implications (Gear and Huntley, 1991); and short-term extreme events that may impact tree population structures (Lloyd and Graumlich, 1995). Thus, the same types of individualistic behavior of species observed in physiological attributes are mirrored in long-term and large-scale vegetation dynamics (Graumlich, 1994).

Future climates are likely to be characterized by combinations of temperature and precipitation that are not replicated on the contemporary landscape. Any predictions of vegetation response to climatic changes must be based on an improved understanding of the relationship between climatic variation and vegetation processes; this is where analyses of high-resolution proxy data can be of use.

---

important (Rapp, 1960), and several authors have reported possible links between rockfall activity and freeze–thaw mechanisms linked to climate change (Senarclens-Grancy, 1958; Heuberger, 1966).

A further mechanism that would be responsible for decreased slope stability in a warmer climate is the reduced cohesion of the soil through permafrost degradation (Haeberli *et al*., 1990; see also Chapter 7). With the melting of the present permafrost zones at high mountain elevations, rock and mudslide events can be expected to increase in number and possibly in severity. This will certainly have a number of economic consequences for mountain communities, where the costs of repair to damaged communications infrastructure and buildings will rise in proportion to the number of landslide events. In many mountainous regions, tourist resorts such as those in the Alps and the Rocky Mountains or large urban areas close to mountains (suburbs of South American Andean cities, Hong Kong, or Los Angeles, for example) have spread into high-risk areas, and these will be increasingly endangered by slope instability.

5.2.3.   *Impacts on Ecological Systems*

While the authors acknowledge that climatic change on fauna will be important, priority is given here to vegetation response, particularly because vegetation dynamics will determine future distributions of animal habitats (both directly for herbivores and indirectly for predators).

The potential impacts of future climatic changes on mountain ecosystems and nature reserves have become an increasingly important issue in the study of long-term biodiversity management and protection (Peters and Darling, 1985; McNeely, 1990; Halpin, 1994; OTA, 1993). Projected changes in global temperatures and local precipitation patterns could significantly alter the altitudinal ranges of important species within existing

mountain belts and create additional environmental stresses on already fragile mountain ecosystems (Guisan *et al*., 1995).

On a global scale, plant life at high elevations is primarily constrained by direct and indirect effects of low temperature and perhaps also by reduced partial pressure of CO_2. Other atmospheric influences, such as increased radiation, high wind speeds, or insufficient water supply may come into play, but only on a regional scale (Lüdi, 1938; Fliri, 1975; Lauscher, 1977; Körner and Larcher, 1988; Barry, 1992). Plants respond to these climatological influences through a number of morphological and physiological adjustments, such as stunted growth forms and small leaves, low thermal requirements for basic life functions, and reproductive strategies that avoid the risk associated with early life phases.

5.2.3.1.   *Inference from the Past*

Paleoenvironmental information, including tree-ring data and pollen loadings, serves as an indicator of past climate-vegetation relationships. Paleoecology offers insights into the nature of climate-vegetation interactions. The indirect record of the response of organisms to environmental changes of the past is equivalent to results from natural, if unplanned, experiments (Davis, 1989). Because these natural experiments typically include conditions not observed in the 20th century, the paleorecord documents biotic responses to a substantially broader range of environmental variations than can be obtained through observations.

Paleoecological and paleoclimatic studies are of key importance in establishing baselines and are the only means available for determining amplitudes and rates of change of vegetation to natural climate variations. In addition, paleoenvironmental data are essential for model simulations and scenario generation.

5.2.3.2.   Ecophysiological Responses

It is known from both common sense and paleoenvironmental research that plant communities respond to a general increase in temperature through a shift toward higher latitudes and altitudes. However, this shift is controlled by ecophysiological processes at the individual plant level, involving direct and indirect effects of temperature increase, photoperiod constraints, and competition processes.

Callaghan and Jonasson (1994) show that direct effects of increased temperature on aboveground processes tend to dominate over indirect effects on belowground processes and that these will be greatest at locations where current climates are extreme (Bugmann and Fischlin, 1994). Reduced duration of snow cover is likely to be important for vegetation in a warmer climate (Körner, 1994).

Heide and coworkers have clearly shown that photoperiod constraints in cold climates may be strong and of overriding importance (Heide, 1985; Solhaug, 1991). For most native species, the precise photoperiodic requirements and their interaction with temperature are not known, thus making it difficult to estimate plant migration based on temperature scenarios alone (Ozenda and Borel, 1991). According to Heide (1989, 1990), some alpine grasses have no photoperiod requirements for initiating growth and are therefore affected by spring frosts. For example, in northern Sweden, Molau (1993) has shown that increased length of the growing season and increased summer temperature are the two components of climate change that will have the greatest impact on reproduction and population dynamics in arctic and alpine plants.

If climatic change leads to warmer and locally drier conditions, mountain vegetation could suffer as a result of increased evapotranspiration. This is most likely for continental and Mediterranean mountains. A change in regional distribution of air humidity could strongly modify the tree species composition of mountain forests; drier conditions, for example, would give continental species an advantage. If changes in water supply were to occur during summer, they would also become effective indirectly by influencing topsoil processes and plant nutrition (Bowman *et al.*, 1993; Baron *et al.*, 1994). When temperatures are low, microbial activity in alpine soils is concentrated in the top few centimeters. This is the part of the soil where nutrient recycling and most of the root growth takes place; when this top layer desiccates, mineral cycling is blocked (Körner, 1989). Regular rainfall is thus a prerequisite for plant nutrition. Because most alpine plants are inherently slow growers, any enhancement of nutrient supply will stimulate the few potentially fast-growing species in a community, eliminate others, and thus cause substantial changes in vegetation structure.

The length and depth of snow cover, often correlated with mean temperature and precipitation, is one of the key climatic factors in alpine ecosystems (Barry and Van Wie, 1974; Aulitzky *et al.,* 1982; Ozenda, 1985; Burrows, 1990;

Musselmann, 1994). Snow cover provides frost protection for plants in winter and water supply in spring. Alpine plant communities are characterized by a very short growing season (i.e., the snow-free period) and require water to commence growth. Ozenda and Borel (1991) predict that the most threatened vegetation communities will be those that live in snow beds and in hollows because these groups are subjected to summer drying.

5.2.3.3.   Geographical Distribution and Migratory Responses

A general hypothesis presented by Peters and Darling (1985) and others concerns the potential movement of the climatic ranges of species along altitudinal, thermally defined gradients. This conceptual model implies that the boundaries of present species' climatic ranges will respond symetrically to changes in temperature related to the adiabatic lapse rate for a particular mountain site. The general biogeographical rule used to derive this conceptual model is attributed to the "Hopkins bioclimatic law" (MacArthur, 1972; Peters and Darling, 1985), which relates a 3°C change in temperature to a 500 m change in altitude. According to this conceptual model, the expected impacts of climate change in mountainous nature reserves would include the loss of the coolest climatic zones at the peaks of the mountains and the linear shift of all remaining vegetation belts upslope. Because mountaintops are smaller than bases, the present belts at high elevations would occupy smaller and smaller areas, and the corresponding species would have smaller populations and might thus become more vulnerable to genetic and environmental pressure (Peters and Darling, 1985; Hansen-Bristow *et al.*, 1988; Bortenschlager, 1993).

Examples of past extinctions attributed to upward shifts are found in Central and South America, where vegetation zones have moved upward by 1000–1500 m since the last glacial maximum (Flenley, 1979; van der Hammen, 1974). Romme and Turner (1991), in their study on possible implications of climate change for ecosystems in Yellowstone National Park (USA), project species extinctions as a result of fragmentation and shrinking mountaintop habitats.

In the Alps, the main climatic space contraction and fragmentation of plant populations would be in the present alpine and nival belts, where rare and endemic species with low dispersal capacities could become extinct. Because the alpine belt contains a non-negligible part of the endemic alpine flora (15%; Ozenda and Borel, 1991), the potential impact of climate change on floristic diversity in the Alps could be significant. Halpin (1994) states that the process is more complex than suggested above. Even if vegetation belts do not move up as a whole in response to global climate change, the ecological potential of sites will change in relation to shifts in climatic features.

The impact of climatic change on altitudinal distribution of vegetation cannot be analyzed without taking into account interference with latitudinal distribution. Especially at low altitudes, Mediterranean tree species can substitute for sub-montane belt species. In the southern French Alps, if a warming and

---

Box 5-5. Climate Change Impacts on Vegetation in the Scandinavian Mountains

A simple correlative and qualitative model (Holten and Carey, 1992; Holten, 1995) based on important controlling factors for plant distribution indicates that six continental eutrophic mountain plant species may come under direct threat of extinction in a "Step 2" of climate change impacts on the Fennoscandian range. "Step 2" represents the long-term (several centuries) consequences when climate exceeds the Holocene thermal optimum, resulting in both qualitative and quantitative changes in vegetation. Another 11 species regarded as potentially vulnerable may experience substantial reduction and fragmentation of their populations. The most threatened species are characterized by rarity, low competitive ability, narrow habitat amplitude, and a distributional optimum in the middle alpine zone. Increased drought and overheating will probably have the most negative short-term (50–150 years) effects on mountain plant populations. In the long term (after several centuries), if the boreal forest invades parts of the low-alpine zone, many mountain plant species will be vulnerable to extinction because of their lower competitive ability relative to boreal plants.

---

a decrease in precipitation were to occur, Ozenda and Borel (1991) predict a northward progression of Mediterranean ecotypes ("steppization" of ecosystems). Kienast *et al*. (1995) predict steppization on no more than 5% of today's forested areas in Switzerland. On the Italian slopes of the Alps, the northward progression of Mediterranean influences would probably be more important. A similar (xeric) change is less likely to take place in the southeastern part of the range (Julian and Carnic Alps), where a much more humid climate exists.

5.2.3.4. *Modeling of Communities and Ecosystems Responses*

There are a number of ecosystem models currently available that can be used to test the sensitivity of a particular system to processes such as nutrient cycling (e.g., CENTURY, TEM), investigate species composition under changed environmental conditions (e.g., BIOME, DOLY, MAPSS), or assess forest health (e.g., FORET).

A number of modeling studies that were based on forest gap models (Shugart, 1984) have been conducted to assess the impacts of climatic change on forest biomass and species composition in mountainous regions (e.g., Kienast, 1991; Kräuchi and Kienast, 1993; Bugmann, 1994; Bugmann and Fischlin, 1994; Kräuchi, 1994). Although several different models and climate scenarios were used in these studies, they yielded quite similar conclusions regarding the sensitivity of forests in the European Alps. As an example of such a model application, Figure 5-2 illustrates the modeled forest changes in the alpine zone under differing climatic scenarios. Potential regional development of forest vegetation (using the FORSUM model; Kräuchi, 1994) at the Derborence site in the Swiss Alps is illustrated for no change in climate (upper) and for the IPCC IS92A scenario (lower). The forest at this location is currently changing as a result of successional processes. While the overall forest biomass might remain the same, the species composition will be different under the two climates, with a reduction in the competitive dominance of *Picea abies* and an increase in the proportion of broadleaves under the IS92A scenario (Kräuchi, 1994).

Model studies for Australian mountain vegetation show that there is the potential for the expansion of woody vegetation,

both trees and shrubs, in response to rising temperature (Grabherr *et al*., 1994; Williams and Costin, 1994). The treeline may rise by 100 m for each degree increase in mean annual temperature (Galloway, 1989). Elevated summer temperatures may also lead to an expansion of shrub communities (Williams, 1990).

VEMAP (1985), a continental-scale vegetation response study of the United States, considered how three biogeographical models (BIOME2, DOLY, MAPSS; Woodward *et al*., 1995) respond to doubled-CO_2 climate scenarios. Results on a coarse (0.5° latitude/longitude) grid showed alpine and subalpine regions in the western United States retreating to higher elevation and decreasing in area, while the subalpine montane forest boundary shifted upward. Two models also projected upward shifts in the lower montane boundary, while one produced a lowering of this boundary.

It should be emphasized that there are considerable limitations in present-day simulation techniques for assessing ecosystem response to climate change, in particular the temporal changes of these responses. In general, increases in atmospheric temperature will affect the structure and function of vegetation, as well as species composition where time may not be sufficient to allow species to migrate to suitable habitats (Kienast, 1991; Bugman, 1994; Klötzli, 1994).

5.2.4. *Impacts on Human/Socioeconomic Systems*

Because of the diversity of mountain economies, from exclusively tourist-based ones to those characterized by centuries-old subsistence agriculture, no single impact study will adequately represent the range of potential socioeconomic responses to climate change. A case-by-case approach is therefore essential to understand how, for example, mountain agriculture may change in Bolivia, tourism may change in Switzerland, or hydropower resources may be affected in New Zealand.

Because humans have influenced mountain ecosystems in many different ways throughout history, anthropogenic impacts generally cannot be dissociated from climate change

impacts. Climatic influences are often obscured by the impact of change in land use. An example is the fragmentation of the forest and natural vegetation cover. Because of persistent anthropogenic influences in the past, timberline in mountains such as the Alps has dropped 150–400 m compared to its uppermost position during the postglacial optimum (Holtmeier, 1994). At present, the climatic limit of tree growth in the Alps is situated above the actual forest limit (Thinon, 1992; Tessier *et al.*, 1993). By reducing species diversity and even intraspecies genetic variability of some species, humans have reduced the ability of alpine vegetation to respond to climate change (David, 1993; Peterson, 1994).

5.2.4.1.   *Mountain Agriculture*

Mountains contribute a substantial proportion of the world's agricultural production in terms of economic value. Upland regions are characterized by altitudinal climatic gradients that can lead to rapid changes in agricultural potential over comparatively short horizontal distances. Where elevations are high enough, a level eventually will be reached where agricultural production ceases to be profitable or where production losses become unacceptably high. Upland crop production, practiced close to the margins of viable production, can be highly sensitive to variations in climate. The nature of that
Figure 5-2: Example of simulations of forest response to different climate change scenarios in the alpine zone. Simulated forest succession on a subalpine site (mean annual temperature: 6°C; mean annual precipitation: 1,200 mm; subsoil: limestone and some flysch intersections) assuming today's climatic pattern (upper) and the IPCC IS92a climate scenario (lower; ΔT: +1°C in 2025; ΔT: +3°C in 2100) using FORSUM, a JABOWA/FORET-type gap model (Kräuchi, 1994). The main difference in the transient response in species composition between the baseline climate and the IS92a climate is the reduced importance of *Picea abies* combined with an increasing percentage of deciduous trees. The establishment of *Quercus petraea* and A*cerplatanoides* is particularly stimulated. The site might undergo a transition from *Piceo-Abietion (Adenostylo-Abietetum* or *Equiseto-Abietetum)* to *Abieti-Fagetum*.

Box 5-6. Impacts of Climate Change on Agriculture in Upland Regions of China and Japan

Climatic warming will in general increase agricultural productivity in China (Gao *et al*., 1993). Under the present climate, crops such as maize and rice suffer from low temperature and frost in northeast and southwest mountainous regions (Ma and Liang, 1990; Li *et al*., 1993). The yield for crops in these areas is expected to rise with increasing temperatures (Hulme *et al*., 1992). According to a study by Li *et al*. (1993), a mean warming of 0.4–1.0°C in the mountain regions of southwest China will move the upper boundary for growing grain by 80–170 m, and the growing areas will expand. However, there is uncertainty related to expansion of growing areas because soils are very important limiting factors for grain production. Specific soil properties include physical and chemical conditions that control plant growth, such as permeability, water holding capacity, acidity, soil structure, and density. In addition, the specific varieties that are presently used in mountain agriculture may need to be altered in order to keep up with global warming and thus present an additional economic hardship to the system.

To examine the effect of climatic variability on rice suitability, simple empirical indices have been developed relating rice yield to July/August mean air temperature in upland regions of Tohoku and Hokkaido in northern Japan (Yoshino *et al*., 1988). In combination with information about regional lapse rates of temperature, estimates have been made of the effects of anomalous weather on yield and on potentially cultivable areas for both cool and warm departures from a current mean climate. The results indicate that a July/August temperature departure of -1.1°C in Hokkaido would reduce yields by some 25% relative to the average, and the potentially cultivable area would contract to elevations below 100 m in a small area of southwestern Hokkaido, where the Sea of Japan acts to ameliorate the climate. A comparable anomaly in Tohoku (-1.0°C) would produce a 13% yield shortfall, and the cultivable area would contract by some 20%, to areas below about 200 m.

Conversely, in warmer-than-average years, higher yields would occur in association with an upward shift in limits of potential cultivation (Carter and Parry, 1994). A temperature rise of more than 3°C would also lead to a yield increase, but while current varieties of rice tend to respond positively to small temperature increments, they are less well adapted to large departures. It is likely that later-maturing varieties would be adopted under much warmer conditions to exploit the greater warmth. Under this scenario, most of the land below 500 m could become viable in Hokkaido, as could land up to 600 m in Tohoku.

sensitivity varies according to the region, crop, and agricultural system of interest. In some cases, the limits to crop cultivation appear to be closely related to levels of economic return. Yield variability often increases at higher elevation, so climate change may mean a greater risk of yield shortfall, rather than a change in mean yield (Carter and Parry, 1994).

Several authors have predicted that currently viable areas of crop production will change as a result of climate change (Alps: Balteanu *et al*., 1987; Japan: Yoshino *et al*., 1988; New Zealand: Salinger *et al*., 1989; and Kenya: Downing, 1992), although other constraints such as soil types may make agriculture unsuitable at these higher elevations. In-depth studies of the effects of climatic change in Ecuador's Central Sierra (Parry, 1978; Bravo *et al*., 1988) and Papua New Guinea (Allen *et al*., 1989) have shown that crop growth and yield are controlled by complex interactions among different climatic factors and that specific methods of cultivation may permit crop survival in sites where the microclimates would otherwise be unsuitable. Such specific details cannot be included in GCM-based impact assessments, which have suggested both positive and negative impacts—such as decreasing frost risks in the Mexican highlands (Liverman and O'Brien, 1991) and less productive upland agriculture in Asian mountains, where impacts would depend on various factors, particularly types of cultivars and the availability of irrigation (Parry *et al*., 1992).

Given the wide range of microclimates already existing in mountain areas that have been exploited through cultivation of diverse crops, direct negative effects of climate change on crop yields may not be too great. While crop yields may rise if moisture is not limiting, increases in the number of extreme events may offset any potential benefits. In addition, increases in both crop and animal yields may be negated by greater populations of pests and disease-causing organisms, many of which have distributions that are climatically controlled.

More important in certain parts of the developing world is the potential for complete disruption of the life pattern of mountain villages that climate change may represent in terms of food production and water management. People in the more remote regions of the Himalayas or Andes have for centuries managed to strike a delicate balance with fragile mountain environments; this balance would likely be disrupted by climate change, and it would take a long time for a new equilibrium to be established. In cases such as this, positive impacts of climate change (e.g., increased agricultural production and/or increased potential of water resources) are unlikely because the combined stressors, including negative effects of tourism, would overwhelm any adaptation capacity of the environment.

Compounded with these effects are those related to augmented duration and/or intensity of precipitation, which would

enhance soil degradation (erosion, leaching, and so forth) and lead to loss of agricultural productivity.

5.2.4.2. *Hydropower*

An important socioeconomic consequence of global warming on the hydrological cycle is linked to potential changes in runoff extremes. Not only the mountain population but also the people in the plains downstream (a large proportion of the world population) presently depend on unregulated river systems and thus are particularly vulnerable to climate-driven hydrological change. Current difficulties in implementing water resource development projects will be compounded by uncertainties related to hydrologic responses to possible climate change. Among these, possible increases in sediment loading would perturb the functioning of power-generating infrastructure.

Sensitivity of mountain hydrology to climate change is a key factor that needs to be considered when planning hydropower infrastructure. In the future, a warmer and perhaps wetter greenhouse climate needs to be considered. The impact of climate on water resources in alpine areas has previously been examined by Gleick (1986, 1987a, 1987b) and Martinec and Rango (1989). Similar studies have related electricity demand to climate (Warren and LeDuc, 1981; Leffler *et al*., 1985; Maunder, 1986; Downton *et al*., 1988). However, few have attempted to integrate these impacts of climate change by considering both electricity supply and electricity consumption (Jäger, 1983).

Mountain runoff (electricity supply) and electricity consumption (demand) are both sensitive to changes in precipitation and temperature. Long-term changes in future climate will have a significant impact on the seasonal distribution of snow storage, runoff from hydroelectric catchments, and aggregated electricity consumption. On the basis of a study made in the Southern Alps of New Zealand, Garr and Fitzharris (1994) conclude that according to future climate scenarios (New Zealand Ministry for the Environment, 1990), the seasonal variation of electricity consumption will be less pronounced than at present—with the largest changes in winter, which corresponds to the time of peak heating requirements. There will also be less seasonal variation in runoff and more opportunity to generate power from existing hydroelectric stations. The electricity system will be less vulnerable to climate variability, in that water supply will increase but demand will be reduced. These conclusions suggest that climate change will have important implications for hydroelectricity systems in other mountain areas as well.

5.2.4.3. *Commercial Activities: Timber and Mining*

Commercial utilization of mountain forests can be affected directly and indirectly by climate change. Direct effects include loss of viability of commercial species, including problems in regeneration and lower seedling survival. Indirect effects relate to disturbances such as fire, insect, and disease losses. These indirect effects depend on the influence of climate on the disturbance agents themselves, as discussed more fully in Chapter 1.

Many of the commercially viable mineral deposits in the world are located in mountain regions. While climate has only a minor direct influence on exploitation of these resources, it may exert a significant indirect influence. Mining causes a surface disruption and requires roads and other infrastructure. Changes in climate that lead to increases in precipitation frequency and/or intensity exacerbate the potential for mass wasting and erosion associated with these developments. Furthermore, the economics of mineral exploitation often requires *in situ* processing of the extracted ore—for example, smeltering and hydrochemical processing. In the latter case, climate, especially precipitation and temperature, is a critical factor in process design.

5.2.4.4. *Tourism*

Resources required for tourism are climate-dependent—that is, their availability may be affected in the short and long term by variability, extremes, and shifts in climatic means. These resources include the landscapes of natural and anthropogenically influenced ecosystems and climatic conditions that are suitable for specific activities (Price, 1994).

Impacts of climate change on tourism in mountain areas may be divided into two types: direct and indirect. The former would result from changes in the atmospheric resources necessary for specific activities (e.g., clean air, snow). Indirect changes may result from these changes and from wider-scale socioeconomic changes, for example, fuel prices and patterns of demand for specific activities or destinations. Various indirect impacts may also derive from changes in mountain landscapes—the "capital" of tourism (Krippendorf, 1984)—which might lead potential tourists to perceive them as less attractive, and consequently to seek out new locations. There also may be new competition from other tourist locations as climates change, particularly on seasonal timeframes, especially in relation to vacation periods.

5.2.4.4.1. *Winter tourism*

Scenarios derived from GCMs have been used to examine the possible implications of climate change for skiing in Australia (Galloway, 1988; Hewitt, 1994; Whetton, 1994), Austria (Breiling and Charamza, 1994), eastern Canada (McBoyle and Wall, 1987; Lamothe and Périard, 1988), and Switzerland (Abegg and Froesch, 1994). These studies show that, because the length of the skiing season is sensitive to quite small climatic changes, there could be considerable socioeconomic disruption in communities that have invested heavily in the skiing industry. To some extent, such impacts might be offset by new opportunities in the summer season and also by investment in new technologies, such as snow-making equipment, as long as climatic conditions remain within appropriate bounds. Such

investments, following seasons with little snow, have provided some "insurance" in mountain regions of North America. Investment in snow-making equipment has been somewhat less widespread in some European countries such as Switzerland (Broggi and Willi, 1989), despite the fact that seasons with little snow, especially at critical times such as during the Christmas and New Year period, can be economically devastating to mountain communities. Artificial snow-making often raises environmental concern because of the quantities of energy and water required for snow-making, the disturbances generated during the operation of the equipment, and the damage to vegetation observed following the melting of the artificial snow cover.

5.2.4.4.2. *Mountain-protected areas*

Types of tourism vary from "wilderness tourism" in relatively pristine ecosystems to highly developed resorts designed initially for downhill skiing and, increasingly, for year-round use. The question of the management of protected areas in North American mountains under global climate change has been considered by Peine and Martinka (1992), Peterson *et al*. (1990), and Peine and Fox (1995). These studies predict increasing conflicts between different objectives, particularly recreational use and the protection of ecosystems and species.

Strategies advanced for mitigating adverse effects of global climate change include the establishment of refugia (i.e., areas protected by law from human influences). Mountain-protected areas represent a topographically complex environment that is important for the economic and spiritual sustenance of many human cultures. As human populations continue to grow, use of this biologically diverse resource has accelerated, highlighting a strategic role for protected areas that includes both conservation and scientific interests. From a global conservation perspective, protecting representative samples of mountain resources is a high-priority goal. At the same time, scientists are more frequently using protected areas as controls for land-use research and as sites for long-term environmental monitoring. Despite their environmental and scientific value, however, such preserves represent small and fragmented landscapes, making them vulnerable to species migrations and extinctions.

5.3. Future Research and Monitoring Needs

Future research needed to understand and predict effects of climatic change on mountain regions should represent balance and coordination between field studies, including paleoenvironmental data collection; monitoring; experimental studies; and modeling (Guisan *et al*., 1995). Research requirements include:

- Specific regional field studies (transects, data acquisition, mapping, observations at high elevation, and so on).
- Paleo data to establish baselines, to evaluate responses of ecosystems to natural climate variability, and to provide data for model verification

- Monitoring to establish long-term baseline data, in particular in potentially sensitive regions (e.g., remote areas, high elevations)
- Experimental studies to improve fundamental understanding, to test hypotheses, and to provide empirical information for modeling studies
- Modeling to ameliorate climate scenarios using various downscaling approaches, to improve understanding of how topographic and edaphic variability influence ecosystems and natural resources on the regional scale, and to improve mechanistic modeling of physical, biological, and socioeconomic systems
- Integrated assessment models to address the complex interrelationships of different systems in mountain regions and to provide valuable multidisciplinary information to a range of end-users, including policymakers.

CONTENTS

EXECUTIVE SUMMARY

Although there are many different systems for defining and classifying wetlands, for this chapter we define wetlands generally as areas of land where the water table is at or near the surface for some defined period of time, leading to unique physiochemical and biological processes and conditions characteristic of waterlogged systems. Wetlands exist in both inland and coastal areas, covering approximately 4–6% of the Earth's land surface. They are found on every continent except Antarctica and in every climate from the tropics to the tundra. This chapter examines the possible impacts of climate change on non-tidal (primarily inland) freshwater wetlands.

Wetlands have many functions that have socioeconomic benefits: They provide refuge and breeding ground for many species, including commercially valuable ones; they are areas of high biodiversity; they control floods and droughts and improve water quality; and they are used for recreation and education. The direct economic value of these benefits varies between regions.

Human activities—such as the conversion of wetlands to agricultural and forest lands, construction of dams and embankments, and peat mining—already pose a serious threat to wetlands worldwide. Mainly as a result of these activities, it is estimated that more than half of the world's wetlands have disappeared during the last century. These anthropogenic effects are most notable in densely populated areas and are expected to increase, especially in developing countries.

We are highly confident that climate change will have its greatest effect on wetlands by altering their hydrologic regimes. Any alterations of these regimes will influence biological, biogeochemical, and hydrological functions in wetland ecosystems, thereby affecting the socioeconomic benefits of wetlands that are valued by humans. Due to the heterogeneity of non-tidal wetlands, and because their hydrologic conditions vary greatly within and among different wetland types and sites, the impacts of climate change on these ecosystems will be site-specific. Impacts can be generalized for specific wetland types and, to some degree, wetland regions. However, generalization across wetland types is difficult and cannot be made in terms of locations or wetland categories.

We are highly confident that hydrologic changes or other disturbances that change the vegetation types in wetland areas will affect other wetland functions as well. However, many wetlands have inherently high spatial and temporal variability in plant communities due to climatic variations (e.g., seasonal flooding or drought) and variations in microtopography. We are confident that in some wetlands a changed plant community as a result of climate change will resemble at least some component of the existing community.

We are highly confident that climate change will affect the cycling of carbon in wetlands: Some carbon-sequestering wetlands will change from CO_2 sinks to sources due to a lowering of the water table or increased temperature. Changes in the source/sink relationship of wetlands have already occurred in parts of the arctic region. Climate change leading to an alteration in the degree of saturation and flooding of wetlands would affect both the magnitude and the timing of CH_4 emissions. Drying of northern wetlands could lead to declines in CH_4 emissions.

We are confident that climate change will affect the areal extent and distribution of wetlands, although at present it is not possible to estimate future areal size and distribution of wetlands from climate-change scenarios. Regional studies from east China, the United States, and southern Europe indicate that the area of wetlands will decrease if the climate becomes warmer. Climate warming also would have severe impacts on wetlands in arctic and subarctic regions in this respect because it would result in a melting of permafrost, which is the key factor in maintaining high water tables in these ecosystems.

Adaptation, conservation, and restoration of wetlands in response to climate change varies among wetland types and the specific function being considered. For regional and global functions (e.g., trace-gas fluxes and carbon storage), there are no human responses that can be applied at the scale necessary. For wetland functions that are local in scale (habitat value, pollution trapping, and to some degree flood control), possibilities exist for adaptation, creation, and restoration. However, wetland creation and restoration technologies are just developing, and we do not yet have reliable techniques to create wetlands for many specific purposes.

6.1. Introduction

6.1.1. Aims and Goals of the Chapter

This chapter examines the potential impacts of climate change on non-tidal wetland ecosystems and the possible options for responding to these changes. Tidal wetlands are covered in Chapter 9.

This chapter gives particular emphasis to the possible impacts of climate change on the areal extent, distribution, and functions of non-tidal wetlands, in the context of other natural or anthropogenic stressors that are likely to affect these ecosystems simultaneously. In addition to describing the importance of different climate variables and the range of factors that determine the sensitivity of individual wetlands, the chapter uses four case studies to illustrate the effects of climate change on certain defined wetland areas: the Sahel, northern boreal wetlands, Kalimantan (Indonesia), and the Florida Everglades.

This is the first time that IPCC has attempted a detailed assessment of the potential impacts of climate change on the structure and function of wetlands. Previous assessments briefly touched upon wetlands in a qualitative discussion of methane (CH_4) sources and sinks (Melillo *et al*., 1990) and discussed wetlands in the context of ecosystem responses to increased CO_2 concentrations, illustrated by case studies of the arctic tundra and a salt marsh.

The present assessment is hindered because the literature on wetlands is highly variable in quality and coverage and large gaps in knowledge remain regarding many of their regulating processes. In particular, relatively few studies exist on the impacts of climate change on inland wetlands; most that do exist have been carried out on specific wetland sites and/or have tended to focus on the Northern Hemisphere. These factors are reflected in the examples and conclusions in this chapter and in the emphasis on case studies. Recently, wetlands and wetland-related topics have begun to receive increasingly greater attention, and new information is expected to be published in the near future.

6.1.2. Definition

Wetlands exist in both inland and coastal areas, covering approximately 4–6% of the Earth's land surface. A wide variety of wetland definitions are found in the literature. Cowardin *et al*. (1979) argue that there is no single, correct, indisputable, ecologically sound definition for wetlands, primarily because of the diversity of wetlands and because the demarcation between dry and wet environments lies along a continuum. In general, a wetland describes any area of land where the water table is at or near the surface for some defined period of time, leading to unique physiochemical and biological processes and conditions characteristic of shallowly flooded systems (Mitsch and Gosselink, 1993). This chapter will discuss both permanent and temporary wetlands.

6.1.3. Classification

Wetlands usually are categorized according to their characteristic vegetation; their location (coastal or inland); the salinity of the water they contain; or other biological, chemical, hydrological, and geographical features. Coastal wetlands are influenced by the ebb and flow of tides and may include tidal salt marshes, tidal freshwater marshes, and mangrove swamps (see Chapter 9).

This chapter covers inland wetlands, or those not subject to tidal influences—including peatlands, swamps, marshes, and floodplains. Peatlands consist of bogs and fens, which may be forested, and are peat-accumulating wetlands in moist climates (peat is partially decomposed plant material). Bogs are acidic, poor in nutrients, and receive water from precipitation only, whereas fens are generally circumneutral, richer in nutrients, and receive water primarily from overland flow and/or groundwater. Swamps or forested wetlands are areas with little or no peat accumulation. Marshes or herbaceous wetlands and floodplains are flooded areas along rivers or lakes (Zoltai and Pollet, 1983).

More than seventy global classification schemes exist internationally. Because the response of wetlands to climate change tends to be site- or region-specific, no existing scheme is useful for this chapter in relating geographic or physical features with climate responses. For this reason, this chapter will focus on describing the climate and other variables that determine the response of individual wetland sites, rather than attempting to correlate responses with particular wetland types.

Many studies have shown that hydrologic parameters are strong controllers of wetland ecosystem structure and function (Gosselink and Turner, 1978; Novitzki, 1989; Kangas, 1990). The source, renewal rate, and timing of the water regime directly control the spatial and temporal heterogeneity of wetland ecosystem structure and function. The hydroperiod—defined as the depth, frequency, duration, and season of flooding—is usually the single most important regulator in wetlands, controlling many of their important characteristics (Lugo *et al*., 1990a). The hydroperiod is determined by the climate, topography, catchment area, soils, and geology of the region in which the wetland is situated (Armentano, 1990).

For this assessment, we focus on climate-change effects on hydrology as an integrative tool for our analysis. However, these effects are highly site-specific, and there are few general, categorical conclusions that can be drawn. There is extreme hydrological variation between and even within individual wetlands, such as differences in the direction of water flow (vertical, unidirectional, or bidirectional; Lugo *et al*., 1990b). This variability, coupled with the resolution at which these hydrological differences can be found, reinforces the need to describe wetland responses on a site-by-site basis. It is possible to generalize impacts for specific wetland types and, to some degree, wetland regions, but it is difficult to generalize across different wetland types.

6.1.4. Global Distribution of Wetlands

Wetlands are found on every continent except Antarctica and in every climate from the tropics to the tundra (Mitsch and Wu, 1995; Mitsch and Gosselink, 1993). Matthews and Fung (1987) recently conducted extensive surveys to determine the distribution of wetlands on a global scale and estimate that wetlands account for an area of 5.3×10^6 km^2, or approximately 4% of the Earth's land surface (Figures 6-1 and 6-2). This estimate is similar to other recent estimates (e.g., Aselmann and Crutzen, 1989) but indicates a possible reduction from previous estimates of around 6% (Bazilivich *et al*, 1971; Maltby and Turner, 1983). However, any estimate of global coverage will depend significantly on the definition of a wetland that is used.

6.1.5. Current Wetland Stressors

Wetlands already are threatened by a range of environmental factors, which can be natural or anthropogenic. It is estimated that more than half of the world's wetlands have disappeared since 1900. In the lower 48 states of the United States, approximately 53% of the original wetland area has been lost; 87% of this loss is attributed to agricultural development, 8% to urban development, and 5% to other conversions (Maltby, 1986). The same is valid for most of the developed regions of the world. The status of wetlands in developing countries is currently unknown to a large extent, but population pressures in many regions are steadily increasing the demand for food (Dugan, 1988), which can lead to wetland loss due to agricultural development. Many wetlands, especially in tropical regions, have so far escaped the impacts of human activities owing to their remoteness and unsuitability for agriculture (see Section 6.5.4). However, in recent decades, population pressures and technological advances have extended human influences into previously undisturbed areas (Armentano, 1990). For example, in 1989 it was calculated that only 82% of Indonesia's peat swamp forests remained in their original condition (Silvius, 1989); for some provinces (e.g., South Sumatra), it is predicted that no swamp forest will be left by the year 2000 (PHPA and AWB, 1990). Table 6-1 summarizes the main causes of present-day wetland loss.

6.2. Global Importance of Wetlands

Wetlands have many functions that are considered to have socioeconomic value: They provide refuge and breeding ground for many species, including commercially valuable furbearers, waterfowl, and timber; they often contain a high diversity of species; they control floods and droughts and improve water quality; and they can be used for recreation and education. The socioeconomic value of wetlands will vary from region to region, depending on which wetland functions the local economies regard as valuable. Table 6-2 identifies wetland types with their values.

Some wetlands (usually peatlands) contain potential energy for human consumption. In developing countries with shortages of energy and fuel, peat harvesting can be an attractive financial proposition if extensive peat deposits are available. This can
Figure 6-1: Global distribution of wetland ecosystems (modified after Matthews and Fung, 1987). Lighter areas denote wetlands.
Figure 6-2: Distributions of wetland types along 10° latitudinal belts (modified after Matthews and Fung, 1987).

have the effect of replacing imported energy sources and reducing foreign-exchange requirements (Bord na Móna, 1985). However, large-scale harvesting of peat has led to the destruction of peatland ecosystems, and peat mining has the dual effect of removing a CO_2 sink (but a source of CH_4) and adding to the CO_2 in the atmosphere (see Rodhe and Svensson, 1995).

In the recent past, nonconsumptive benefits of wetlands such as recreation (Mercer, 1990), archaeology (Coles, 1990), education, and science usually were given lower priority in management plans than directly consumptive values because they are highly aesthetic and their values are difficult to quantify (Reimold and Hardinsky, 1979). However, these values have been given much greater attention in recent years, and wetlands worldwide are starting to be considered highly valuable areas to conserve.

6.2.1. *Habitats and Diversity*

The total biodiversity (flora and fauna) of wetlands generally is high in comparison with terrestrial ecosystems. Wetlands provide protective cover and essential feeding, breeding, and maturation areas for a wide range of invertebrates, as well as cold- and warm-blooded vertebrates (Gosselink and Maltby, 1990; Clark, 1979). Some animals are entirely dependent on wetland habitats; others are only partially so. In North America, for example, muskrats and beavers fall into the dependent group, whereas raccoons and various species of deer fall into the non-dependent one. In many areas, the remoteness and inaccessibility of wetlands has attracted species that may not be totally wetland dependent but take advantage of the protection and

shelter they provide. For example, the Pantanal in Brazil, Paraguay, and Bolivia provides an important habitat for the jaguar (Dugan, 1993).

Probably the best known function of wetlands is as a provider of year-round habitats, breeding areas, and wintering sites for migratory birds, depending on their location (Bellrose and Trudeau, 1988; Dugan, 1993). One example is the prairie pot-hole region in the United States, where the value of the region as habitat for breeding birds, especially waterfowl, has been thoroughly documented. Annual production is correlated with the number of wet basins for many duck species (Boyd, 1981; Krapu *et al.*, 1983; Reynolds, 1987). More than half of the waterfowl production in North America occurs within this region (Batt *et al.*, 1989).

6.2.2. *Biogeochemical Values*

Wetlands play an important role in the global budgets of carbon (C) and the trace gases CH_4 and nitrous oxide (N_2O). Wetland soils represent a major pool of C that may respond dynamically to climate change (Woodwell *et al.*, 1995). Boreal wetlands, which are extremely susceptible to climate change, are a major contributor to the global CH_4 budget (Matthews and Fung, 1987).

Wetlands are efficient in trapping pollution and processing wastes in human-dominated landscapes. Wetlands have been found to be important "sinks" for pollutants moving from upland areas, preventing their movement into surface water and groundwater (Mitsch and Gosselink, 1993); indeed, artificial

wetlands are being used to treat wastewater. Declines in these functions due to climate change could have important economic and aesthetic implications, particularly in heavily developed areas (Arheimer and Wittgren, 1994).

6.3. Sensitivities and Impacts

6.3.1. Which Wetlands are Most Vulnerable to Climate Change?

It is difficult to determine the vulnerability of specific types of non-tidal wetlands to climate change. One line of reasoning suggests that wetlands in naturally stressed environments appear to tolerate less additional stress than those located in favorable conditions (Lugo and Brown, 1984), meaning that they are more vulnerable to the alterations in hydrological regimes that are expected to result from climate change. By this reasoning, depressional wetlands (found in depressions in the landscape) with small watershed areas and situated in areas where the climate is either dry or wet at present will be most susceptible to these effects (Mitsch and Wu, 1995). In contrast, wetlands along floodplains and lakes should be able to adapt to a changing climate by migrating along river edges up- and downstream as well as up- and downslope to follow water— although the efficiency of such migration will be dependent on a number of factors, including catchment area, topography, and human settlements.

A second line of reasoning suggests that wetland types that have a large degree of inherent exposure to high spatial and temporal variation in environmental conditions may have a greater potential for adaptation to climate change (see Section 6.4).

Arctic and subarctic peatlands will be extremely vulnerable to climate change if warmer temperatures lead to a thawing of the permafrost layer and affect their hydrology through drainage or flooding (Gorham, 1994; Oechel and Vourlitis, 1994; OTA, 1993). These wetlands have a limited capacity to adapt to climate change because it is unlikely that new permafrost areas will form. In addition, non-tidal wetlands located near the coast are vulnerable to changes in climate due to sea-level rise, which would have severe impacts resulting from chemical and hydrological changes caused by intrusion of saline seawater (see Section 6.5.5).

6.3.2. Importance of Different Climate Variables

No single factor determines how climate change will affect individual wetland ecosystems. The variables that are predicted to change include temperature, precipitation, and CO_2 concentrations, resulting cumulatively in changes in water availability. Changes in the frequency and duration of flooding and drought and any alterations in disturbance regimes will be particularly important in determining how the ecological functions of wetlands ultimately are affected.

6.3.2.1. Temperature

Temperature is an important factor controlling many of the ecological and physical functions of wetlands. Primary productivity, microbial activity, and habitat are all controlled to a certain extent by temperature. Temperature also affects evapotranspiration rates, which has implications for the hydrological regime of wetlands by transporting water from the ecosystem to the atmosphere.

6.3.2.2. Precipitation

Precipitation regulates the direct inflow and amount of water to wetland ecosystems. However, the effect of a change in precipitation on a given wetland will depend on the type of wetland and the topographic and geographic characteristics of the region (drainage area, relief, and so forth). For example, very large wetlands, like the Okawango delta in Africa, are supplied with water from a considerable distance. In this case, the spatial variability of climate change could affect the balance between supply and evaporative demand. Further, in wetlands located along floodplains, a change in water availability throughout the drainage area or region will affect flooding and the hydrological regime in complex ways.

Poiani *et al.* (1995) show that the seasonality of precipitation changes is very important to wetland ecosystems. Climate change affecting spring precipitation and runoff may have the greatest impact on wetland hydrology and vegetation. Some modeling studies have indicated that there may be a threshold temperature beyond which changes in precipitation become less important to wetland hydrology. In one study, Poiani and Johnson (1993) conclude that precipitation changes are much less influential on hydrological regimes under a +4°C scenario than under a +2°C scenario.

6.3.2.3. CO_2 Concentration

Current research suggests that elevated CO_2 levels may have a direct fertilization effect on some types of vegetation, leading to higher production rates (Idso and Kimball, 1993). Elevated CO_2 concentrations seem to increase plant tolerance to stress, including photoinhibition, high or low temperature extremes, drought, and waterlogging (Hogan *et al.*, 1991). However, multi-species, intact ecosystems may show complex responses to an increase in CO_2 concentrations (Korner and Arnone, 1992). Elevated CO_2 concentrations in the atmosphere also may affect the rate of evapotranspiration through changes in water usage by plants (Bunce, 1992; Kimball and Idso, 1983). However, the effects of increased CO_2 on transpiration and water-use efficiency appear to decrease as water availability increases or as temperature decreases (Oechel and Strain, 1985). Any changes in transpiration may influence regional water balances and hydrological regimes because vegetation is a critical component of the cycling of water between soils and the atmosphere (Salati and Vose, 1984). Until detailed mechanistic questions regarding the

biochemistry and physiology of wetland vegetation can be resolved, the extent to which wetlands will respond to increased CO_2 concentrations remains uncertain (Larson, 1994).

6.3.2.4.   *Extreme Events*

Wetlands are sensitive to extreme climate events such as heavy spring flooding and summer drought (Gorham, 1991). Potential changes in precipitation patterns related to the amplitude, periodicity, or frequency of extreme events are critical components in modeling wetland responses to climate change (Poiani and Johnson, 1993). Extreme droughts make wetlands more sensitive to fire (see Sections 6.5.4 and 6.5.5; Gorham, 1994), which could impact ecological functions such as vegetation cover, habitat value, and carbon cycling. At the same time, such biomass burning is likely to result in massive emissions of smoke particles (aerosols) to the atmosphere, which may offset some warming, at least regionally (Penner *et al*., 1992). Sea-level rise may affect some inland wetlands, causing saltwater intrusion that could result in an encroachment of salt-tolerant wetland communities.

6.3.2.5.   *Water Availability and Movement*

Combined changes in temperature, evapotranspiration, precipitation, and CO_2 concentrations ultimately affect the hydrologic regime in a wetland ecosystem. It is critical to consider these combined effects because responses can be nonlinear. For example, it has been found that relatively small differences in precipitation can produce substantial differences in water level, especially for smaller temperature increases (Poiani and Johnson, 1993). Whereas decreased water availability will cause wetland loss due to concomitant drying, climate models suggest that some areas will become wetter—particularly high-latitudes in the winter. Although few studies have examined the potential impacts in these cases, it is conceivable that wetter conditions could be conducive to wetland development in areas not currently occupied by wetlands—as has occurred in areas of the Sahel (see Section 6.5.2).

In some cases, the movement of water in itself can benefit wetlands because it contributes to nutrient transport, aeration, and so forth, and because species can more readily distribute themselves according to the hydrological conditions to which they are adapted. Floods also create currents capable of exporting toxic compounds that otherwise could accumulate in sediments (Lugo *et al*., 1990a). However, extremely intense hydrological fluxes tend to stress wetland ecosystems.

6.3.3.   *Effects on Wetlands Due to Climate Change*

Climate changes affecting the areal extent, distribution, and hydrological regimes of wetlands are expected to have important effects on their ecological functions. These effects must be assessed in light of many uncertainties, particularly concerning

the interactions of atmospheric water, surface water, and groundwater components of wetlands (Winter, 1988).

6.3.3.1.   *Areal Extent and Distribution*

At present, regional scenarios do not provide adequate information to determine the direction or magnitude of change in the areal extent of wetlands (Gorham, 1991). It seems likely that some wetland regions will become moisture-limited, while other non-wetland areas will develop a climate conducive for wetland development. At this time, however, any estimation of the change in global areal extent would be very uncertain (see Gorham, 1991).

A few studies have attempted to estimate possible regional changes in wetland distribution, although they tend to involve areas that are projected to experience net losses in water availability rather than areas that are expected to experience increases. For example, a study by Brock and van Vierssen (1992) of hydrophyte-dominated wetlands in southern semi-arid regions of Europe concludes that an increase in temperature of 3–4°C would decrease the areal extent of habitat for hydrophytes by 70 to 85% within 5 years—suggesting that wetlands in other semi-arid and arid regions will be very sensitive to climate warming (see Section 6.5.2).

Poiani and Johnson (1993) conducted a study to understand how possible changes in the areal extent of a semipermanent wetland in the prairie pothole region of the United States might affect its ecological functions. For this study, they developed a simulation model for hydrological and vegetation responses. Using output from the Goddard Institute for Space Studies (GISS) general circulation model (GCM) for current and doubled-CO_2 climates (mean monthly air-temperature increase of 3 to 6°C and precipitation ranging from -17% to +29%) in an 11-year simulation, they project a 3% increase in the overall size of this wetland under current climate but a decrease of nearly 12% under the greenhouse scenario. Further, the areas of open water would decrease from 51% at the beginning of the simulation to 0% by the fourth year, allowing emergent plant species to spread over the entire wetland. This change would have serious implications for the wildlife in the region because these areas are extremely important breeding areas for waterfowl (see Section 6.2.1). This study indicates that even if the total decrease in wetland area due to a warmer climate is relatively small (12%), the overall change in wetland characteristics can have severe effects on many of the existing functions and values of wetlands. The model also indicates that wetland size, depth, and vegetative characteristics are more sensitive to changes in temperature than to either increases or decreases in precipitation.

Another study of the prairie pothole region (Larson, in press) examines the relationship between climate variables and the percentage of wet basins, using a multiple linear-regression model. This study focuses on closed-basin wetlands surrounded by either grassland or aspen parkland. The study found that when temperatures increase by 3°C in subsequent model runs

(15 years simulated), the Canadian and U.S. grassland models project declines in the percentage of wet basins of 15% and 28%, respectively. The aspen parkland model, however, projects a decline of 56% in the number of wet basins with increased temperatures. Model response to changes in precipitation were uniform and small across the region. An important consequence of geographical differences in wetland response to temperature is that as waterfowl extend their migrations farther north in drought years, they may face decreased probability of finding suitable wetlands.

A study by Zhang and Song (1993) examines the possible effects of climate change on the areal extent of the wetlands of eastern China, where 75% of the country's wetlands are located. The study examines climate change under six hypothetical climate scenarios (precipitation increasing or decreasing by 10% and temperature increasing 1, 2, and 3°C); the areal extent of herbaceous wetlands declines under all scenarios.

At high northern latitudes, warming could cause a poleward migration of the northern treeline. This shift would decrease the winter albedo because the tree canopy has much lower albedo than exposed snow surfaces (Bonan *et al.*, 1992), greatly affecting regional climate by absorbing more of the sun's incoming energy.

Another implication for northern peatlands is the expected melting of permafrost due to higher temperatures (see Chapter 7). Harriss (1987) concludes that an increase in temperature of 2°C would shift the southern boundary of permafrost in the Northern Hemisphere to the north. The melting of permafrost is likely to have drastic effects on peatland hydrology and landscape patterns, leading to lowered water tables in some areas and flooded thaw lakes in others, as well as to thermokarst erosion (Billings, 1987; Gorham, 1991). It has been suggested (Zoltai and Wein, 1990) that such melting may shift bogs on permafrost back to fens, from which they originated after the warm mid-Holocene period. Vegetetation could shift from black spruce/Sphagnum/lichen (which are typical for bog ecosystems) to grasses, sedges, and reeds. Further, the rate of climate-change impacts on northern peatlands may be such that it causes degradation of southern regions much faster than the northern regions can expand northward (Gorham, 1991). These shifts also would have implications for the carbon cycle, as well as the flux of especially CH_4 from northern peatlands (see Section 6.5.3).

6.3.3.2. Functions

Functions are processes necessary for the self-maintenance of ecosystems, such as primary production, nutrient cycling and decomposition. Wetland functions can be categorized as biological, biogeochemical, or hydrological. These are distinct from, but often translate into, the socioeconomic values perceived by society (Brinson, 1993). None of these categories is exclusive, and each may influence the other; for example, any changes in wetland plant species have far-reaching effects on a wide range of wetland functions due to the unique structural, chemical, and ecological characteristics of different plants.

6.3.3.2.1. Biological functions

Biological functions relate to vegetation, habitats, and species diversity. Climate changes resulting in increased or decreased temperature and water availability will affect the composition and production of vegetation, the quality and areal extent of habitat available for species, and species composition and diversity (Thompson and Hamilton, 1983; Junk, 1983, 1993; Bradbury and Grace, 1983; Reader, 1978; Bernard and Gorham, 1978).

The species composition of plant communities in wetlands is critically affected by water movement and hydroperiod (Lugo *et al.*, 1990a). Often, extended flooding and a longer hydroperiod will result in tree mortality and the replacement of forest by herbaceous vegetation (Lugo *et al.*, 1990a). A long-term lowering of the water table would probably lead to similar changes in the composition and production of the vegetation as found in drainages made for forestry (e.g., in Sweden and Finland).

In forested wetlands subjected to drainage, the lowering of the water table has resulted in an increase in tree-stand volume (Keltikangas *et al.*, 1986; Hånell, 1988). Based on data from several different wetland types given by Hånell (1988), Rodhe and Svensson (1995) calculate that the increase in tree-stand volume could range between 1.2–6.0 kg dry biomass/m². Similar results are reported in studies on wetlands in Finland (Ilvessalo and Ilvessalo, 1975).

Changes in wetland plant communities can have important effects on decomposition, nutrient cycling, and plant production functions. The nature and amount of plant litter production strongly influences wetland soil microbial populations (Melillo *et al.*, 1982; McClaugherty *et al.*, 1985; Bowden, 1987). Several studies have found strong links between wetland plant community types and microbial decomposition and nutrient-cycling processes in fens and bogs (Svensson, 1976, 1980; Svensson and Rosswall, 1984; Verhoeven *et al.*, 1990; Verhoeven and Arts, 1992; van Vuuren *et al.*, 1992, 1993; Koerselman *et al.*, 1993). Microbial decomposition of litter and the release or "mineralization" of nutrients contained therein enhances plant productivity and litter quality (nutrient content, degradability; Pastor, 1984). Different plant communities demonstrate different rates of nitrogen availability to plants, carbon storage, and microbial processing of pollutants (Rosswall and Granhall, 1980; Pastor *et al.*, 1984; Morris, 1991; Duncan and Groffman, 1994; Weisner *et al.*, 1994; Schipper *et al.*, 1994).

The physical and chemical characteristics of plants also strongly influence insect species and populations, which provide life-support functions for wetland-dependent birds, fish, and mammals (Mitsch and Gosselink, 1986; Kiviat, 1989). In conservation biology, there is intense interest in the effects of changes

in plant species on the habitat value of wetlands (Bratton, 1982; Harty, 1986; Mooney and Drake, 1986; Center *et al.*, 1991; McKnight, 1993).

6.3.3.2.2. Biogeochemical functions

Biogeochemical functions include pollution trapping and waste processing, carbon cycling (Svensson, 1986; Armentano and Menges, 1986; Silvola, 1986; Sjörs, 1980; Gorham, 1990, 1991; Miller *et al.*, 1983; Marion and Oechel, 1993), and the flux of greenhouse gases (Svensson *et al.*, 1975; Svensson, 1976; Aselmann and Crutzen, 1989; Matthews and Fung, 1987; Bartlett and Harriss, 1993; Matthews, 1993; Bartlett *et al.*, 1989; Urban *et al.*, 1988; Freeman *et al.*, 1993; Martikainen *et al.*, 1993; Pulliam, 1993).

Wetlands, and especially peatlands, play a significant role in the carbon cycle and presently are net sinks of carbon. A recent compilation of estimates of the amount of carbon held in soil as organic matter (Woodwell *et al.*, 1995) gave a mean of 1,601 Gt, of which about 20% (412 Gt of C) is stored in peatlands. Estimated average accumulation rates for boreal and subarctic peatlands range from 0.05–0.11 Gt C/yr (Armentano and Menges, 1986; Silvola, 1986; Sjörs, 1980; Gorham, 1990, 1991; Miller *et al.*, 1983; Marion and Oechel, 1993). However, some peats may have reached a balance between the degradation and addition rates of organic matter (Malmer, 1992; Warner *et al.*, 1993).

Laboratory experiments and field studies have shown that lowering the water table by 20–30 cm could increase CO_2 fluxes from peat soil 1.5–2.5-fold (Silvola *et al.*, 1985; Moore and Knowles, 1989). However, it seems that changes in the water table are more significant between 0–30 cm than between 30–60 cm (Silvola *et al.*, 1985). Any lowering of the water table would mean, on the average, an extra carbon release of about 100–300 g C/m²/yr. Further, an increase in temperature of 1–5°C in northern peatlands could decrease carbon accumulation by 10–60% due to enhanced microbial activity (see Section 6.5.3). Very little is known about peatlands in tropical regions, and there is some disagreement about whether tropical peatlands at present function as net carbon sinks or sources (Immirzi and Maltby, 1992; Sorensen, 1993; Sieffermann *et al.*, 1988; see Section 6.5.4). They are, however, large carbon stores, and any significant changes in the degree of storage have implications for carbon cycling.

In the recent geologic past, the tundra was a sink of 0.1–0.3 Gt C/yr (Miller *et al.*, 1983; Marion and Oechel, 1993). However, recent climatic warming in the arctic (see Lachenbruch and Marshall, 1986; Chapman and Walsh, 1993), coupled with the concomitant drying of the active layer and the lowering of the water table, has shifted areas of the arctic from sinks to sources of CO_2 (Oechel *et al.*, 1993). For example, arctic areas that were sinks of 0.1 Gt C/yr now are sources of 0.1–0.6 Gt C/yr (Oechel *et al.*, 1993; Zimov *et al.*, 1993). This illustration of a response of a northern wetland to warming suggests a major

change in ecosystem function that may be an early indication of global change in a natural ecosystem.

Although wetland vegetation fixes atmospheric CO_2, biogeochemical processes give rise to other greenhouse gases, such as CH_4. The estimated contribution of wetlands to the annual atmospheric CH_4 burden is 55–150 Mt/yr (Prather *et al.*, 1994). However, the flux measurements on which these estimates are based are biased toward wetlands in northern North America and the Scandinavian countries (Bartlett and Harriss, 1993; Matthews, 1993). Climate change leading to an alteration in the degree of saturation and flooding of wetlands would affect both the magnitude and the timing of CH_4 emissions (see Section 6.5.3.2). Drying of northern wetlands could lead to declines in CH_4 emissions (Roulet *et al.*, 1993; Martikainen *et al.*, 1995). Although emissions of N_2O from wetlands usually are low (Urban *et al.*, 1988; Freeman *et al.*, 1993; Martikainen *et al.*, 1995), a lowering of the water table could increase emissions.

Climate change also can affect the chemical properties of wetlands. Some non-tidal wetlands are saline due to the surplus of evapotranspiration over precipitation. If rates of evapotranspiration increase, there is a risk that more salts will accumulate in these wetlands, which could impair the value of wetlands due to the loss of intolerant species. Wetlands that are presently freshwater could become saline. However, in regions facing a decrease in evapotranspiration, the existing saline wetlands could gradually change as salinity decreases. This will affect the chemical properties of the wetlands—which, in turn, has consequences for biological and ecological characteristics, affecting vegetation, habitat value, and species composition (including the invertebrate community; Swanson *et al.*, 1988).

An increase in temperature also will affect processes such as pollution trapping and waste processing because these processes are regulated by microbial activity and plant uptake, which are important sinks for nutrients (such as nitrogen and phosphorus) and various kinds of pollutants (heavy metals, pesticides and herbicides; Gilliam *et al.*, 1988; van der Valk *et al.*, 1979; Brinson, 1990; Brix and Schierup, 1989; Johnston, 1991; Mitsch and Gosselink, 1993). However, the key features to which these water-quality functions are connected are coupled to the water regimes of wetlands (Kadlec, 1989), so it is impossible to make any general statements about the impact of climate change on these functions.

6.3.3.2.3. Hydrological functions

Hydrological functions include flood control (Andriesse, 1988; Novitzki, 1979; Boelter, 1966; Gosselink and Maltby, 1990) and aquifer recharge (Bernaldez *et al.*, 1993). Wetlands temporarily store runoff water, thereby reducing floodwater peaks and protecting downstream areas (Andriesse, 1988; Novitzki, 1979; Boelter, 1966; Gosselink and Maltby, 1990). A reduction of wetland area due to climate change could severely hamper flood-control efforts in some regions. Under certain conditions,

climate change could enhance recharge to major aquifers by overlying wetlands—particularly in arid or semi-arid regions, where groundwater is of considerable importance as a source for public water supply and irrigation (Bernaldez *et al*., 1993; see Section 6.5.2). The contribution of wetlands to groundwater resources depends on the detention of water within the wetland during dry periods; this is likely to be reduced by loss of wetlands (Bernaldez *et al*., 1993).

At northern latitudes, projected higher spring and winter temperatures would likely affect the amount and timing of runoff from snowmelt and rainfall by changing the patterns of soil freezing and thawing (Mimikou *et al*., 1991). It also would decrease the ratio of snow to rain, leading to additional changes in spring snowmelt (Cohen, 1986; Gleick, 1987; Croley, 1990).

6.3.4.   *Interactions Between Climate Change and Other Wetland Stressors*

The impacts of climate change on wetlands will interact with other anthropogenic stresses. Due to the importance of hydrological regime and wetland response, we confine ourselves to discussing the cumulative impacts of hydrological changes in wetlands. Apart from climate change, the most common disturbances to the hydrological regimes of wetland ecosystems are alterations in plant communities, storage of surface water, road construction, drainage of surface water and soil water, alteration of ground water recharge and discharge areas, and pumping of ground water. All of the anthropogenic activities and natural causes mentioned in Table 6-1 will, to various extents, impact the hydrology of wetlands. Drainage for agriculture, for example, would cause drastic changes in water level and means near-total destruction of wetland ecosystems, whereas construction of dams for water management could be less severe if efforts to maintain waterflow through the subjected wetlands are made. Due to site-specific responses by wetland ecosystems and the large range of plausible anthropogenic and natural stressors, a quantitative evaluation of them in combination with climate change is difficult. It is conceivable, however, that within the next decades the main threat to wetlands is likely to be due to anthropogenic activities rather than climate change.

6.4.   **Response Options—Adaptation, Conservation, and Restoration**

The prospects for adaptation, conservation, and restoration of wetland ecosystems in response to climate change varies with wetland type and the specific wetland function being considered. For wetland functions that are an aggregated product of regional or global wetland resources (e.g., trace-gas fluxes, carbon storage), there are no human responses that can be applied at the necessary scale. Moreover, changes in these functions as wetlands adapt to climate change are difficult to predict due to the site-specific nature of wetland responses to climate change.

For wetland functions that are more local in scale (e.g., habitat value and pollutant absorption), prospects for adaptation, conservation, and restoration are better than for large-scale functions. However, these prospects will vary strongly with wetland type. Some wetland types have a higher potential for adaptation to climate change due to their inherent exposure to high spatial and temporal variation in environmental conditions. For example, the prairie pothole wetlands discussed in Section 6.3.3.1 respond dynamically and naturally to wide variation in seasonal and annual climate (van der Valk and Davis, 1978; Poiani and Johnson, 1989).

Other wetland types—for example, boreal peatlands—have high spatial variability in plant communities caused by variation in macro- and microtopography (Sjörs, 1950). Hotter, drier, and/or wetter climates will result in a change in the wetland community in these wetlands, but the natural spatial and temporal variation inherent in these systems suggests that the changed community will resemble at least some component of the existing community (Poiani and Johnson, 1989).

Given the site-specific nature of wetland responses to climate change and the importance of inherent variation in fostering potential for adaptation, wetland conservation and restoration efforts should focus on preserving this variation (McNeely, 1990; Leemans and Halpin, 1992; Peters and Lovejoy, 1992). Wetland restoration and creation technologies have a great potential for ameliorating the effects of climate change on wetland functions. However, wetland ecology is complex, and the enthusiasm for wetland creation and restoration has outpaced the scientific understanding and technological development needed to successfully create wetlands for specific purposes (Reed and Brown, 1992; van der Valk and Jolly, 1992). Key areas of concern in wetland creation are how to establish a persistent and resilient assemblage of desired wetland plants, and a lack of understanding of the relationships between different plant assemblages and a range of wetland functions—from microbial pollutant-attenuation mechanisms to sequestration of soil carbon to food-chain support (Zedler and Weller, 1990; Pickett and Parker, 1994).

6.5.   **Examples and Case Studies**

6.5.1.   *Introduction*

This section uses case studies from certain defined wetland areas and regions to demonstrate climate-change impacts on different wetland types and geographic locations. The areas selected for these studies are the Sahel region of Africa, northern wetlands, the Kalimantan of Indonesia, and the Florida Everglades of the United States. These different locations will provide insight into the uses and responses of peatlands, marshes, and floodplains, as well as measures that are presently being taken in some places to restore wetlands affected by human uses and alterations.

The purpose of the case studies is to illustrate the general concepts described in this chapter through specific examples and

to identify factors that make wetlands more or less vulnerable to any possible changes. The case studies also illustrate the type of information needed for any given location in order to conduct an assessment of potential risks, as well as the specificity of the information that may be gleaned about possible impacts at this time at individual sites.

Most of the case studies deal with the local functions, uses, and benefits of the wetlands and how these will be affected by climate change: These wetlands are valuable to nearby populations as sources of water, as agricultural land, as habitat for species, and for their other hydrological functions. Some of the case studies deal with the biogeochemical functions of wetlands and the ways in which human alterations and climate-change impacts on wetlands could affect the cycling of CO_2, CH_4, and N_2O to the atmosphere, which would result in global-warming feedback.

6.5.2. Case Study: The Sahel

6.5.2.1. Background

The Sahelian wetlands are dynamic ecosystems (see Box 6-1). During the past 2 decades, new wetlands of up to 1,800 hectares have formed, while other wetlands have been degraded (Piaton and Puech, 1992; Brouwer and Mullié, 1994a). Wetlands in the Sahel include the floodplains of the large rivers and Lake Chad, as well as thousands of small permanent and temporary wetland ecosystems scattered throughout the region (see Sally *et al*., 1994; Brouwer and Mullié, 1994a; Windmeijer and Andriesse, 1993). Some of these wetlands, such as the small valley bottoms, contain water only during runoff events.

The small wetlands in the Sahel are very important for agriculture (MHE-DFPP, 1991; MHE-Niger, 1991a; Brouwer and Mullié, 1994b) and are used for dry-season cropping, using

moisture left in the soil after the floods have receded, or for small-scale irrigation. In the period 1984–91, between 42,000 and 64,000 hectares of wetlands were used each year in Niger for dry-season cropping, generating an annual income of $200–$4,300 per hectare (MAE-Niger, 1993; Raverdeau, 1991; Cherefou Mahatan, 1994). In 1990, 4.1×10^6 hectares of dryland cropping (mostly millet) in Niger generated an income of about $70 per hectare. This difference in income per hectare is in part a reflection of the quality of the food produced. The small wetlands also have greater production of fish per hectare and greater density of birds than the large wetlands (Brouwer and Mullié, 1994b; Mullié and Brouwer, 1994).

6.5.2.2. Societal Context

The human carrying capacity of the Sahel region is already matched or exceeded by population density (van der Graaf and Breman, 1993); dryland agriculture or large-scale migration to other parts of the region are unlikely to be able to relieve the situation. As a result, wetlands will be more sought-after, and pressure for conversion of wetlands to rice fields should increase due to increasing urbanization in West Africa and its effects on the demand for rice.

Droughts also tend to increase pressure on wetlands because they affect the migration patterns of people in the area. During the severe droughts of 1975 to 1988, the number of villages on the Nigerian section of Lake Chad increased from 40 to more than 100 (Hutchinson *et al*., 1992). Similarly, the use of the Hadejia-Nguru wetlands in Nigeria for agriculture has increased due to droughts. This increase was not foreseen when plans were made for the construction of dams and irrigation projects in the catchment upstream. Wet periods have traditionally meant migration to the normally drier and less-populated northern and western parts of the Département Tahoua, Niger. Because these people often stayed despite less-abundant

---

Box 6-1. The Wetlands of the Sahel: Effects on Agriculture, Habitat, and Hydrology

Background: The wetlands of the Sahel region of Africa consist of the floodplains of major lakes and rivers, as well as thousands of smaller wetland ecosystems scattered throughout the region. These smaller wetlands are particularly important for agriculture and as a source of income from agriculture; floodplains are important for their hydrological functions. The wetlands in the Sahel are already expected to come under increased pressure for conversion to agriculture and other uses due to urbanization and population growth projected over the next decades.

Possible impacts: With the possible exceptions of eastern Niger and Chad, climate change is expected to decrease the extent of wetlands in the Sahel, due to changes in temperature and precipitation projected by current scenarios. These changes are likely to result in a net loss of water in most of the large rivers in the Sahel over the next 30–60 years, with the exception of the major rivers flowing into Lake Chad. Although few studies exist on the effects on species, the loss of wetlands due to climate change could create a risk of extinction for some local populations of turtles and birds.

Conclusion: Although climate change could have some beneficial effects on the wetland regions of the Sahel, there would be many adverse impacts; some could be potentially irreversible. Even if the predicted decrease in rainfall in the western Sahel were followed by a recovery to present levels or more, part of the damage that is likely to occur in the interim would be very difficult to repair.

rainfall, they increased the pressure on natural resources, including wetlands (DDE-Tahoua, 1993).

6.5.2.3. Climate Change Expected

Rainfall in the Sahel region is greater in the north than in the south (see Nicholson, 1978, 1994; Hutchinson *et al*., 1992). This analysis focuses on the wet season (June–August), when most dryland crops are grown. According to the IPCC Working Group II scenarios (Greco *et al*., 1994), precipitation in the Sahel zone is projected to decrease by 2020 in the Senegal to Burkina area and increase moderately to considerably in Niger and Chad. Temperature is projected to increase by 0.5–1.5 (0–2.0)°C. For the decade around the year 2050, the three models show less agreement overall, although all indicate that eastern Niger is likely to receive more rain. Temperatures would be similar to those around the year 2020, though possibly somewhat higher in the area of the headwaters of the Senegal and Niger rivers. In the headwaters of the Komadougou Yobé river, rainfall around the year 2020 is expected to be somewhat less than at present. For the year 2050, the scenarios are less conclusive: In the area of the headwaters of the major rivers flowing into Lake Chad, rainfall around 2020 and 2050 is expected to be moderately to considerably greater than now.

6.5.2.4. Effects on Water Availability and Vegetation

Overall, these changes suggest that there will be less water in most of the large rivers in the Sahel over the next 30–60 years, with the exception of the major rivers flowing into Lake Chad. This will mean less water available in the floodplains along these rivers, unless there are changes to the management of outflow from dams. Changes to the hydrology of the small wetlands will depend not only on climate change but also on whether they are supplied with surface water or groundwater, on the reaction of the natural vegetation, and on the extent of cropping in their catchment areas.

Recharge to shallow, unconfined groundwater could either increase or decrease as a result of climate change. The groundwater level in southwest Niger increased in the last decade (Leduc *et al*., in press; Bromley *et al*., in press a), either as a recovery from the droughts of 1983–84 and/or 1973–74 or as a response to changes in land use. Annual recharge under millet in southwest Niger is on the order of 1–200 mm, a factor ten times greater than under bush and older fallow vegetation (Gaze *et al*., in press; Bromley *et al*., in press b). Therefore, an increase in the area sown for millet—as noted by Reenberg (1994) and others—could result in a higher recharge to unconfined groundwater and the wetlands fed by such groundwaters.

The dryland areas should experience less evaporative water loss because less rainfall, at least initially, means less perennial vegetation. However, there will be increased runoff until a new vegetative cover is established. This increase in runoff will likely result in increased erosion (see van Molle and van

Ghelue, 1991) and a faster silting up of wetlands. It also could create entirely new wetlands.

Higher temperatures also may adversely affect seedling emergence of millet, the staple cereal over much of the Sahel (see Monteith, 1981)—meaning that less millet would be harvested in the dryland areas and increasing the pressure on wetlands. However, during dry years in eastern Niger, infiltration into the heavier soils in depressions may be so low that cropping becomes unattractive (Reenberg, 1994). During dry years, water is more limiting than nutrients, and cropping on less-fertile upland soils with higher infiltration rates may become more attractive.

Desertification upon drought may result in a loss of wetlands due to moving sands (DDE-Tahoua, 1993; Mahamane Alio and Abdou Halikou, 1993; Framine, 1994). In part, this response can be related to the greater vulnerability of perennial vegetation to desiccation under a monomodal semi-arid rainfall regime (Ellis and Galvin, 1994), when topsoil and seedbanks are washed or blown away during the drought. Droughts may make wetland vegetation more vulnerable to fires intended to improve rangeland vegetation (Hutchinson *et al*., 1992).

6.5.2.5. Effects on Biodiversity

There are few assessments of how these changes could affect local biodiversity. Mullié and Brouwer (1994), following Gibbs (1993), suggest that small wetlands in the Sahel are important for the metapopulation dynamics of certain taxa—meaning that the loss of small wetlands may lead to a significant risk of extinction for local populations of turtles and small birds (Gibbs, 1993). Taxa that are easily transported by wind or birds as adults, eggs, cysts, larvae, and so forth would be subject to less risk (Dumont, 1992; Mullié and Brouwer, 1994; Magadza, 1994).

The importance of wetlands to birds in semi-arid areas can vary greatly from year to year depending on local and regional rainfall (Rose and Scott, 1994). If wetlands in the western Sahel become drier, relatively mobile birds dependent upon wetland habitats will move into wetlands further east (i.e., Niger, northern Nigeria and Cameroon, Chad).

6.5.3. Northern Wetlands: Effects on the Carbon Cycle and Trace-Gas Emissions

6.5.3.1. Peat Accumulation

Peatlands are a major store of organic carbon and contain approximately 20% of the total amount of organic carbon stored in soils (see Section 6.3.3.2). A majority of this is in the Northern Hemisphere as carbon stored in the form of peat (see Box 6-2). Peat formation and accumulation in these wetlands is influenced by climate change: A change in climate would lead to changes in the flux of carbon (CO_2 and CH_4) between these ecosystems and the atmosphere, generating a feedback on climate warming.

Box 6-2. Northern Wetlands: Effects on the Carbon Cycle and Trace-Gas Emissions

Background: Peatlands are a major store of organic carbon and contain approximately 20% of the total amount of organic carbon stored in soils. The northern peatlands account for a majority of this as carbon is stored in the form of peat. This case study demonstrates how changes in climate may affect the flux of carbon (CO_2 and CH_4) and nitrous oxide between these ecosystems and the atmosphere, generating a feedback on climate warming.

Possible impacts: Current scenarios suggest that climate change is likely to increase the flux of CO_2 to the atmosphere because temperatures influence whether carbon litter is accumulated into the peat profile or oxidized. In addition, the position of the water table regulates the extent of oxygen penetration into the peat profile. This means that drainage will cause increased decomposition, leading to increased fluxes of CO_2 to the atmosphere, although this effect will decline over time. Further, a decrease in water availability could lead to a decrease in CH_4 emissions from wetlands. Changes in variables such as the areal extent of wetlands and the duration of the active period will determine whether there will be a change in the total CH_4 flux from a wetland. A lowering of the water table would probably not affect nitrous oxide emissions from bogs but could lead to an increase of emissions from fens, although emissions of nitrous oxide from wetlands tend to be low.

Conclusion: Changes in the source/sink relationship have already occurred in wetlands in some parts of the world. Both climate change and human (non-climate) factors are likely to further affect the biogeochemical functions of wetlands.

Wetland vegetation fixes CO_2 from the atmosphere and eventually is added to the top layers of the wetland soil as organic litter. Part of the organic litter is oxidized and emitted as CO_2, and some is accumulated as peat. Several investigations have shown that soil CO_2 efflux from peatlands is strongly related to temperature (Svensson *et al.*, 1975; Svensson, 1980; Glenn *et al.*, 1993; Crill, 1991), although Moore (1986) found a poor correlation between temperature and CO_2 emission rates. Since most of the CO_2 emitted is produced by the upper soil layers (Stewart and Wheatly, 1990), it mainly originates from organic material that has not yet become a part of the peat proper, known as the catotelm. Carbon litter reaching the soil may be either oxidized (emitted as CO_2) or accumulated. Thus, a change in CO_2 emissions will be directly correlated to the portion of organic matter transferred to the catotelm. Because the CH_4 formed will be accompanied by a nearly equal amount of CO_2 (see Gujer and Zehnder, 1978), this relation should hold for most peatland types.

According to one CO_2 efflux temperature-moisture regression model (Svensson, 1980) of the transfer rate of organic matter to the catotelm due to changes in temperature, CO_2 emissions should rise by 12% for each degree Celsius increase in average temperature, given the mean seasonal moisture level. Accordingly, a temperature increase of 1–5°C would result in a 10–60% decrease in the rate at which organic matter is transferred to the catotelm.

Peat accumulation has varied substantially over past millennia (see Malmer, 1992), which is reflected in the quality of peat as a substrate for decomposers. The degradation rate of deep peat is limited by substrate quality rather than by abiotic factors (Hogg *et al.*, 1992). Therefore, the decomposition rate in deep peat will be fairly constant and only marginally affected by changes in temperature. Such constancy would improve the usefulness of the model described above in predicting changes

in peat accumulation in response to a temperature change. Changes in hydrology also will influence the accumulation rate of peat because the position of the water table regulates the extent of oxygen penetration into the peat profile. The effect of a lowered water table due to climate change can be compared to the effects noted after drainage of peatlands for forest production. Drainage results in an increased decomposition rate and elevated fluxes of CO_2 to the atmosphere (Silvola *et al.*, 1985; Silvola, 1986; Moore and Knowles, 1989): A 25-cm lowering of the water table gave rise to a twofold increase in CO_2 emissions from peat (Silvola *et al.*, 1985; Moore and Knowles, 1989). Depending on the type of peatland, this elevated flux may reduce carbon accumulation or even reverse the net flux of carbon to make the peatland a net source of atmospheric CO_2. Drained minerotrophic forested peatlands have been reported to respond in the latter way, whereas nutrient-poor peatlands may continue to accumulate carbon at a predrainage level (Laine *et al.*, 1994; see also Tamm, 1951, 1965). Average CO_2 evolution from northern peatlands has been estimated at about 200 gC/m²/yr (Silvola *et al.*, 1985; Moore 1986, 1989). Following drainage, an elevated CO_2 flow will decline over time (see Armentano and Menges, 1986) owing to substrate depletion as the more easily decomposable fractions of the peat become depleted. However, a drier climate will continue to "drain" the peat successively for a long period; the decline will occur later. To estimate the importance of this, it is assumed that the drainage response reported by Silvola *et al.* (1985) is linear with depth. The increase in CO_2 flows at subsequent drawdowns of 5 cm would then be 40 gC/m²/yr or another 20% per depth interval.

The scenarios for 2020 and 2050 for the areas of boreal and subarctic peatlands project a temperature increase of 1–2°C and a decrease in soil moisture. Based on this temperature change, it seems reasonable to expect a 25% decrease in the addition of organic matter to the catotelm. It is assumed that

this effect would be amplified in response to a decrease in soil moisture. Thus, it is conceivable that the peat accumulation rate will decrease to half of the present rate or even less (i.e., <0.025–0.055 Gt C/yr). Boreal peatlands may even become net sources of atmospheric CO_2. In concluding his discussion of the response of northern wetlands to predicted climate change, Gorham (1991) gives the extreme example of a 1-cm break-down of the boreal peat layers worldwide. This would result in 2 Gt C/yr, which corresponds to more than a third of the present release of carbon to the atmosphere via fossil fuel combustion. The response in net primary production in relation to climate change is more difficult to predict and may enhance or reduce the effects caused by the estimated changes in the degradation features of peatlands (see Malmer, 1992).

6.5.3.2.   *Climatic Controls on Methane Flux*

The net emission of CH_4 from peatlands is dependent on how much CH_4 is formed in the anaerobic parts of the profile and the amount oxidized in the oxic zones. Because the position of the water table and the associated capillary fringe determine the thickness of the zones of production and oxidation of CH_4, the flux of CH_4 is intimately tied to the surface hydrology of the wetland—which in turn is controlled by climate (precipitation and evaporation) and the topographic and geologic setting (surface and subsurface water flow). A decrease in water availability in the peat can lead to a decrease in CH_4 emissions (Whalen *et al*., 1996; Sundh *et al*., 1994a, 1994b; Martikainen *et al*., 1995; Roulet *et al*., 1993). Deeper penetration of oxygen into the peat also will enhance the capacity of the peat to act as a CH_4-oxidizing filter for CH_4 diffusing from the CH_4-forming sources below. Changes in the direction or magnitude of any or all of the controlling variables discussed above will affect the CH_4 flux. A change in the total CH_4 flux from northern wetlands can be expected if the areal extent of wetlands changes, the duration of the active period changes, and/or the per-unit-area production or oxidation of CH_4 changes.

The relations among moisture content, temperature, and CH_4 flux in individual wetlands have received much attention (Bartlett *et al*., 1992; Crill *et al*., 1988; Dise *et al*., 1992; Moore and Knowles, 1989; Moore and Dalva, 1993; Moore and Roulet, 1993; Svensson, 1976; Svensson and Rosswall, 1984). These relations have been used to estimate qualitatively the year-to-year variation in the flux and the possible direction of change based on changes in temperature and precipitation obtained in 2 x CO_2 scenarios (Table 6-3). Four different approaches have been used to address this issue: (1) correlation of the time series of CH_4 fluxes with the time series of temperature and moisture using interannual data sets; (2) direct observations of changes in CH_4 flux in manipulation experiments that simulate expected changes in wetlands due to climate change; (3) modeling of variability of CH_4 flux using existing climate records and regressions between temperature and CH_4 flux; and (4) modeling of thermal and hydrological regimes of wetlands in 2 x CO_2 climate scenarios and then modeling of change in CH_4 flux using regressions relating CH_4 flux to temperature and moisture in order to predict a change in

flux. These studies have shown that the flux of CH_4 is moderately sensitive to changes in temperature and very sensitive to changes in moisture. Using these relative sensitivities as a guide, a qualitative assessment of CH_4 flux from northern wetlands according to six possible climate scenarios is made (Table 6-3). At present, it is not possible to obtain reliable quantitative estimates of the change in flux because the surface hydrology of general circulation models is too coarse to adequately represent the small changes in moisture regime that probably affect the CH_4 flux.

6.5.3.3.   *Effects on Nitrous Oxide Emissions*

Emissions of N_2O from northern wetlands are low. *In situ* chamber measurements and laboratory experiments with intact peat cores have revealed emissions below 0.025 g N_2O-N/m²/yr (Urban *et al*., 1988; Freeman *et al*., 1993; Martikainen *et al*., 1993). A lowering of the water table of bogs will not affect their N_2O emissions, whereas it could strongly increase emissions from fens. Annual emission rates in the range of 0.05–0.14 g N_2O-N/m²/yr have been reported for drained peat by Martikainen *et al*. (1993) and Freeman *et al*. (1993). The difference between bogs and fens can be explained partly by the fact that drained peat profiles of fens have the capacity to nitrify (Lång *et al*., 1994). N_2O emissions from drained boreal fens are lower than those from drained agricultural organic soils but 10–100 times higher than the rates from coniferous forest soils (Martikainen *et al*., 1993).

6.5.4.   **Case Study: Kalimantan**

6.5.4.1.   *Background*

Kalimantan is one of the largest islands (539,460 km²) in the Indonesian archipelago (see Box 6-3). The region has a humid tropical climate, with high temperatures and high precipitation. The peatlands of Kalimantan probably play a major role in determining local climate at the present time, although there is no substantial evidence to confirm this.

The largest wetland areas are found in low-lying alluvial plains and basins and flat-bottomed valleys. Most of the freshwater wetlands in the area are forested swamps, specifically either freshwater swamp forests or peat swamp forests (Silvius, 1989). The freshwater swamp forests are rich in epiphytes, rattans, and palms. They provide shelter for a range of rare and endangered species of wildlife, including numerous bird species. The peat swamp forests are a further developmental stage of the freshwater swamp forest. Deep peats are found in the central and western parts of the island (Sieffermann *et al*., 1988, 1992; Rielly *et al*., 1992). The peat swamp forests have a relatively high diversity of tree species, but the variety of wildlife tends to be poorer than in freshwater swamp forests (Whitten *et al*., 1987). Because of the high acidity of the peats and the fact that they are difficult to drain, peat swamp forests are of limited agricultural value (Silvius, 1989). Both swamp types are important watershed areas

capable of absorbing and storing excess water and reducing flooding in adjacent areas. They also are an important forestry resource, with many commercially valuable timber species.

The wetlands of Kalimantan currently are deteriorating through the loss of the natural ecosystem, including primary forest cover. Deforestation, drainage, and agriculture all limit the buffering capacity of developed wetlands, causing changes that are long-term and irreversible. Because much of the human settlement at the present time is located in the coastal zone, peat swamp forest on the deeper interior peats has not been subject to large-scale harvesting. These areas are used mainly for timber extraction rather than agriculture; hence, their vegetation cover remains relatively unmodified.

6.5.4.2. *Effects of Temperature Change*

The projected climate change for the region involves an increase in temperature ranging from 0–1.5°C. The effects of

Table 6-3: *Potential changes in CH_4 flux from northern wetlands due to changes in the thermal and moisture regime (adapted with additions from Matthews, 1993).*

Study Description and Location	Change in Thermal and/or Moisture Regime	Observed or Modeled Change in CH_4 Flux	Relative Sensitivity
Field observations of CH_4 flux and temperatures among tundra wetlands of the North Slope (Alaska) with differing moisture levels (1987–1989)[1]	$\Delta T = +4°C$ $\Delta T = +4°C$; wetter $\Delta T = +4°C$; drier	Four-fold increase Four- to five-fold increase Two-fold increase	Large positive sensitivity to temperature increase; small positive sensitivity to moisture change
Field observations of CH_4 flux from permanent tundra wetland sites (Alaska)[2]	4-year variation in temperature and moisture	4 times variation in flux: Flux increased with warmer, wetter conditions	Large positive sensitivity to both temperature and moisture changes
Field observations of CH_4 flux from drained boreal wetlands (Canada)[3]	$\Delta WT = -10$ cm $\Delta WT > -10$ cm	Elimination of CH_4 flux Wetland became small CH_4 sink	Large positive sensitivity to moisture change
Field observations of CH_4 flux from drained boreal wetlands (Finland)[4]	$\Delta WT = -4$ cm $\Delta WT = -20$ cm	Five-fold decrease Elimination of CH_4 flux	Large positive sensitivity to moisture change
Modeling study based on 20th-century historical summer temperature anomalies for five high-latitude wetland regions and a temperature/CH_4 flux regression model[5]	$\Delta T = \pm 2°C$	$\pm 15\%$ variance in flux	Moderate sensitivity to temperature
Modeling study simulating change in summer temperature and water table for a northern fen (Canada) in a 2 x CO_2 scenario (+3°C, +1 mm/d P) and temperature/CH_4 flux, and water table/CH_4 flux regression models[6]	$\Delta T \approx +0.8°C$ $\Delta T = +2°C$ $\Delta WT = -14$ cm	+5% increase +15% increase -80% decrease	Moderate sensitivity to temperature; large sensitivity to moisture

Notes: ΔT = change in temperature; ΔWT = change in water table; P = precipitation.

Box 6-3. The Forested Swamps of Kalimantan: Effects on Habitat, Hydrology, and Carbon Cycling

Background: The wetlands of Kalimantan are found in low-lying alluvial plains and basins and flat-bottomed valleys. Most of the freshwater wetlands in the region are classified as forested swamps, specifically as either freshwater swamp forests or peat swamp forests. The freshwater swamp forests are important in providing shelter for rare and endangered species; both types are important as watersheds and habitats for valuable tree species. They also are carbon sinks but release carbon into the atmosphere when water declines. The Kalimantan wetlands currently are stressed by the loss of the natural ecosystem through deforestation, drainage, and agriculture. These activities limit the buffering capacity of developed wetlands, causing changes that tend to be long-term and irreversible. However, these inland wetlands have escaped some interference because most of the human settlements are located along the coastal zones.

Possible impacts: Increased temperatures are likely to result in a longer period of reduced rainfall because higher temperatures will cause evapotranspiration to exceed precipitation. This is likely to have deleterious effects on the vegetation and hydrology of these wetlands. Climate change also could enhance peat losses in the region that currently result from human interference. On the other hand, increased precipitation in the dry season is likely to be beneficial, as the lower water levels that are typical in this season lead to a net loss of carbon into the atmosphere and an increased risk of fire (one of the greatest threats to their functioning).

Conclusion: It is possible that some measures may be taken in this region in the near future to abate the detrimental impacts caused by human (non-climate) stresses on these wetlands. The extent to which adaptations will be sufficient to counteract changes imposed by a changing climate as well cannot be determined. However, human activities that reduce the resiliency of these wetlands, as well as planned development of previously undisturbed areas of swamp forest, will likely lead to considerably enhanced carbon transfer from the wetlands to the atmosphere, even without climate change.

---

higher temperature and longer dry periods combine to produce a longer period when evapotranspiration exceeds rainfall and effective rainfall is greatly reduced. This, linked to increasing human activity on peatlands—such as timber extraction, agricultural development, and construction work—could have serious consequences.

Much of the Kalimantan lowland area is subjected to a distinct dry season from July to September or October in which there are high water losses from wetlands as a result of direct evaporation and evapotranspiration. Thus, water levels drop and peat oxidation occurs, with a net loss of carbon to the atmosphere. The spread of fire is one of the greatest threats to the functioning of these wetlands. Peat fires occur frequently in the region, creating palls of smoke sufficiently heavy to close local airports. In 1983–84, fires destroyed 3.5 Mha of both dipterocarp and peat swamp forest in Kalimantan, resulting in a direct economic cost of $2–12 million and an incalculable ecological cost (Maltby, 1986). The risk of fires spreading from cultivated to forest areas increases during the dry season and would increase if the dry season were extended.

6.5.4.3. Effects of Precipitation Change

Estimated precipitation changes for the area range from -20% during winter to +40% during the summer. The higher "summer" (i.e., dry-season) values are beneficial to the peatlands because this is the time when they experience the greatest drawdown of the water table. A decrease of precipitation in the wet season could be significant if, as a result, the dry season is extended.

Large-scale removal of the forests and drainage of the underlying peats could prevent further peat formation. The high peats of Kalimantan already appear to be degrading (Sieffermann *et al*., 1988) and losing carbon directly through oxidation to the atmosphere or indirectly in surface drainage waters, followed by oxidation of carbon compounds at a later stage. Climate change would most surely exacerbate this degradation, leading to peat losses in this region.

6.5.4.4.   Remediation Possibilities

A forest-management project in Kalimantan currently being sponsored by the British Overseas Development Administration will include suggestions for the sustainable management of the peat swamp forests. The resulting guidelines should help preserve the forest cover on the deeper peats, particularly if extraction methods do not intensify. Indonesian authorities also are introducing stricter regulations and controls on unnatural fires resulting from illegal land clearance and settlement. However, in 1986–89, a feasibility study was carried out to investigate the potential of using deep peat to generate electricity.

The extent to which these potential management changes will be sufficient to counteract the effects of climate change cannot be determined. However, utilization of the forests on these peats and planned development of previously undisturbed areas will likely lead to considerably larger carbon transfer from wetlands to the atmosphere even without climate change.

6.5.5. Case Study: The Florida Everglades

6.5.5.1. Background

The Everglades is a 500,000-hectare freshwater peatland dominated by vast expanses of sedge and sawgrass, interspersed with shallow-water aquatic communities (sloughs), wet prairies, and tree islands (Loveless, 1959; Gunderson, 1994). Peat accumulation and the subsequent formation of the Everglades began approximately 5,000 years ago as sea-level rise slowed after an initial rapid rise during deglaciation (Gleason and Stone, 1994). As recently as a century ago, the Everglades encompassed more than 1,000,000 hectares, but drainage for agriculture and urban development has resulted in the loss of more than half of the ecosystem (Kushlan, 1989; Davis *et al*., 1994). The remaining area has been dramatically altered by construction of impoundments, canals, levees, and water-control structures; the system is managed, primarily, as a water source (Light and Dineen, 1994). During the wet season (June–November), excess water from agricultural land and suburban areas is pumped into the Everglades; during the dry season (December–May), the Everglades serves as a water source (DeGrove, 1984). In addition, approximately 50% of the water from the Kissimmee River/Lake Okeechobee complex—the "headwaters" of the Everglades—is diverted by canals to the Atlantic Ocean and the Gulf of Mexico before recharging the wetland (Light and Dineen, 1994). Thus, the present-day Everglades is characterized by a general reduction in the hydroperiod (Fennema *et al*., 1994; Stephens, 1984; SFWMD, 1992; Walters *et al*., 1992).

Long-term rates of peat accretion in the Everglades average 0.8–2.0 mm/yr, based on ^{14}C dating of the basal peat (McDowell *et al*., 1969) and ^{210}Pb dating of peat cores (Craft and Richardson, 1993). However, alterations of the natural hydroperiod and nutrient regimes in the Everglades have resulted in changes in the rate of peat accretion. Areas experiencing reduced hydrology (caused by overdrainage) exhibit lower rates of accretion (1.6–2.0 mm/yr) compared to areas of extended hydroperiod (2.8–3.2 mm/yr) (Craft and Richardson, 1993). Likewise, pollen analysis of peat cores indicates a decrease in the extent of wetland vegetation such as sawgrass and slough and a concurrent increase in terrestrial "weedy" species (ragweed and pigweed) since drainage activities were initiated (Bartow *et al*., 1994). Thus, future changes in the Everglades ecosystem caused by global warming must be interpreted in the context of recent anthropogenic alterations of hydrology and nutrient regimes (see Box 6-4).

6.5.5.2. Effects of Sea-Level Rise

The most immediate effect of climate change will be accelerated sea-level rise, resulting in saltwater intrusion into the lower part of the glades from Florida Bay (Wanless *et al*., 1994). Increased salinity would result in encroachment of salt-tolerant wetland communities such as mangroves and salt marshes. The areal extent of freshwater communities such as sawgrass, slough, and wet prairie will decrease, and the amount of organic carbon sequestered also will decrease. Another biogeochemical consequence of saltwater intrusion is a shift in anaerobic decomposition away from methanogenesis toward nitrate and sulfate reduction.

6.5.5.3. Effects of Temperature Change

Temperature is expected to increase from 0.5 to1.5°C, likely resulting in an increase in evapotranspiration—which may

---

Box 6-4. The Florida Everglades: Effects on Water Supply and Critical Habitats

Background: The Everglades is a freshwater peatland dominated by sedge and sawgrass, with sloughs, wet prairies, and tree islands. The Everglades is important as a habitat for wildlife, fish, and plant species and as a water source for the neighboring community. It is estimated that drainage for agriculture and urban development in the past century has resulted in a loss of more than half of the ecosystem, and the remaining wetlands have been altered by other construction and so forth.

Possible impacts: Sea-level rise is expected to be perhaps the most important variable that will affect the Everglades, causing saltwater intrusion that is likely to result in an encroachment of salt-tolerant wetland communities. This would decrease the areal extent of the freshwater wetlands, with some effects on anaerobic decomposition. The increased evapotranspiration expected in some seasons would exacerbate this saltwater intrusion. Increased temperature is likely to cause a northward migration of some introduced species but could be conducive for other species. Climate change also is expected to affect the hydrology of the wetlands, causing higher water levels in the winter and lower levels in the summer. This could result in the loss of critical habitats such as sawgrass and wet prairie communities, although these losses are likely to be offset by an increase in woody shrubs and trees.

Conclusion: Overall, the impacts that are projected as a result of climate change would adversely affect the end-users of the ecosystem: waterfowl, fish, and other wildlife; hunters, fishers, and tourists; and surrounding populations that rely upon the Everglades for freshwater resources. However, some action is currently underway to modify the water-control structure in an effort to restore the Everglades.

further exacerbate saltwater intrusion into the Everglades. Although more water will be lost to evapotranspiration, it is likely that oxidation and subsidence of the peat soils will not be dramatically affected because rising sea level will augment the groundwater table, particularly in the southern Everglades. Another consequence of increased temperature may be the northward migration of introduced species such as *Melaleuca quinquenervia*. *Melaleuca,* which has overtaken large areas of the southern Everglades, is seemingly kept in check by frost (Bodle *et al*., 1994). However, increased temperatures caused by climate change might enable *Melaleuca* to colonize large areas of the northern Everglades.

6.5.5.4.   *Effects of Precipitation Change*

Precipitation is projected to decrease during summer (0–20%) and increase during winter (0–20%). The winter months correspond to the dry season (November–May), when approximately 25% (10–15 inches) of the 50 to 60 inches of annual rainfall occurs (MacVicar and Lin, 1984). It is likely that an increase in rainfall during this season will reduce the rate of drawdown that normally occurs during this time. The reduction in summer rainfall in the wet season (May–October) should result in a lowering of the water table compared to current levels. These combined seasonal changes in rainfall should dampen the oscillations between the summer wet season and the winter dry season. As a result, water levels in the Everglades probably will be somewhat higher in the winter and somewhat lower in the summer than they are at present.

A dampening of the annual hydroperiod fluctuation may result in a decrease in the extent of sawgrass, the dominant plant community in the Everglades. Sawgrass communities are partly maintained by fire (Gunderson, 1994); increased rainfall during the dry season may reduce the frequency of fires—in particular, the severe fires that occur in the beginning of the wet season (May) that often burn large areas of the Everglades (Gunderson and Snyder, 1994). It is likely that wet prairie communities also will decrease in extent. These communities, which are important foraging habitat for wading birds (Hoffman *et al*., 1994), frequently dry down during the spring (Goodrick, 1984). The dampening of the annual hydroperiod fluctuations caused by global warming will likely result in the loss of much of this critical habitat. The decline of sawgrass and wet prairie communities probably will be offset by an increase in woody shrubs and trees. These species are not generally fire-tolerant and often compete more effectively against emergents when water levels are stable.

6.5.5.5.   *Socioeconomic Consequences*

It is likely that the greatest impact of climate change will be the loss of freshwater resources that sustain the burgeoning human population of south Florida, as well as the unique Everglades wetland. Competition for this diminishing resource will surely result in a no-win situation for humans and the Everglades under a scenario of global warming and rising sea level.

On a positive note, the U.S. Army Corps of Engineers, which oversees the water resources of south Florida, is evaluating modifications to the system of impoundments, canals, levees, and water-control structures in order to restore the Everglades (and other south Florida ecosystems) while providing for other water-related needs in the region (U.S. ACOE, 1994). This ambitious project, which could cost upward of $2 billion, is designed to increase the spatial extent of wetlands and restore the hydrology and water-quality conditions of the Everglades and other south Florida ecosystems.

6.6.   **Future Research Needs**

Wetlands are highly valued in many areas. The lack of data to fully address their responses to climate change calls for several areas of research in the future:

- Site-specific responses are variable. There is a strong need for a local and regional coupling of climate-change predictions with known responses of specific wetlands, which would allow for modeling of the necessary interactive responses of the hydroperiod, temperature, and water availability at these scales. A network of different wetland sites in different regions of the globe should be established to form the base for such research.
- The feedback on climate by changes in trace-gas flows from wetlands, especially CO_2 and CH_4, upon a climate change calls for a strengthening of ongoing research in this field. This will aid in the judgments necessary for the introduction of adaptation and remediation measures on wetlands.
- The vast "grey" literature existing on different wetland subjects within the frames of local, regional, and country research reports should be examined to further substantiate site-specific responses by different wetlands, including changes in species composition, biogeochemistry, and socioeconomic consequences.

CONTENTS

EXECUTIVE SUMMARY

The cryosphere covers a substantial amount of the Earth's surface and is very sensitive to climate change. This chapter updates the 1990 IPCC Impacts Assessment—which examined snow, glaciers, and permafrost—but also considers snow avalanches and sea, river, and lake ice. Impacts on feedbacks to global climate and sea level caused by changes in the cryosphere are covered in other chapters of the IPCC Second Assessment Report.

This chapter arrives at the following conclusions:

- Many components of the cryosphere are sensitive to changes in atmospheric temperature because of their thermal proximity to melting. The extent of glaciers has often been used as an indicator of past global temperatures (High Confidence).
- Projected warming of the climate will reduce the area and volume of the cryosphere. This reduction will have significant impacts on related ecosystems, associated people, and their livelihoods (High Confidence).
- There will be striking changes in the landscapes of many high mountain ranges and of lands at northern high latitudes (High Confidence). These changes may be exacerbated where they are accompanied by growing numbers of people and increased economic activity (Medium Confidence).

From an examination of past measurements of the cryosphere, the following 20th-century trends are observed:

- Obvious thinning, mass-loss, and retreat of mountain glaciers (High Confidence): The extent of alpine ice in the European Alps probably is more reduced today than at any time during the past 5,000 years.
- Borehole measurements show that permafrost is warming in some areas but not everywhere (Medium Confidence).
- Later freeze-up and earlier break-up dates for river and lake ice in the tundra and boreal lands: These are at least a week different compared to last century (Medium Confidence).
- No convincing evidence of trends in Antarctic or Arctic sea-ice extent (Low Confidence).
- Much variability of seasonal snow from year to year but no definitive trends, except that the areal extent of Northern Hemisphere continental snow cover has decreased since 1987 (High Confidence).
- Little change in the gross features of ice sheets (Medium Confidence).

If projections of climate for the year 2050 are realized (UKMO transient experiment data; Greco *et al*., 1994), then the following impacts on the cryosphere are likely:

- Pronounced reductions in seasonal snow, permafrost, glacier, and periglacial belts of the world, with a corresponding shift in landscape processes (High Confidence).
- Disappearance of up to a quarter of the presently existing mountain glacier mass (Medium Confidence).
- Increases in the thickness of the active layer of permafrost and the disappearance of extensive areas of discontinuous permafrost in continental and mountain areas (High Confidence).
- Less ice on rivers and lakes. Freeze-up dates will be delayed, and break-up will begin earlier. The river-ice season could be shortened by up to a month. Many rivers within the temperate regions will become ice-free or develop only intermittent or partial ice coverage (Medium Confidence).
- A large change in the extent and thickness of sea ice, not only from warming but also from changes in circulation patterns of both atmosphere and oceans. There is likely to be substantially less sea ice in the Arctic Ocean (Medium Confidence).
- Major changes in the volume and extent of ice sheets and deep, continuous permafrost are unlikely by 2050 because they are very cold and react with longer time lags (High Confidence); however, unforeseen changes in the West Antarctic ice sheet still could occur (Low Confidence).

As a result of these changes in the cryosphere, the following impacts on other systems are expected:

- More water will be released from regions with extensive glaciers (High Confidence). In some semi-arid places near high mountains, such as in central Asia and Argentina, this glacial runoff may increase water resources. In other places, summer water resources may diminish as glaciers disappear (Medium Confidence).
- In temperate mountain regions, reduced snow cover will cause moderation of the seasonal flow regime of rivers, so that winter runoff increases and spring runoff decreases (Medium Confidence). Such changes may benefit the hydroelectricity industry (Medium Confidence).
- Reduced snow cover and glaciers will detract from the scenic appeal of many alpine landscapes

(Medium Confidence). For temperate mountains, less snow will restrict alpine tourism and limit the ski industry to higher alpine areas than at present. Snow seasons will tend to be shorter and less reliable, and there will be detrimental socioeconomic impacts on mountain communities that depend on winter tourism.

- Widespread loss of permafrost over extensive continental and mountain areas will trigger erosion or subsidence of ice-rich landscapes, change hydrologic processes, and release carbon dioxide and methane to the atmosphere (Medium Confidence).
- Cryospheric change will reduce slope stability and increase the incidence of natural hazards for people, structures, and communication links in mountain lands and continental permafrost areas. Buildings, other structures, pipelines, and communication links will be threatened (Medium Confidence).
- Engineering and agricultural practices will need to adjust to changes in snow, ice, and permafrost distributions (High Confidence).

- Thawing of permafrost could lead to disruption of existing petroleum production and distribution systems in the tundra, unless mitigation techniques are adopted. Reduced sea ice may aid new exploration and production of oil in the Arctic basin (Medium Confidence).
- Less sea ice could reduce the renewal of deep waters of the North Atlantic, affect the ocean conveyor system, decrease albedo, and consequently induce climate feedbacks (Low Confidence).
- Improved opportunities for water transport, tourism, and trade at high latitudes are expected from a reduction in sea, river, and lake ice. These will have important implications for the people and economies of the Arctic rim (Medium Confidence).

7.1. Introduction

The cryosphere, which represents all global snow, ice, and permafrost, contains nearly 80% of all freshwater. It includes seasonal snow, mountain glaciers, ice caps, ice sheets, seasonally frozen soils, permafrost, river ice, lake ice, and sea ice (Table 7-1). Permafrost underlies as much as 25% of the global land surface. Seasonal snow has the largest area of any component of the cryosphere; at its maximum in late winter it covers almost 50% of the land surface of the Northern Hemisphere. A huge proportion of the mass of the cryosphere is contained in ice sheets, but at time scales of a century or less they are least sensitive to climate change.

The cryosphere is an important part of Earth's geographical and climate systems, and its components change over diverse time scales. Areas of snow and sea ice expand and contract markedly with the seasons (Table 7-1), and ice sheets underwent vast change as the Earth became warmer or cooler from the last interglacial period. During the previous interglacial—when global temperature was higher than at present—the global cryosphere was smaller, but it had twice its current mass during the last glaciation.

This chapter brings up to date the 1990 IPCC Impacts Assessment that dealt with seasonal snow cover, ice, and permafrost (Street

Table 7-1: *Estimate of the size of the cryosphere (modified from U.S. DOE, 1985; Barry, 1985; Street and Melnikov, 1990; Meier, 1993; Gloersen et al., 1992; and Chapter 7, Changes in Sea Level, of the Working Group I volume).*

Source	Area (10⁶ km²)	Ice Volume (10⁶ km³)
Seasonal Snow		
N. Hemisphere winter	46.3	<0.01
N. Hemisphere summer	3.7	
S. Hemisphere winter	0.9	
S. Hemisphere summer	<0.1	
Ice Caps and Glaciers	0.6	0.09
Ice Sheets		
Greenland	1.7	2.95
West Antarctica	2.4	3.40
East Antarctica	9.9	25.92
Antarctic ice shelves	1.6	0.79
Permafrost	25.4	0.16
River and Lake Ice	<1.0	
Sea Ice		
N. Hemisphere winter	16.0	0.05
N. Hemisphere summer	9.0	0.03
S. Hemisphere winter	19.0	0.03
S. Hemisphere summer	3.5	<0.01

and Melnikov, 1990) and the IPCC 1992 Supplementary Report (Melnikov and Street, 1992). Snow avalanches and sea, river, and lake ice are considered for the first time, and substantial new material has been added on glaciers and permafrost. How each component of the cryosphere is changing and its sensitivity to climate change is assessed, as is the impact of climate change on the cryosphere by about 2050. How these changes in the cryosphere might affect other physical and human systems is also described. Critical information we need to know is identified in the final section.

Although the cryosphere forms an integral part of the climate system, the ways in which it generates important feedbacks into the climate system are not discussed because this information is contained in the Working Group I volume. Similarly, the interaction of ice sheets and sea-level change are considered in detail in the Working Group I volume (see Chapter 7, *Changes in Sea Level*). A summary of ice sheets and climate change is offered here in Box 7-1.

7.2. Is the Cryosphere Changing?

7.2.1. Snow

Snow tends to be a very transient part of the Earth's surface, often lasting for only a few days or months. Monitoring of global seasonal snow is practical only with satellite remote sensing, so there are no reliable records prior to 1971. Records since then show considerable variability in the Northern Hemisphere continental snow cover from year to year (Figure 7-1), which makes long-term trends difficult to detect. The extent of snow has been less since 1987 (Robinson *et al.*, 1993), with the largest negative snow anomalies occurring in spring. Recent analysis of directly measured snow cover over the North American Great Plains (Brown *et al.*, 1994) reveals

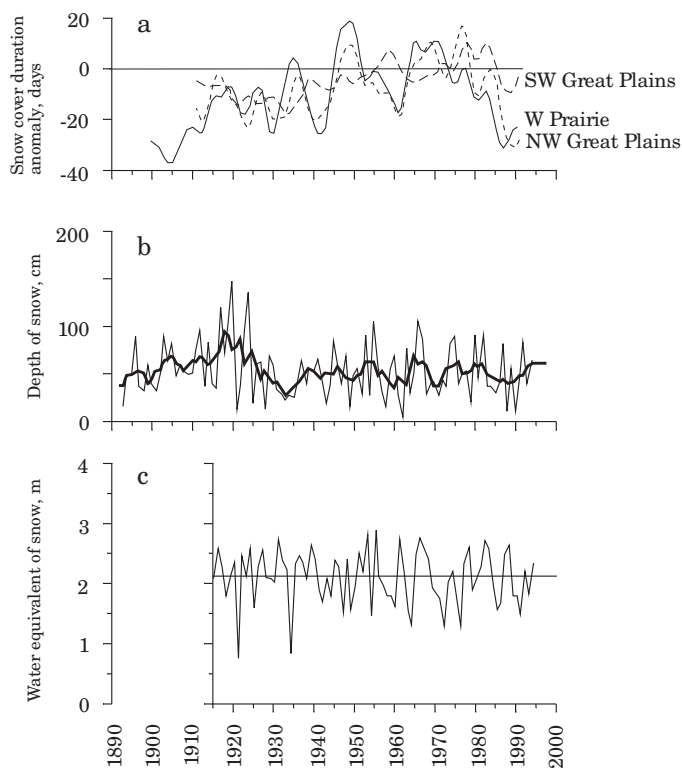
Figure 7-1: Seasonal snow cover anomalies in the Northern Hemisphere for 1971–1994 (after Robinson *et al.*, 1993). Each vertical line represents a season, with the dark line a 12-month running mean.


Figure 7-2: Historical variability of snow for three different settings: (a) Snow-cover duration anomalies over the continental interior of North America (after Brown *et al*., 1994); (b) depth of seasonal snow at an alpine area at Davos, elevation 1560 m, in Switzerland, as measured every 1 January 1893–1994 (updated from Foehn, 1990); and (c) water equivalent of snow near the equilibrium line of a glacier at Claridenfirn, elevation 2700 m, in Switzerland, as measured every spring 1914–1993 (updated from Müller and Kaeppenburger, 1991).

an increase over the past century (Figure 7-2a) but a decline over the Canadian Prairies.

The longest alpine snow-cover time series come from the European Alps. Recently, there has been a trend to lower snow depths in early winter but delayed ablation in spring; however, the century-long record for Davos (Figure 7-2b) shows no obvious trend in snow depth but large interannual variability (Foehn, 1990). This lack of any trend is reinforced by Figure 7-2c, which shows snow water equivalent near the glacier equilibrium line at Claridenfirn (Müller and Kaeppenberger, 1991). Elsewhere, a remarkable decrease in accumulated and maximum snow depth is reported since the 1987–88 winter over a wide area of western Japan. Here, snowfall normally is heavy and is affected by the winter monsoon (Morinaga and Yasunari, 1993).

Few observations assess long-term trends in the structure of snow. In the European Alps, it is summarized by ram (ramsonde) profiles, which are catagorized into six main types. Each type has a certain potential for snow avalanche formation and is linked to a specific winter climate. Over the last 50 years in Switzerland there has been no trend in ram profiles. A few long-term records of avalanche occurrence have been assembled,

notably from Iceland (Bjornson, 1980), Europe (Fitzharris and Bakkehoi, 1986), western Canada (Fitzharris and Schaerer, 1980), and the United States (Armstrong, 1978). They demonstrate that although avalanches reach catastrophic proportions in a few winters, there are no clear temporal trends or regular periodicities.

7.2.2. *Ice Caps and Glaciers*

Internationally coordinated, long-term monitoring of glaciers started in 1894 and today involves collection and publication of standardized information on the distribution and variability of glaciers over space (glacier inventories) and time (glacier fluctuations: mass balance, length change). Information on special events (instabilities, catastrophic changes) also is available (UNEP, 1993). The results of long observational series on fluctuations of mountain glaciers represent convincing evidence of past climatic change on a global scale [e.g., IAHS(ICSI)/UNEP/UNESCO, 1988, 1989, 1993, 1994].

Mass loss and retreat of glaciers is common in many mountain areas of the world. Oerlemans (1994) looks at glacial retreat on a global level, using a scaling system to classify different glaciers. He concludes that during the period 1884–1978, mean global glacial retreat corresponded to a calculated warming of $0.66 \pm 0.10°C$ per century. Chapter 7, *Changes in Sea Level*, of the Working Group I volume suggests that glaciers have lost sufficient ice over the last 100 years to raise sea level by 0.2–0.4 mm/yr. Recent analyses by Oerlemans and Fortuin (1992), Meier (1993), and Dyurgerov (1994) all show negative global ice-mass balances during this century. Although the glacial signal appears homogeneous at the global scale, there is great variability at local and regional scales and over shorter time periods of years to decades (Letréguilly and Reynaud, 1989).

Since the end of the Little Ice Age, the glaciers of the European Alps have lost about 30 to 40% of their surface area and about 50% of their ice volume. On average, this rate of icemelt is roughly one order of magnitude higher than the overall mean calculated for the end of the last glaciation and is broadly consistent with anthropogenic greenhouse forcing of 2–3 W/m². The recent discovery of a stone-age man from cold ice/permafrost on a high-altitude ridge of the Oetztal Alps confirms the results of earlier moraine investigations: The extent of Alpine ice probably is more reduced today than at any time during the past 5,000 years. Glacier wastage in the European Alps appears to be accelerating (Haeberli, 1994).

In the circum-Arctic, there is a consistent tendency for negative mass balances over the past 30 years. Mass balances of two Canadian ice caps are slightly negative (Koerner and Brugman, 1991), but these are so cold that the main signal is likely to be in the change of firn temperatures. The general picture from West Greenland is that of a strong retreat through this century, with a trim line zone around many glacier lobes. For the North Greenland mountain glaciers and ice caps, the situation is less clear, but the general impression is that changes are small. East

Greenland mountain glaciers seem to have behaved as the West Greenland ones, but surging advances occur frequently in certain regions (Weidick, 1991a-d). The longest glacier record for northern Sweden shows a preponderance of negative mass-balance years since 1946 (Letréguilly and Reynaud, 1989). In Spitsbergen, several glaciers have been losing mass (Hagen and Liestol, 1990), although the extent of glaciers probably was less about 5,000 years ago (Fujii *et al.,* 1990).

In Asia, the area of glaciers in Kazakhstan reduced by 14%, their number diminished by 15%, and the general volume of ice reduced by 11% between 1955 and 1979 (Glazyrin *et al.*, 1986, 1990; Dikikh and Dikikh, 1990; Kotlyakov *et al.,* 1991; Popovnin, 1987). Fluctuations of 224 glaciers in Central Asia from the 1950s to the 1980s can be summarized as retreating (73%), advancing (15%), and stable (12%) (Shi and Ren, 1988, 1990).

The general picture of ice retreat continues for mountains in the tropics. It began around the middle of the 19th century in the Ecuadorian Andes and in New Guinea but only after 1880 in East Africa (Hastenrath, 1994). Schubert (1992) documents fast, ongoing glacier shrinkage in Venezuela, as do Hastenrath and Ames (1995) for the Yanamarey glacier in the Cordillera Blanca of Peru.

The Southern Hemisphere record is not as detailed as that for the Northern Hemisphere. In New Zealand, Ruddell (1990) shows that most glaciers have retreated during the 20th century, some by three kilometers or more. The surface of the Tasman Glacier has thinned by more than 100 m. This widespread recession has reversed for western glaciers since about 1983. In South America, the Upsala glacier has retreated about 60 m/yr over the last 60 years, and this rate seems to be accelerating (Malagnino and Strelin, 1992). The area of the South Patagonian Ice Field has diminished by about 500 km² from 13,500 km² in 41 years. Surface lowering also has been considerable—more than 100 m at ablation areas of some glaciers (Aniya *et al.,* 1992). The Soler Glacier thinned at a rate of 5.2 m/yr from 1983 to 1985 (Aniya *et al.,* 1992), and the surface of Tyndall Glacier (one of the southernmost outlet glaciers) lowered by 20 m between 1985 and 1990 (a rate of 4.0 m/yr), according to Kadota *et al*. (1992). A few glaciers are advancing: The Pio XI glacier in Patagonia is larger now than it has been at any time in the past 6,000 years (Warren, 1994).

Frontal positions of alpine glaciers of the Dry Valleys in Antarctica have fluctuated, with no apparent trends (Chinn, 1993). On sub-Antarctic Heard Island, in the Indian Ocean, there has been widespread retreat since 1947—with some small glaciers decreasing in area by as much as 65% (Allison and Keate, 1986).

7.2.3. *Permafrost*

Permafrost—ground material that remains below freezing—underlies continental areas in the tundra and some boreal lands

Contemporary climate

2°C warming

Permafrost

☐ None ☐ Discontinuous ■ Widespread ■ Contin uous
Figure 7-3: Distribution of Northern Hemisphere permafrost for (a) the present and (b) 2050 (based on Nelson and Outcalt, 1987; Anisimov and Nelson, 1995).

to considerable depths. It also is present under shallow polar seabeds, in ice-free areas in Antarctica, on some sub-Antarctic islands, and in many mountain ranges and high plateaus of the world (Cheng and Dramis, 1992; Harris and Giardino, 1994; King and Åkermann, 1994; Qiu, 1994). Figure 7-3a shows the contemporary distribution of permafrost in the Northern Hemisphere. Some is relict, having formed during colder glacial periods, but has survived due to the negative heat balance at the ground surface or the very long time it takes for deep permafrost to thaw. There also are many sedimentary structures that show that permafrost was once more extensive than today.

Long-term measurements in deep boreholes in Alaska (Harrison, 1991; Zhang and Osterkamp, 1993), Canada

(Taylor, 1991), and elsewhere (Koster *et al.,* 1994) demonstrate a distinct but spatially heterogeneous warming trend in low-land permafrost. In northern Alaska, Lachenbruch and Marshall (1986) have demonstrated a warming of the per-mafrost of 2–4°C over the last century. Temperatures along the coast have varied over a range of 4°C (Osterkamp, 1994). During the last two decades, permafrost in Russia and China also has warmed (Pavlov, 1994; Wang and French, 1994). Some discontinuous permafrost in the southern half of Alaska is currently thawing (Osterkamp, 1994).

First attempts are now being made to monitor the long-term evolution of high-mountain permafrost by aerial photogram-metry of permafrost creep, borehole measurements of per-mafrost deformation and temperature, data archiving from geo-physical surface soundings for later repetition, and qualitative analysis of infrared aerial photography (Francou and Reynaud, 1992; Haeberli *et al.,* 1993; Harris, 1990; Vonder Mühll and Schmid, 1993; Wagner, 1992).

7.2.4.   *River and Lake Ice*

Chronologies of river and lake ice formation and disappearance provide broad indicators of climate change over extensive low-land areas, in much the same way that glaciers provide indica-tors for mountains (Palecki and Barry, 1986; Reycraft and Skinner, 1993). River-ice data have been summarized for homogenous hydrologic regions of the former Soviet Union (FSU) over the period 1893–1985 and adjusted to account for any effects of water-resource development (Soldatova, 1992). Although there is appreciable interdecadal variability, there are significant long-term spatial patterns and temporal trends. Freeze-up on rivers such as the Danube, Dnieper, Don, Lower Volga, and rivers of the Black Sea region is now delayed by an average of two to three weeks compared with the early part of the record. Further east, a weaker trend to earlier freeze-up dates is observed for the Yenisey and Lena (Ginzburg *et al.,* 1992).

The same broad-scale pattern is evident for break-up dates (Soldatova, 1993). Break-up on major rivers such as the Upper Volga, Oka, Don, Upper Ob, and Irtysh has advanced by an average of 7–10 days during the last century. In some rivers, such as the Lower Don, the overall result is a reduction in the winter ice season by as much as a month. In Central and Eastern Siberia (e.g., Middle to Lower Yenisey and Upper Lena), some rivers exhibit later break-up dates and, hence, an overall expansion of the ice season. In northern Scandinavia, historical records as far back as 1693 indicate that break-up in the Tornelven river is occurring much earlier during the 20th century than in earlier times (Zachrisson, 1989).

Assel *et al.* (1995) analyze lake-ice freeze-up and break-up in North America using records from 1823–1994 at six sites throughout the Great Lakes. Freeze-up dates gradually become later and ice-loss dates gradually earlier from the beginning of the record to the 1890s but have remained relatively constant during the 20th century. Ice-loss dates at deeper-water environments

with mixing of offshore waters were earlier during the 1940s and 1970s but later during the 1960s. Global warming during the 1980s was marked by a trend toward earlier ice-loss dates. Other North American lake-ice chronologies are presented by Hanson *et al.* (1992) and Reycraft and Skinner (1993).

7.2.5.   *Sea Ice*

The most effective means of measuring sea-ice extent is through the use of satellite-borne passive microwave radiome-ters, but these data are available only from 1973 onward. They show no convincing evidence of trends in global sea-ice extent (Gloersen *et al.,* 1992; Parkinson and Cavalieri, 1989; Gloersen and Campbell, 1991). Studies of regional changes in both the Arctic and Antarctic indicate some trends (e.g., Mysak and Manak, 1989; Gloersen and Campbell, 1991; Parkinson, 1992), but longer data sets are needed because they are only of decadal length.

Knowledge of the regional variability of ice thickness comes almost entirely from upward sonar profiling by submarines (Wadhams, 1990a; Wadhams and Comiso, 1992), such as the large-scale maps of mean ice thickness in the Arctic shown in Figure 7-4 (based on Sanderson, 1988; Vinje, 1989; Wadhams, 1992). Variations in ice thickness are in accord with the pre-dictions of numerical models, which take account of ice dynamics and deformation, as well as ice thermodynamics. Measurements from a series of submarine transects near the North Pole show large interannual variability in ice draft over the period 1979–1990 (McLaren *et al.,* 1992). There is evi-dence of a decline in mean thickness in the late 1980s relative to the late 1970s (Wadhams, 1994). Etkin (1991) found that ice breakup correlated well with melting degree-days in some areas of Hudson Bay and James Bay (Canada), but in other areas of the bays it was more strongly influenced by ice advec-tion, freshwater inflow, and conditions within the air-water-ice boundary layer.

Winter pack ice around Antarctica has major climatic importance. The annual variation in sea-ice area is very large—from 3 x 10^6 km^2 in February to 19 x 10^6 km^2 in September (Gloersen *et al.,* 1992). No change in the thickness of Antarctic sea ice can be detected from the limited information available. The only sys-tematic data have been obtained by repetitive drilling in a region of first-year ice from the eastern Weddell-Enderby Basin. The modal ice thickness is 0.5–0.6 m, and maximum observed keel drafts are about 6 m. In the limited regions of the Antarctic where multiyear ice occurs, there is a preferred ice thickness of about 1.4 m (Wadhams and Crane, 1991; Lange and Eicken, 1991).

7.3.   **How Sensitive is the Cryosphere to Climate Change?**

7.3.1.   *Snow*

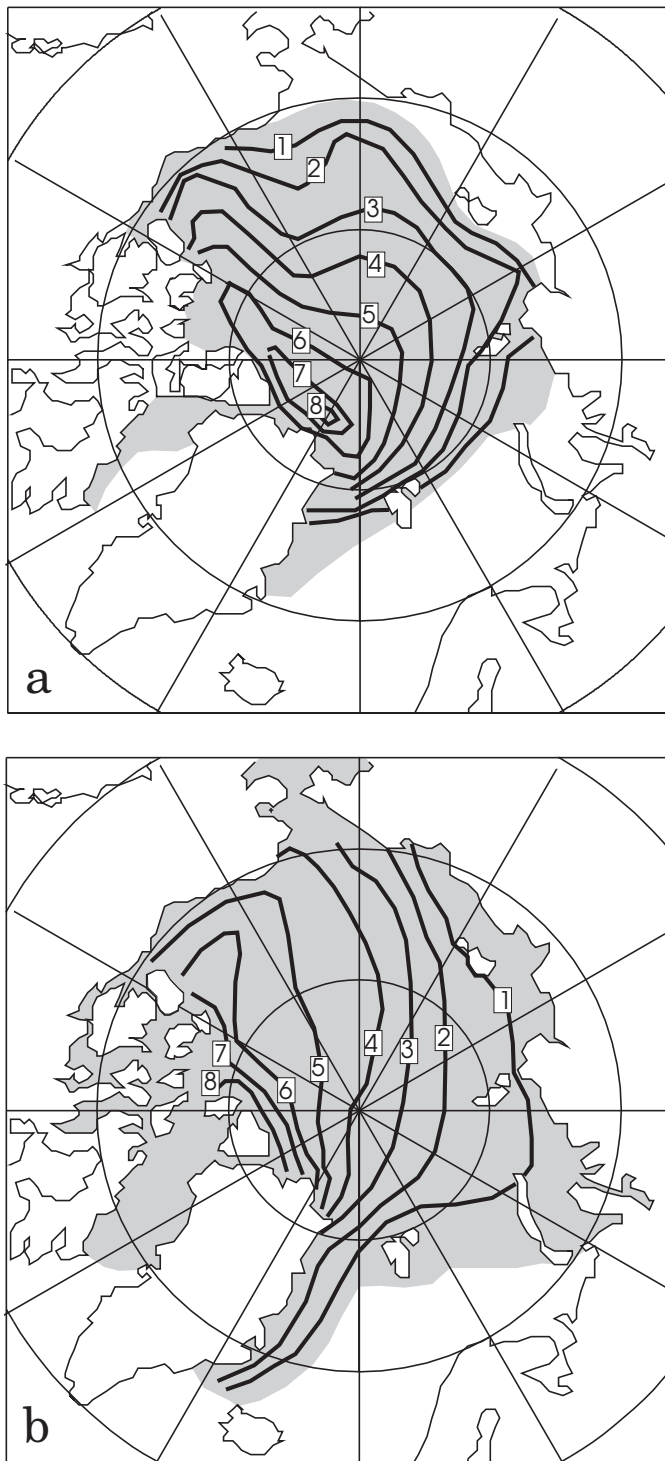
Snow cover in temperate regions is generally thin (a few meters to a few centimeters) and often close to its melting


Figure 7-4: Estimated mean thickness of Arctic Basin sea ice in meters for (a) summer and (b) winter (after Sanderson, 1988; Bourke and Garrett, 1987). The data do not include open water, thus overestimating mean ice draft.

point; consequently, both continental and alpine snow covers are very sensitive to climate change. Karl *et al*. (1993) found that a 1°C increase in the annual temperature of the Northern Hemisphere results in a 20% reduction in North American snow cover. Snow accumulation and melt models can estimate water stored as seasonal snow in alpine areas and can be used to examine its sensitivity to climate change. For the Southern Alps of New Zealand, Fitzharris and Garr (1995) found that water stored as seasonal snow declines as temperature increases and precipitation decreases but that the relationship is not linear. Seasonal snow is more sensitive to decreases in temperature than to increases. As precipitation increases, snow accumulation becomes less sensitive to temperature changes. The volume of water stored also depends on catchment hypsometry. In Australia, the duration of snow cover is found to be very sensitive to changes in temperature. Large increases in precipitation (50%) are necessary to offset even a 0.5°C warming (CSIRO, 1994).

Large, catastrophic avalanches are mostly the result of special weather situations lasting for 5 to 10 days. In the Swiss Alps, only nine weather types out of a possible twenty-nine have been responsible for past catastrophic avalanche cycles. These large avalanche episodes are thus sensitive to the frequency of particular weather types. Similar findings also come from Norway (Fitzharris and Bakkehoi, 1986) and Canada (Fitzharris, 1987).

7.3.2. Ice Caps and Glaciers

In the chain of processes linking climate and glacial fluctuations, mass balance is the direct, undelayed reaction; glacier length variation is the indirect, delayed response. Averaged for glaciers with comparable geometry and over time intervals of decades, changes in length provide an integrated and smoothed signal of climate change. At shorter time scales, glaciers will vary markedly with climate change, especially temperature. The nature of the response to warming will vary from glacier to glacier depending on accompanying precipitation change, the mass-balance gradient, and hypsometry.

Most glaciers of the world are more sensitive to changes in temperature than to any other climatic element. In the case of many Asian glaciers, where precipitation occurs mainly during the summer monsoon season, temperature has a double impact. The first impact is an increase in the absorption of solar radiation due to a lowering of the surface albedo as snowfall is converted to rainfall. The second effect is an increase in the energy exchange between the atmosphere and the glacier surface (Ageta and Kadota, 1992). Many maritime glaciers, which have large mass turnover, are more sensitive to changes in precipitation than to temperature. This complex dependence of glacier mass balance on temperature, precipitation, and radiation makes it difficult to define their sensitivity to climate change.

A number of approaches are used to express the sensitivity of glaciers to climate. Where there are long glacier records for calibration, regression equations are used to relate mass balance to summer mean temperature and annual (or winter) precipitation (Laumann and Tvede, 1989; Chen, 1991). Changes in summer ablation rates at the margins of Greenland glaciers are nearly linear with changes in summer temperature, with sensitivities ranging from 0.43–0.57 m/yr/°C (water equivalent; Braithwaite

and Olesen, 1990). Although these empirical relationships are valuable for regions in which they have been developed, they are not always applicable to other mountain areas with different climate and terrain. The sensitivity of glacier ablation has been assessed for number of melting degree-days (dd) for a range of glaciers by Braithwaite and Olesen (1989, 1990, 1993). Ablation sensitivity for ice varies from 5.5 to 7.6 mm/dd (Braithwaite and Oleson, 1989). Values for snow range from 1.0 to 5.7 mm/dd (Johannesson *et al.*, 1993). Hydrometeorological models are similar but include precipitation as well as temperature; they also usually estimate the mass balance (e.g., Woo and Fitzharris, 1992) and sometimes the water balance (e.g., Tangborn, 1980). Energy-balance models also have been used to assess the sensitivity of glacier ablation to climate (Oerlemans, 1991; Oerlemans *et al.*, 1993); they are appealing because they are more physically based, but they require input parameters that are difficult to obtain.

Glaciers are sensitive to changes in atmospheric circulation patterns, but it is difficult to quantify the response. The behavior of the Franz Josef glacier in New Zealand this century can be qualitatively explained by changes in the westerlies and shifts in the subtropical high-pressure zone (Fitzharris *et al.*, 1992). A major advance since 1983 appears to be consistent with circulation changes induced by three large El Niño events. In the first half of the 20th century, warming accounted for most of the ice thinning observed on Mount Kenya. However, from 1963 to 1987, greater atmospheric humidity was instrumental in enhancing melt—perhaps a consequence of enhanced evaporation in the Indian Ocean and its subsequent advection over East Africa by the prevailing atmospheric circulation patterns (Hastenrath, 1992, 1994; Hastenrath and Kruss, 1992). In the Canadian High Arctic, mass-balance and ice-core melt studies show that when the circumpolar vortex shifts to the Asian side of the Arctic Ocean and the North American trough is replaced by a blocking ridge, high-arctic glaciers experience high melt (Alt, 1987).

7.3.3.   *Permafrost*

The direct influence of climate on permafrost includes the effects of air temperatures and solar radiation. Permafrost also is influenced indirectly by local factors, many of which also have a climate component. These include the thickness and duration of snow cover, the type of vegetation, the properties of the organic layer and soil, and the characteristics of running water (Harris and Corte, 1992; Schmitt, 1993). These factors interact in complex ways, making it difficult to asses the sensitivity of permafrost, and its response, to climate change (Koster, 1991, 1994; Koster and Nieuwenhuijzen, 1992; Koster *et al.*, 1994; Nelson and Anismov, 1993). However, climatic warming usually causes an increase in the thickness of the active layer via melting at the permafrost table (the active layer is the zone of annual freezing and thawing above permafrost). Surface disturbances appear in the first few years, but changes in temperature profiles within the permafrost may be delayed by decades to centuries. The response of permafrost is very

dependent on initial ground temperatures and the latent heat (Geo-engineering Ltd, 1995). Displacement of the permafrost base—the final response—takes years to millennia, depending on the depth, thickness, and conductivity of the Earth material. Discontinuous permafrost tends to be most sensitive to climate change because it is usually within one or two degrees of 0°C. Many surface processes that preserve permafrost also are affected by climate change.

Depending on initial conditions, even small changes in climatic regimes cause permafrost to thaw. Simulations performed by Riseborough and Smith (1993) suggest that the rate of thaw and ultimate disappearance of a relatively thin (4.5 m) permafrost profile is highly dependent on the interannual variability of temperature. The broad sensitivity of permafrost to climate change is documented in the former Soviet Union and China, where the permafrost distribution changed substantially during warmer periods of the Quaternary (Kondratjeva *et al.*, 1993; Qiu and Cheng, 1995). The southern limit of lowland permafrost moved at 60 km/°C (Cui and Xie, 1984). In the alpine permafrost of Tibet, the lower elevation changed by 160 m/°C (Cui, 1980). On the northern slope of the Himalayas, the sensitivity is about 80 m/°C (Xie, 1996).

7.3.4.   *River and Lake Ice*

Ginzburg *et al.* (1992) and Soldatova (1993) show that ice formation and break-up correlate with air temperature in the preceding autumn and spring months but not with winter temperatures. Spring warming is more important to the timing of break-up than the overall winter severity and peak ice thickness. Assessing ice chronology and seasonal temperature data from Scandinavia, Canada, and the FSU leads to an estimated sensitivity of both freeze-up and break-up of 5 days/°C. The sensitivity for the length of the ice season is about 10 days/°C.

Freeze-up and ice-loss dates for lakes correlate with autumn and winter air temperatures. Assel and Robertson (1995) show that the sensitivity of freeze-up dates for the Great Lakes is approximately 7 days/°C. For sixty-three smaller lakes in Finland, Palecki and Barry (1986) suggest 5.5 days/°C. Anderson *et al.* (1995) show that interannual variation in ice break-up for twenty U.S. lakes can be explained by ENSO.

7.3.5.   *Sea Ice*

The thickness of fast ice—which grows in fjords, bays, and inlets in the Arctic; along the open coast in shallow water; and in channels of restricted dimensions—is correlated to the number of degree-days of freezing since the beginning of winter. In pack ice, however, the relationship between ice extent or ice thickness and temperature is less clear. Chapman and Walsh (1993) report that there is a statistically significant decrease in Arctic sea-ice extent in winter correlated with atmospheric warming, but there are no trends in winter Arctic ice extent or in the Antarctic.

The sensitivity of oceanic sea-ice cover to climate change is not well-understood. From the data comparisons made so far by McLaren (1989), Wadhams (1989, 1990a), and McLaren *et al*. (1992), the following tentative conclusions can be drawn.

Ice reaching the Fram Strait via the Trans Polar Drift Stream along routes where it is not heavily influenced by a downstream land boundary shows great consistency in its mean thickness from season to season and from year to year, at latitudes from 84°30'N to 80°N and in the vicinity of 0° longitude. Ice upstream of the land boundary of Greenland shows great changes in mean ice draft due to anomalies in the balance between pressure-ridge formation through convergence and open-water formation through divergence. The overall extent of sea ice is largely determined by ice transport via currents and wind and is not necessarily directly related to *in situ* freezing and melting controlled by temperature (Allison, Brandt, and Warren, 1993; Allison and Worby, 1994). As yet, there is no conclusive evidence of systematic thermodynamic thinning of the sea-ice cover, as might be caused by global warming.

Ocean circulation systems—such as the Atlantic conveyor belt—are thought to be sensitive to changes in sea-ice export from the Arctic (Aagaard and Carmack, 1989). Salt flux from local ice production plays an important role in triggering narrow convective plumes in the central gyre region of the Greenland Sea in winter (Rudels, 1990). Here frazil and pancake ice production due to cold-air outbreaks from Greenland can yield high salt fluxes. There already is evidence that a reduction in ice production has produced an ocean response in the form of reduced volume and depth of convection (Schlosser *et al.,* 1991).

7.4.   What Will Be the Impact of Future Climate Change on the Cryosphere?

Outputs from three Transient General Circulation Models (GCMs) in Greco *et al*. (1994) were applied to the major cryospheric regions of the world in order to assess impacts for the decade about 2050. They predict that most regions of the cryosphere will warm by 0.5–2.5°C, but some will be wetter and others drier. The amount of warming is consistent among

---

Box 7-1. Ice Sheets

The great ice sheets of Antarctica and Greenland have changed little in extent during this century. Dynamic response times of ice sheets to climate change are on the order of thousands of years, so they are not necessarily in equilibrium with current climate. Observational evidence for Antarctic and Greenland ice sheets is insufficient to determine whether they are in balance or have decreased or increased in volume over the last 100 years (see Chapter 7, *Changes in Sea Level*, in the Working Group I volume). Zwally *et al*. (1989) note that the Greenland ice sheet surface elevation is increasing by 0.23 m/yr, but this issue of stability remains contentious (Douglas *et al.,* 1990; Jacobs, 1992). There is evidence for recent increases in snow accumulation in East Antarctica (Morgan *et al.,* 1991). On the other hand, Kameda *et al*. (1990) report that the thickness of this ice sheet has decreased by about 350 m during the last 2,000 years.

If Antarctica were to warm in the future, its mass balance would be positive (see Chapter 7, *Changes in Sea Level*, in the Working Group I volume). The rise in temperature would be insufficient to initiate melt but would increase snowfall. Concern has been expressed that the West Antarctic ice sheet may "surge." Working Group I projects that the probability of this occuring within the next century "may be relatively remote, but not zero." There is considerable doubt regarding the possible dynamic response of ice sheets.

The response of Greenland to warming is likely to be different. Both the melt rates at the margins and the accumulation rates in the interior should increase. The former rate is expected to dominate. Thus, the mass balance would become negative as temperatures rise. Several studies have examined precipitation variations over Greenland (e.g., Bromwich *et al*., 1993; Kapsner *et al*., 1995). The likely changes in atmospheric circulation and moisture flux (Calanca and Ohmura, 1994) must be determined before future snowfall can be predicted. Surface topography also plays an important role in determining regional accumulation on the Greenland ice sheet (Ohmura and Reeh, 1991).

Most sheets descend to sea level, where they produce icebergs as pieces break off and float away. These endanger shipping. In Greenland, most iceberg calving comes from a relatively small number of fast-moving tidewater glaciers (Reeh, 1989). Antarctic ice shelves are much larger and grow for periods of 20 to 100 years, regularly calving only relatively small icebergs before enormous pieces break off (Orheim, 1988). For example, giant icebergs have calved from the Filchner, Larsen, Ross, and Shackleton Ice Shelves in recent years. The northerly Wordie Ice Shelf may be systematically breaking up (Doake and Vaughan, 1991), and there have been large changes to the Larsen Ice Shelf culminating in recent large calving rates (Skvarca, 1993, 1994)—including the breakout of a vast iceberg in February 1995. Despite these findings, there is no clear consensus as to whether the frequency of icebergs, and their danger to shipping, will change with global warming.

the three GCMs in most, though not all, cryospheric regions, but predictions for precipitation are discordant among the three GCMs and must be considered less reliable. Assessments of impacts in this chapter generally are made using output from the UKTR model, mainly because of the better resolution of maps in Greco *et al*. (1994) over alpine and polar regions. See Box 7-1 for a discussion of the possible impacts of climate change brought about by the interaction of ice sheets and sea-level change.

7.4.1.   *Snow*

Continental snow cover will be diminished in extent, duration, and depth by the UKTR climate scenarios in Greco *et al*. (1994). Winter snowlines could move further north by 5–10° latitude. The snow season could be shortened by more than a month, depending on snow depth. In North America, climatic warming based on the Boer *et al*. (1992) scenario would cause a 40% decrease in snow-cover duration over the Canadian Prairies and a 70% decrease over the Great Plains (Brown *et al*., 1994). Using CCM1 model output for the whole Northern Hemisphere, the area of seasonal snow in February may diminish by 6–20%, with a mean decrease of 12 x 10^6 km^2 (Henderson-Sellers and Hansen, 1995).

Snowfall will begin later and snowmelt will be earlier than at present, so the snow-free season will be extended. The advance in melt time is likely to be less pronounced in the High Arctic, where the snow is so cold that it requires significant warming to produce consistent melt (more than 10°C at many locations). More frequent periods of open water for rivers, lakes, and seas will produce greater snowfall downwind. This will be important near Hudson Bay, the Great Lakes, the Barents Sea, and the Sea of Okhotsk. In the Antarctic, summer temperatures are so low that the present regime of little or no snowmelt will persist.

In alpine areas, the snow line could rise by 100–400 m, depending on precipitation. Higuchi (1991) shows that as warming occurs for many Asian mountains, there is a tendency for rainfall to occur at the expense of snowfall, although the extent of this shift depends on location. Less snow will accumulate at low elevations, but there may be more above the freezing level from any increased precipitation. Martinec *et al*. (1994) and Rango and Martinec (1994) have examined the behavior of a snowmelt-runoff model in various catchments for different climate scenarios. With a rise of 1°C, snow cover would be depleted in winter due to conversion of precipitation to rainfall and increased snowmelt. Five days into the melt season, snow depth would be depleted to the equivalent of 9 days under the present climate. It is estimated that for the New Zealand Alps, total water stored as snow would be reduced by 20% of present for a climate scenario that is 2°C warmer but 10% wetter than present (Garr and Fitzharris, 1994). Impacts of best- and worst-case scenarios on snow cover in the Victorian Alps (Australia) are presented in CSIRO (1994). Simulated average snow cover and the frequency of years with more than 60 days of cover decline at all sites. For the worst

case, snow-cover duration at even the highest sites (1,900 m) is halved by 2030 and is near zero by 2070.

7.4.2.   *Ice Caps and Glaciers*

Empirical and energy-balance models both indicate that a large fraction (about one-third to one-half) of presently existing mountain glacier mass could disappear with anticipated warming over the next 100 years (Kuhn, 1993; Oerlemans and Fortuin, 1992). By 2050, up to a quarter of mountain glacier mass could have melted. The scenarios of Greco *et al*. (1994) indicate that some mountain areas will experience an increase in precipitation. Because models demonstrate that increases in temperature usually dominate changes in precipitation, mass balances of glaciers will become negative rather than positive. Glaciers are likely to shrink even where mountains become wetter. An upward shift of the equilibrium line by some 200 to 300 m and annual ice thickness losses of 1 to 2 m are expected for temperate glaciers.

Many mountain chains will lose major parts of their glacier cover within decades. Haeberli and Hoelzle (1995), who have developed algorithms for analyzing glacier inventory data, show that glacier mass in the European Alps could be reduced to a few percent within decades if current warming continues. Nevertheless, the largest alpine glaciers—such as those found around the Gulf of Alaska and in Patagonia, Karakoram, Pamir, Tien Shan, and the Himalayas—should continue to exist into the 22nd century. At high altitudes and high latitudes, glaciers and ice caps may change little in size, but warming of cold firn areas will be pronounced. Their mass balance may be affected through enhanced ablation at low altitudes, while accumulation at higher zones could increase. As an analog, Miller and de Vernal (1992) report that some Arctic glaciers did not shrink during warmer parts of the Holocene but actually grew due to increased precipitation.

There will be pronounced alterations to glacier melt runoff as the climate changes. Glaciers will provide extra runoff as the ice disappears. In most mountain regions, this will happen for a few decades, then cease. For those with very large glaciers, the extra runoff may persist for a century or more and may provide a substantial increase to regional water resources. As the area of ice eventually diminishes, glacial runoff will wane. Tentative estimates have been made for Central Asia (Kotlyakov *et al*., 1991) based on mass balances from a small number of Tien Shan glaciers for the period 1959–1992. Extrapolation to the whole of Central Asia suggests glacier mass has decreased by 804 km^3 over that time, representing a 15% increase in glacial runoff. Projections to 2100 are presented in Table 7-2; these data assume that glacial runoff varies as a linear function of glacier area.

An alternative approach is based on calculations of ablation and equilibrium-line altitude, according to given climatic scenarios (Kotlyakov *et al*., 1991; Glazyrin *et al*., 1990; Dikikh and Dikikh, 1990). Ablation intensifies in Central Asia with

Table 7-2: *Present and possible future extent of glaciation and glacial runoff in Central Asia (after Kotlyakov et al., 1991).*

Component	Present	2100
Area of glaciers (km^2)	115,000	80,000
Decrease of glacier mass (km^3/yr)	25	18
Runoff due to precipitation (km^3/yr)	73	50
Glacial runoff (km^3/yr)	98	68

climate warming because conditions become even more continental. Annual mass balance decreases. These estimates give a high rate of glacier degradation and large alteration of runoff (Figure 7-5). By 2050, the volume of runoff from glaciers in Central Asia is projected to increase threefold.

7.4.3. Permafrost

Anisimov and Nelson (1995) have compiled global permafrost maps for the present day and for a 2050 scenario (see Figure 7-3b). The compilation uses a predictive climate-based permafrost model, in which permafrost is classified on the basis of "surface frost index" (Nelson and Anisimov, 1993) and which also considers the influence of snow cover on the soil thermal regime. Calculated contemporary boundaries, based on the Global Ecosystem Database (GED), show good agreement with Figure 7-3a. Table 7-3 provides the areal extent of permafrost distribution in the Northern Hemisphere for two climate scenarios (GED contemporary and 2050). A 16% shrinkage in total permafrost area is projected by 2050. Subsurface conditions may not be in equilirium with the surface area shown. Some may take hundreds of years to respond. The extent of permafrost zones in the Southern Hemisphere, which cover only approximately 0.5 x 10^6 km^2 in total, also is likely to decrease.
Figure 7-5: Changes in recent and future runoff from Tuyuksu glacier, Zailiyski Alatau, Central Asia (after Kotlyakov *et al.*, 1991). Values represent runoff due to ice loss, expressed as departures from long-term mean.

There will be poleward shift of discontinuous and continuous permafrost zones (Woo *et al.*, 1992; Nelson and Anisimov, 1993). These estimates only treat degradation of near-surface permafrost; more attention must be given to the role of latent heat associated with ablation of ground ice. Simulations conducted by Riseborough (1990) indicate that areas with abundant ground ice, such as western Siberia (Burns *et al.*, 1993), may retain substantial amounts of permafrost that are not in equilibrium with new temperature conditions imposed at the surface. The relict permafrost of the southern part of West Siberia, which may well date from the last glacial epoch, is a present-day example of resistance to changes of temperature in deep-seated, ice-rich permafrost (Kondratjeva *et al.*, 1993).

In areas where permafrost is discontinuous, long-term warming ultimately will lead to its thinning and general disappearance (Wright *et al.*, 1994). Long-term temperature measurements in discontinuous permafrost in Alaska indicate that an increase in surface temperature of 2°C would cause most of the permafrost south of the Yukon River and on the south side of the Seward Peninsula to thaw. In continuous permafrost, a warming of the permafrost, thickening of the active layer, and changes in thaw lake dynamics are likely. Initial degradation will be contemporaneous with the alteration of the climatic signal (Osterkamp, 1994; Kane *et al.*, 1991), but as the thaw plane penetrates more deeply, lag times will increase.

Xie (in press) estimates that the southern boundary of permafrost in northeast China could be at 48°N latitude by the year 2100, and the predominantly continuous permafrost zone may recede to 52°N—similar to that in the Climatic Optimum of the Holocene (Lu Guowei *et al.*, 1993). In Tibet, it is estimated that an air-temperature warming of 3°C would raise the permafrost limit to an elevation of 4,600 m. Continuous frozen ground would disappear, except in the northwestern part of the plateau and areas around the Fenghuo Shan, in the event of a 5°C rise in temperature (Xie, in press).

In the FSU and Europe, reconstructions of the permafrost zone in past warm and cold periods are used as palaeoanalogues (Velichko and Nechaev, 1992; Vanderberghe, 1993). The most significant change in the thermal regime will occur in the high

Table 7-3: *Calculated contemporary and future areas of permafrost in the Northern Hemisphere (10^6 km^2) (based on Nelson and Anisimov, 1993).*

Zone	Contemporary	2050	% Change
Continuous Permafrost	11.7	8.5	-27
Discontinuous Permafrost	5.6	5.0	-11
Sporadic Permafrost	8.1	7.9	-2
Total	**25.4**	**21.4**	**-16**

latitudes within the present-day zones of the tundra and boreal forest. With a rise in temperature of 1°C, the permafrost would be partially preserved to the east of the Pechora river. In the south of Yamal and Gydan, discontinuous permafrost would prevail. Continuous permafrost would be restricted to north of 70°N. It would remain to the east of the Yenisey at the same latitudes. The active layer of fine-grained soils could increase by 20–30 cm. With a temperature rise of 2°C, continuous permafrost would disappear in the north of Europe. From the Lower Ob to the Lower Hatanga, as well as in the Anadyr lowland, only island and discontinuous permafrost would survive. Continuous permafrost would exist only in the lowlands of the Taimyr Peninsula, Lena, lower Kolyma, and lower Indigirka basins. The stratum of seasonal thawing would increase by 40–50 cm. These changes will result in the activation of solifluction, thermokarst and thermoerosion processes, an increase in bogs, and alterations to large tracts of vegetation—which in turn will alter food sources for traditional tundra species within permafrost areas.

Other mathematical models assess permafrost dynamics during warming (MacInnes *et al.,* 1990; Burgess and Riseborough, 1990; Romanovsky, Maximova, and Seregina, 1991; Romanovsky, Garagula, and Seregina, 1991; Osterkamp and Gosink, 1991; Nixon and Taylor, 1994; Nixon *et al.,* 1995). Changes in permafrost temperatures and thaw depths under an increase in annual average air temperatures of 2 and 4°C are simulated by Vyalov *et al.* (1993). Results indicate that warming in the tundra will produce a slight increase in thawing depths, with no radical changes in permafrost conditions. Further south, more marked effects could occur—with a shift to discontinuous permafrost, formation of taliks, and degradation of ground ice. If warming is long-lasting, the permafrost line would recede northward by 500 km along 70°E longitude and by 1,200 km along 100°E longitude. Given an average thawing rate of 100 mm/yr, thawing of the upper 10 m would take a century. Lower limits of permafrost in mountain areas could rise by several hundred meters, although this is dependent on future snow depths (Hoelzle and Haeberli, 1995). Owing to the slow reaction of thermal conditions at depth, pronounced disequilibria are most likely to result over extended time periods and wide areas.

Ice-saturated permafrost forms an impervious layer to deep infiltration of water, maintaining high water tables and poorly aerated soils. Significant increases in active layer depth or loss of permafrost is expected to cause drying of upper soil layers in most regions, as well as enhanced decomposition of soil organic matter. Loss of a sizable portion of more than 50 Gt of carbon in Arctic soils and 450 Gt of carbon in soils of all tundra ecosystems could cause an appreciable positive feedback on the atmospheric rise of carbon dioxide. Marion and Oechel (1993) have examined Holocene rates of soil carbon change along a latitudinal transect across arctic Alaska and conclude that arctic areas will continue to act as a small sink for carbon.

Recent warming and drying apparently have shifted arctic ecosystems from carbon sequestration (as occurred during the Holocene and historical past) to carbon dioxide loss to the atmosphere (Oechel *et al.,* 1993). Estimates of present losses of carbon dioxide from arctic terrestrial ecosystems to the atmosphere range from 0.2 Gt of carbon (Oechel *et al.,* 1993) to much higher values in winter for the Russian Arctic (Zimov *et al.,* 1993; Kolchugina and Vinson, 1993). Malmer (1992) estimates that about 25% or less of the carbon may be released in the form of methane (CH_4). A climatic shift to warmer temperatures in the future would increase the release of CH_4 from deep peat deposits, particularly from tundra soils. It is expected that the release of CO_2 would increase, though not by more than 25% of its present level (Malmer, 1992). Wetter soils could lead to increased methane loss, and a drier tundra might become a sink for atmospheric methane (Christensen, 1991, 1993; Fukuda, 1994).

Large amounts of natural gas—mostly methane—are stored in the form of gas hydrates, although their distribution is not well-known. In the Canadian Arctic Islands and Beaufort-Mackenzie region, analysis of thermal and geophysical logs indicates that $2–4 \times 10^3$ Gt of methane is stored as hydrates. Decomposition is occurring presently beneath the shelves of the Arctic Ocean in response to the increase of surface temperatures accompanying the recent marine transgression. For the Beaufort Shelf, an estimated 10^5 m^3/km^2 may decompose over the next century (Judge and Majorowicz, 1992; Judge *et al.,* 1994).

There are very few data for the methane content of permafrost itself. Samples obtained near Fairbanks (Kvenvolden and Lorenson, 1993) and the Prudhoe Bay area (Moraes and Khalil, 1993; Rasmussen *et al.,* 1993) suggest substantial variability. Dallimore and Collett (1995) found high methane concentrations in ice-bonded sediments and gas releases suggest that pore-space hydrate may be found at depths as shallow as 119 m. This raises the possibility that gas hydrates could occur at much shallower depth and be more rapidly influenced by climate change than previously thought. Fukuda (1994) estimates methane emissions from melting ground ice in northern Siberia cover the range 2–10 Mt/yr.

7.4.4. *River and Lake Ice*

Under conditions of overall annual warming, the duration of river-ice cover would be reduced through a delay in the timing of freeze-up and an advancement of break-up (Gray and Prowse, 1993). For freeze-up, higher water and air temperatures in the autumn would combine to delay the time of first ice formation and eventual freeze-up. If there also is a reduction in the rate of autumn cooling, the interval between these two events also will increase. The frequency and magnitude of major frazil-ice growth periods could be reduced. This may alter the types of ice that constitute the freeze-up cover and has implications for hydrotechnical problems associated with particular ice forms.

Many rivers within temperate regions would tend to become ice-free or develop only intermittent or partial ice coverage. Ice

growth and thickness would be reduced. In colder regions, the present ice season could be shortened by up to a month by 2050. Warmer winters would cause more mid-winter break-ups as rapid snowmelt, initiated particularly by rain-on-snow events, becomes more common. Warmer spring air temperatures may affect break-up severity, but the results would be highly site-specific because break-up is the result of a complex balancing between downstream resistance (ice strength and thickness) and upstream forces (flood wave). Although thinner ice produced by a warmer winter would tend to promote a thermal break-up, this might be counteracted to some degree by the earlier timing of the event, reducing break-up severity (Prowse *et al.*, 1990).

Changes in the size of the spring flood wave depend on two climate-related factors: the rate of spring warming and the water equivalent of the accumulated winter snowpack. Whereas greater and more-rapid snowmelt runoff favors an increase in break-up severity, the reverse is true for smaller snowpacks and more protracted melt. The final effect on break-up also will depend on the potentially conflicting roles of ice strength and thickness.

For arctic lakes, the duration of ice cover would be shortened (Assel *et al.*, 1995). A longer open-water period, together with warmer summer conditions, would increase evaporative loss from lakes. Some patchy wetlands and shallow lakes owe their existence to a positive water balance and the presence of an impermeable permafrost substrate that inhibits deep percolation. Enhanced evaporation and ground thaw would cause some to disappear. Using a 20-year period of record, Schindler *et al*. (1990) found that climate warming increased the length of the ice-free season by 3 weeks, as well as having numerous indirect effects (see Chapter 10).

If the warming of the 1980s continues unabated over the next 10–20 years, ice cover on the Great Lakes of North America will likely be similar to or less than that during the 1983 ice season, which was one of the mildest winters of the past 200 years. Mid-lake ice cover did not form, and ice duration and thickness were less than normal (Assel *et al.*, 1985). Complete freezing will become increasingly infrequent for larger and deeper embayments in the Great Lakes. The duration of ice cover will decrease as freeze-up dates occur later and ice-loss dates occur earlier. Winters without freeze-up will begin to occur at small inland lakes in the region. Winter lake evaporation also may increase due to the decreased ice cover.

7.4.5. Sea Ice

GCM experiments with simplified treatments of sea-ice processes predict large reductions in sea-ice extent but produce widely varying results and do not portray extent and seasonal changes of sea ice for the current climate very well. Boer *et al*. (1992) estimate that with a doubling of greenhouse gases, sea ice would cover only about 50% of its present area. CCM1 model output presented in Henderson-Sellers and Hansen (1995) projects a 43% reduction for the Southern Hemisphere and a 33% reduction for the Northern Hemisphere. The global area of sea ice is projected to shrink by up to 17 x 10^6 km^2.

Using empirical ice growth-melt models, Wadhams (1990b) predicts that in the Northwest Passage and Northern Sea Route, a century of warming would lead to a decline in winter fast-ice thickness from 1.8–2.5 m at present to 1.4–1.8 m and an increase in the ice-free season of 41–100 days. This effect will be of great importance for the extension of the navigation season in the Russian Northern Sea Route and the Northwest Passage. A possible feedback with snow thickness may alter these relationships. As Arctic warming increases open-water area, precipitation may increase and cause thicker snow cover. The growth rate of land fast ice will decrease, as has been directly observed (Brown and Cote, 1992). But if snow thickness is increased to the point where not all ice is melted in summer, then the protection that it offers the ice surface from summer melt could lead to an increase, rather than decrease, in equilibrium ice thickness.

Predicting future thickness of moving pack ice is a difficult problem, because dynamics (ocean and wind currents), rather than thermodynamics (radiation and heat components), determine its area-averaged mean thickness. Wind stress acting on the ice surface causes the ice cover to open up to form leads. Later under a convergent stress, refrozen leads and thinner ice elements are crushed to form pressure ridges. Exchanges of heat, salt and momentum are all different from those that would occur in a fast ice cover. The effects of variable thickness are very important. The area-averaged growth rate of ice is dominated (especially in autumn and early winter when much lead and ridge creation take place) by the small fraction of the sea surface occupied by ice less than 1 m thick. In fast ice, climatic warming will increase sea-air heat transfer by reducing ice growth rates. However, over open leads a warming will decrease the sea-air heat transfer, so the area-averaged change in this quantity over moving ice (hence its feedback effect on climatic change itself) depends on the change in the rate of creation of new lead area. This is itself a function of a change in the ice dynamics, either driving forces (wind field) or response (ice rheology). Hibler (1989) pointed out a further factor relevant to coastal zones of the Arctic Ocean, such as off the Canadian Arctic Archipelago, where there is net convergence and the mean thickness is very high (7 m or more) due to ridging. Here the mean thickness is determined by mechanical factors, largely the strength of the ice, and is likely to be insensitive to global warming.

Ice dynamics also have other effects. In the Eurasian Basin of the Arctic the average surface ice drift pattern is a current (the Trans Polar Drift Stream) which transports ice across the Basin, out through Fram Strait, and south via the East Greenland Current into the Greenland and Iceland Seas, where it melts. The net result is a heat transfer from the upper ocean in sub-Arctic seas into the atmosphere above the Arctic Basin. A change in area-averaged freezing rate in the Basin would thus cause a change of similar sign to the magnitude of this long-range heat transport.

An identical argument applies to salt flux, which is positive into the upper ocean in ice growth areas and negative in melt areas. Salt is transported northward via the southward (Lemke *et al.,* 1990) ice drift. A relative increase in area-averaged melt would cause increased stabilization of the upper layer of polar surface water, and hence a reduction in heat flux by mixing across the pycnocline. A relative increase in freezing would cause destabilization and possible overturning and convection.

If ice were to retreat entirely from the central gyre region of the Greenland Sea, it may cause deep convection to cease. Already there is evidence from tracer studies (Schlosser *et al.,* 1991) of a marked reduction in the renewal of the deep waters of the Greenland Sea by convection during the last decade. It is not known whether this is part of a natural variation, or a response due to greenhouse warming. If continued, it could have a positive feedback effect on global warming, since the ability of the world ocean to sequestrate carbon dioxide through convection is reduced. Given the complexity of these interactions and feedbacks, it is not at all clear what the overall effect of an air temperature increase on the Arctic ice cover and upper ocean will be. Sensitivity studies using coupled ocean-ice-atmosphere models are required, but results are not yet available.

In the Antarctic, where the sea ice cover is divergent and where land boundaries are less important, it is more reasonable to suppose that the main effect of global warming will be a simple retreat of the ice edge southward. However, Martinson (1990) has demonstrated that even here, a complex set of feedback mechanisms comes into play when the air temperature changes. The balance of lead concentration, upper ocean structure and pycnocline depth adjusts itself to minimize the impact of changes, tending to preserve an ice cover even though it may be thinner and more diffuse.

7.5.   What Will Be the Impact of These Cryospheric Changes?

These changes in the cryosphere will affect many natural and managed ecosystems, as well as socioeconomic systems. Only the most notable are considered here. Two regions will be most affected: Temperate mountains and tundra lands (see Boxes 7-2 and 7-3, respectively).

7.5.1.   *Impact on Hydrology and Water Resources*

The impact of climate change on water resources in alpine areas can be large, as shown by Gleick (1987a, 1987b), Martinec and Rango (1989) and Moore (1992), and are discussed at length in Chapter 10. Seasonal changes can be

---

Box 7-2. Impact on Temperate Mountains

Revegetation of terrain following deglaciation is slow in high-mountain areas. This leaves morainic deposits unprotected against erosion for extended time periods (decades to centuries). There will be increased sediment loads in alpine rivers and accelerated sedimentation in lakes and artificial reservoirs at high altitude. On slopes steeper than about 25–30 degrees, stability problems, such as debris flows, will develop in freshly exposed or thawing non-consolidated sediments.

At places of pronounced glacier retreat, changes in stress distribution and surface temperature conditions in rock walls of deeply cut glacier troughs must also be anticipated, so that massive rock slides will occur in the deglaciated valley (Clague and Evans, 1992, 1994; Evans and Clague, 1993, 1994). Steep hanging glaciers which are partially or entirely frozen to their beds could become less stable. On the other hand, some steep glacier tongues with present-day potential for large ice avalanches will disappear. Lakes dammed by landslides, moraines and glaciers can drain suddenly and produce floods or debris flows orders of magnitude larger than normal stream flow. Processes related to ice retreat such as glacier avalanches, slope instability caused by debuttressing, and glacier floods from moraine or ice-dammed lakes may pose hazards to people, transport routes, and economic infrastrucure in mountain areas. The general tendency in high mountains will be an upslope shifting of hazard zones and widespread reduction in stability of formerly glaciated or perennially frozen slopes (Barsch, 1993; Haeberli, 1992; Gu *et al.,* 1993; Dutto and Mortara, 1992).

Shrinkage of permafrost and snow cover will eliminate snow metamorphism, and avalanche formation in high mountain regions and adjacent lowlands (Keller and Gubler, 1993; Tenthorey, 1992). An increased frequency of catastrophic snow avalanches may occur if sudden cold spells and a mixture of cold and warm air masses are more common in late winter, or if periods of rapid warming are accompanied by heavy rain follow periods of intensive snowfalls. There is insufficient evidence to indicate whether the frequency of such events will change. Avalanches are expected to be less of a hazard than at present.

The empirical basis for assessing alpine hazard probabilities comes from historical documents, statistics of measured time series or traces in nature of past events with long recurrence intervals. A future problem is that these will lose more and more of their significance as climate changes. This is because floods, avalanches, debris flows, and rock falls could have different magnitudes and frequencies than in the present climate, as the condition of the cryosphere in high mountain areas evolves beyond the range of Holocene and historical variability.

Box 7-3. Impact on Tundra Lands

A critical factor influencing the response of tundra to warming depends on the presence of ground ice. Ground ice is generally concentrated in the upper 10 meters of permafrost, the very layers that will thaw first as permafrost degrades. This loss is effectively irreversible, because once the ground ice melts, it cannot be replaced for millenia, even if the climate were to subsequently cool. Response of the permafrost landscape to warming will be profound, but will vary greatly at the local scale, depending on detail of ground ice content. As substantial ice in permafrost is melted, there will be land subsidence. This process of thermokarst erosion will create many ponds and lakes and lead to coastal retreat.

A forerunner of future landscapes can be seen in areas of massive ground ice, such as in Russia, where past climatic warming has altered the landscape by producing extensive flat-bottomed valleys. Ponds within an area of thermokarst topography eventually grow into thaw lakes. These continue to enlarge for decades to centuries, due to wave action and continued thermal erosion of the banks. Liquefaction of the thawed layer will result in mudflows on slopes in terrain that is poorly drained or that contains ice-rich permafrost. On steeper slopes there will also be landslides (Lewkowicz, 1992). Winter discharge of groundwater often leads to ice formation, and this is expected to increase on hillslopes and in the stream channels of the tundra.

Changes in landscape, sea-ice distribution, and river and lake ice could have a major impact on indigenous people who live in Arctic regions and depend upon traditional occupations, food gathering, and hunting (Kassi, 1993; Roots, 1993; Wall, 1993). These include the Inuit of North America and Greenland and the various reindeer herding groups of Eurasia. They depend directly on the living resources of the area and often travel on ice, so their livelihood may be widely affected. Ice roads and crossings are commonly used to link northern settlements. The greatest economic impact is likely to stem from decreases in ice thickness and bearing capacity, which could severely restrict the size and load limit of vehicular traffic (Lonergan *et al.,* 1993). There is likely to be a change in the migration patterns of polar bears and caribou, along with other biological impacts.

There will be considerable impacts of climate change on resource management in the tundra (Wall, 1993). Some infrastructure and mining activities and structures will be threatened by thawing of permafrost. Water resources will change in that the seasonality of river flows will be different. Environmental changes are expected to be greater than for many other places on Earth (Roots, 1993).

marked when the cryosphere is involved in river flow. In their snowmelt runoff simulations, Martinec *et al.* (1994) report that for a 4°C rise in temperature of the Rio Grande basin in the USA, winter runoff increases from 14% of the total annual flow at present to 30%. Summer runoff decreases from 86% of annual flow to 70%. Such changes in snow runoff can affect irrigation water and electricity supply.

Less snow and glacier ice will influence the seasonality of river flow by reducing meltwater production in the warm season. The expected smoothing of the annual runoff amplitude could be both beneficial (e.g., energy production in winter, reduction of summer flood peaks) and adverse (e.g., reduced water supply for summer irrigation in dry areas, more frequent winter floods). As mountain glaciers begin to disappear, then eventually the volume of summer runoff will be reduced due to the loss of ice resources. Consequences for downstream agriculture, which relies on this water for irrigation, are in some places very unfavourable. For example, low and midland parts of Central Asia are likely to gradually change into a more arid, interior desert.

As climatic warming occurs, there will be notable changes in the hydrology of Arctic areas (Woo, 1990). The nival regime runoff pattern will weaken for many rivers in the permafrost region, and the pluvial influence upon runoff will intensify for rivers along the southern margin of the Arctic, regions of Eurasia, and North America. Should climatic change continue, the vegetation will likely be different from today. When the lichens and mosses, that tend to be suppressors of evapotranspiration, are replaced by transpiring plants, evaporative losses will increase. Enhanced evaporation will lower the water table, followed by changes in the peat characteristics as the extensive wetland surfaces become drier (Woo, 1992).

In permafrost regions, increased thawing deepens the active layer, allowing greater infiltration and water storage, especially for rain that falls during the thawed period. Warming of the ground will also lead to the formation of unfrozen zones within the permafrost which provide conduits for groundwater flow. The chemical composition and the amount of groundwater discharge may be changed as sub-permafrost or intra-permafrost water is connected to the surface. In autumn and winter, more groundwater should be available to maintain baseflow, further extending the streamflow season.

Structures such as pipelines, airstrips, community water supply and sewage systems, and building foundations are susceptible to performance problems if existing, frozen foundations or subgrades thaw, even minimally. Special measures

would be needed to ensure the structural stability and dura-bility of installations for tourism, mining industry, and telecommunication in permafrost areas affected by climate warming (Anyia *et al.,* 1992; Haeberli, 1992; Vyalov *et al.,* 1993). Transport links could also be affected. For example, the permafrost zone in China contains more than 3,000 km of railway and over 13,000 km of highway. Thawing induced by climate warming will result in serious disruption and increased maintenance costs from ground subsidence, side-slope slumpings, landslides, icings and ice mound growth (Yang, 1985). On the other hand, many northern cities will spend less money on snow and ice clearance. Engineering design criteria will need to be modified to reflect changing snow and frost climates, deepening of the active layer over permafrost, and warming and ultimate disappearance of mar-ginal or discontinuous permafrost. Present permafrost engi-neering commonly designs for the warmest year in the past 20 years of record (Esch, 1993). Such criteria may need to be reviewed and revised.

Where climate change alters the river-ice regime, substantial effects on the hydrology can be expected that will affect flow, water levels, and storage. For cold continental rivers, many hydrologic extremes, such as low flows and floods, are fre-quently more a function of ice effects than landscape runoff. At freeze-up, the hydraulic resistance of an accumulating cover can induce sufficiently large hydraulic storage that the river flow falls below that normally expected (Gerard, 1990; Gray and Prowse, 1993). Projected climates will delay the timing of freeze-up and so prolong the autumn low flow period. At break-up, the rapid hydraulic storage and release of water by river-ice jams often forms the most significant hydrologic event of the year. Break-up flood levels typically exceed those that develop during the open-water period, even though actual discharge of water is lower. The impact of climatic warming will be to advance the timing of break, but its effect on break-up flooding is not clear.

Of all river-ice processes, ice-jams are the major source of eco-nomic damages, averaging approximately $CDN20–30 million per year in Canada alone (Van Der Vinne *et al.,* 1991). Changes in damages from such events depend on how climate change affects the frequency and severity of river-ice freeze-up and break-up events. Less river ice and a shorter ice season in northward flowing rivers of Canada, Russia and Siberia should enhance north-south river transport. When combined with less sea ice in the Arctic, new opportunites for reorganization of transport networks and trade links will arise. Ultimately those changes could affect trading patterns among Russia, USA, Canada, northern Europe, and Japan.

7.5.2. *Impact on the Hydroelectric Industry*

Altered future climates could have a significant impact on the seasonal distribution of snow storage, runoff into hydro-electric catchments, and aggregated electricity consumption. Garr and Fitzharris (1994) show that in New Zealand the winter

(Austral) gap between electricity consumption and generation is reduced for a climate scenario that might be expected about 2050 (Figure 7-6). The electricity system is made less vulnera-ble to climate variability. Water supply is increased, but demand, which is largely driven by domestic heating, is reduced. There would be less need for new hydro plants and water storage. On the whole, these amount to net benefits. In countries where heating is supplied by natural gas, these changes will be less obvious. Instead the demand may well increase in the summer due to greater use of air conditioners due to a higher frequency of very hot days.

River ice creates a host of hydrotechnical difficulties for the operation of hydropower facilities, ranging from the blockage of trash racks by frazil ice to the curtailment of operations so as to avoid freeze-up flooding. One Canadian hydropower company estimates revenue losses of over $CDN1 million/year associated with the release of sufficient flow to avoid the downstream freeze-off of a major tributary (Foulds, 1988). Major economic savings are likely if the length of the ice sea-son is reduced by climatic warming. Operational problems dur-ing the ice covered period will remain, and could even increase because some rivers may experience a higher frequency of winter break-ups.

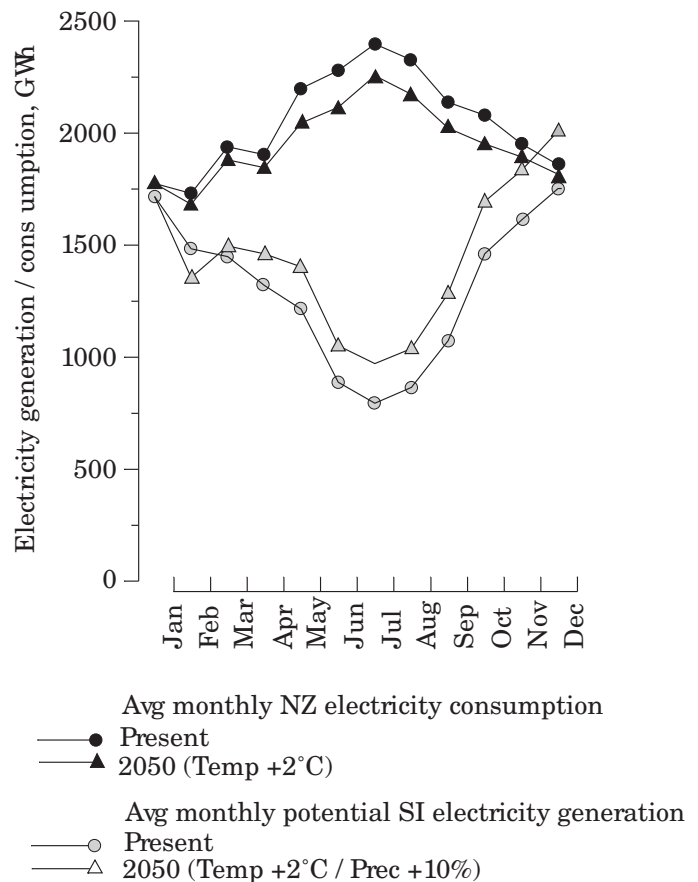

Figure 7-6: Synthesis of hydroelectricity generation and total con-sumption of electricity for New Zealand: The present compared with 2050 (after Garr and Fitzharris, 1994).

7.5.3. Impact on Shipping

In Canada, absence of sea ice south of Labrador would eliminate Canadian Coast Guard ice breaking requirements. This means an annual saving of between $CDN15–20 million. Even larger savings can also be expected in the FSU. The substantial reductions in sea ice in the Arctic Ocean that are expected to occur with climatic warming will increase opportunities for shipping there and open up new trade routes. The effect of annual warming on ice calving, simulated using a simple degree day model (Brown, 1993) shows that for every 1°C of warming there would be a 1° latitude retreat of the iceberg occurrence in the Atlantic Ocean. In the Southern Ocean, any effects of reduced sea ice will be economically less pronounced.

Ice-breakers keep river channels open for ship traffic within Russia on the major northern rivers, and to a limited degree in North America within the Great Lakes system. Considering the high operational costs of ice-breaking, any reduction in the ice season should translate into significant cost-savings. With warming there will be a longer shipping season, allowing increased passage of goods and services and longer time and larger area open for commercial fishing (Reycraft and Skinner, 1993). Changes in fresh colder water in the North Atlantic may change the distribution of fisheries.

7.5.4. Impact on the Oil Industry

Projected climatic warming could extend summer open water in the Beaufort Sea an additional 200–800 km offshore (McGillivray *et al.*, 1993). The fetch, and frequency of extreme wave heights, will therefore increase. It is estimated that the frequency of 6m waves would rise from 16% to 39% of the time (McGillivray *et al.*, 1993). Present design requirements for long-lived coastal and offshore structures, such as oil installations, will be inadequate under these conditions.

A possible beneficial effect would be shorter winters disrupting construction, exploration, and drilling programs. A decrease in thickness of first-year ice of 50–70% is projected for the Arctic, which will extend the drilling seasons for floating vessels considerably. Costs of drilling "downtime" on offshore oil and gas drilling explorations could practically be eliminated due to iceberg and sea-ice absence, saving more than $CDN40 million annually (Stokoe, 1988).

7.5.5. Impact on the Tourist Industry

Many mountainous regions of the world are used for tourism. A prerequisite for such commercially important activities as skiing is an extended snow cover of sufficient depth. Despite increases in precipitation, warming will decrease the cover, depth, and quality of snow and impair winter tourism in most alpine countries. Subsequent socioeconomic consequences could be detrimental for many mountain communities (Foehn, 1990). In the United States, Cline (1992) estimates ski industry

losses from projected warming at $1.7 billion annually. In some countries, ski resorts could be re-established at higher elevations, but this too has associated transportation and emission problems. In others, such as Australia, the ski industry could, under the worst case scenario, be eliminated. Less snow and fewer glaciers on mountains will also diminish the quality of many alpine vistas, where their scenic appeal depends upon their presence in the general landscape. Some countries are still sufficiently high that their mountains will retain snow, so will possess an increasingly scarce, but valuable, scenic and recreational resource.

Reduced sea ice will provide safer approaches for tourist ships and new opportunities for sightseeing around Antarctica and the Arctic.

7.6. What Do We Still Need to Know?

There are many uncertainties in understanding what is currently happening to critical components of the cryosphere, especially ice sheets, sea ice, and permafrost, mainly because existing monitoring systems are inadequate. Critical questions remain about how each component of the cryosphere will react to climate change and a multitude of proposals could be made. The most important are synthesized as follows:

- Climatic scenarios produced by GCMs need to be refined so as to provide more detail for mountain and polar regions. Their output for regions of the globe where snow, ice, and permafrost are dominant needs to be better verified for the present climate. Imprecise estimates of future polar and alpine precipitation, and particularly snow depth, are a major constraint in predicting the behavior of most components of the cryosphere and their impact.

- Research should focus on processes that are driven by interactions between the atmosphere and the cryosphere. Improving understanding of these processes would allow the construction of more sophisticated and realistic climate sensitivity models.

- Monitoring of key components of the cryosphere must continue. The mass balance of the ice sheets of the world is poorly known. Databases need to be further developed and maintained. They provide the benchmark for assessing future change and for model testing. More statistical work is required on existing databases to improve knowledge of cryospheric trends.

- Effects of cryospheric change on other natural systems need to be better understood and quantified, particularly where they affect human communities and economic systems of agriculture, forestry, tourism, transport, and engineered structures. Future response of Arctic sea ice is especially critical because large changes will have profound climatic, economic, trade, and strategic implications.

- New methods are needed to assess probabilities of natural hazard and risk that take into account changing

climate. For hazard mitigation measures in mountain environments of developing countries, transfer of technologies for preparing the necessary assessments would be helpful.

CONTENTS

EXECUTIVE SUMMARY

Global warming as projected by Working Group I of the IPCC will have an effect on sea-surface temperature (SST) and sea level. As a consequence, it is likely that ice cover and oceanic circulation will be affected, and the wave climate will change. The expected changes affect global biogeochemical cycles, as well as ecosystem structure and functions, on a wide variety of time and space scales; however, there is uncertainty as to whether extreme events will change in intensity and frequency. We have a high level of confidence that:

- Redistribution of SST could cause geographical shifts in biota as well as changes in biodiversity, and in polar regions the extinction of some species and proliferation of others. A rise in mean SST in high latitudes should increase the duration of the growing period and the productivity of these regions if light and nutrient conditions remain constant.
- Sea-level changes will occur from thermal expansion and melting of ice, with regional variations due to dynamic effects resulting from wind and atmospheric pressure patterns, regional ocean density differences, and oceanic circulation.
- Changes in the magnitude and temporal pattern of pollutant loading in the coastal ocean will occur as a result of changes in precipitation and runoff.

We can say with a lesser degree of confidence that:

- Changes in circulation and vertical mixing will influence nutrient availability and primary productivity, thereby affecting the efficiency of carbon dioxide uptake by the oceans.
- The oceans' uptake and storage capacity for greenhouse gases will be affected further by changes in nutrient availability in the ocean resulting from other changes in precipitation, runoff, and atmospheric deposition.
- Freshwater influx from the movements and melting of sea ice or ice sheets may lead to a weakening of the global thermohaline circulation, causing unpredictable instabilities in the climate system.

It is presently uncertain whether the frequency and severity of tropical cyclones will increase due to climate change.

The most pervasive effects of global climate change on human uses of the oceans will be due to impacts on biotic resources; transportation and nonliving resource exploitation will be affected to a lesser degree. We can say with a high level of confidence that:

- Increased coral bleaching will occur as a result of a predicted 2°C increase in average global atmospheric temperature by 2050.

- Expanded dredging operations will be necessary to keep major ports open in the Northern Hemisphere, which will increase costs.
- The Northwest Passage and Northern Sea Route of Russia likely will be opened up for routine shipping.
- Growth in the marine instrumentation industry will occur as the need for research and monitoring of climate change increases.

We can say with a lesser degree of confidence that:

- Reduced yields of desirable fish species will occur if average primary productivity decreases.
- If the frequency of tropical storms and hurricanes increases, adverse impacts will be generated for offshore oil and gas activities and for marine transportation in the tropics.
- Marine mineral extraction, except for petroleum hydrocarbons and the marine pharmaceutical and biotechnological industries, is insensitive to global climate change.

Adaptation to the impact of climate change on oceans is limited by the nature of these changes, and the scale at which they are likely to occur:

- No adaptive responses to coral bleaching, even on a regional scale, will be available if average global temperature increases 2°C by 2050. However, reductions in land-based pollution of the marine environment, combined with reductions in habitat degradation/destruction, would produce benefits for fisheries, aquaculture, recreation, and tourism.
- Adaptation options will be available for the offshore oil, gas, and shipping industries if the frequency of tropical storms and hurricanes increases. The options include improved design standards for offshore structures, national and international regulations for shipping, and increased technological capabilities to provide early warning at sea. Governments also can increase attention to institutional design for planning and responding to disasters and acute emergencies.
- Where climate change generates positive effects, market-driven needs will create their own adaptation dynamic. However, adaptation policies will be required to control externalities that are market failures. For instance, opening up both the Northwest Passage and the Russian Northern Sea Route for up to 100 days a year—while a boon to international shipping and consumers in East Asia, North America, and Western Europe—will have to be accompanied by policies designed to limit the total burden of pollutants entering the Arctic environment from ports, ship operations, and accidents.

8.1. Introduction

In this chapter, we attempt to assess the impacts of projected regional and global climate changes on the oceans. Climate change will affect the physical, biological, and biogeochemical characteristics of the oceans at different time and space scales, which should modify their ecological structure and functions and is expected to exert significant feedback controls on the climate system. These changes will be in addition to human activities such as land-use changes, industrialization and urbanization, increased food production, habitat modification, transportation of exotic organisms, and releases of pollutants. The present trends of increasing pollution, development, and overuse are reducing the capacity of coastal oceans and semi-enclosed seas to respond to and compensate for environmental changes that might be brought about by a climate change (GESAMP, 1990).

In providing this assessment, we address questions concerning the functions and characteristics of oceans in relation to their human uses, their responses to large-scale global climate change, the range of available mitigation and adaptation response options, and continuing research and monitoring needs.

8.2. Functions of Oceans

The oceans function as regulators of the Earth's climate and sustain planetary biogeochemical cycles. They also are of significant socioeconomic value as suppliers of resources and products, as sinks for wastes, as areas of recreation and tourism, as a medium for transportation, and as a repository of genetic and biological information. To gain a perspective of the oceans' importance, consider that the global ocean industry (all sectors) realizes about 4% of world gross national product (GNP)—approximately $20 trillion in 1988 (Broadus, 1991).

8.2.1. *Climate Regulator*

The oceans have significant capacity to store heat and are the largest reservoir of the two most important greenhouse gases—water vapor and carbon dioxide (CO_2). The long timescales of vertical circulation in the oceans result in slow turnover of stored heat and CO_2. The properties of oceans are affected by variability resulting from Sun-Earth orbital changes (e.g., seasonal and Milankovitch cycles); interactions among components of the climate system—for example, the atmosphere-cryosphere—modulate these variations and result in climatic variability on other timescales.

Just less than 60% of the Earth's radiative energy from the Sun is received by the ocean, 80% of which is absorbed in the top 10 m of the ocean. Winds and waves mix down a seasonal surface layer of nearly uniform temperature, salinity, and other properties. This layer extends to tens of meters in the tropics and to several hundred meters in high-latitude seas, where oceanic convections are due to the annual cooling of surface waters and where the winds are stronger and the waves larger. The permanent thermocline lies below the seasonal surface layer, down to about 1000 m depth. Circulation down to the upper thermocline is principally wind-driven and is characterized by basin-scale gyres and intensive western boundary currents such as the Gulf Stream and the Kuroshio. The oceans transport about the same amount of heat poleward as the atmosphere (Trenberth and Solomon, 1994), and these western boundary currents are the most important carriers.

The lower thermocline and the abyssal ocean represent nearly 90% of the volume of the oceans, and most of this water is colder than 5°C. It is dominated by thermohaline circulation driven by differences in density. Globally, the oceanic thermohaline circulation can provide a substantial buffer against greenhouse warming. It incorporates both heat and CO_2 from the atmosphere at higher latitudes and releases them at lower latitudes decades or centuries later. Thus, it plays an important role in controlling the distribution of both heat and greenhouse gases and, as a consequence, modulating global climate.

About 57% of oceanic volume is colder than 2°C. Except for the Arctic Ocean and the nearby part of the Atlantic Ocean, these characteristics can only be derived from Antarctic bottom water (Gordon, 1991). Therefore, a significant part of global thermohaline circulation is driven by the formation and sinking of Antarctic bottom water, principally in the Weddel Sea. As a consequence, the Antarctic Ocean is quite important for the global climate, but its role in contributing variability to climate is not understood. Further, changes in the formation of deep water in the North Atlantic are usually considered to be part of the processes by which the Earth moves from an ice age to an interglacial and back again. This process is explained in Box 8-1.

Studies of gases trapped in polar ice cores have shown that the concentration of atmospheric CO_2 has undergone variations that parallel climatic changes (Barnola *et al*., 1987). The strong correlation between variations of polar temperature and atmospheric carbon dioxide concentration in comparison with the Sun-Earth orbit-induced glacial-interglacial cycles strongly suggests the existence of feedback mechanisms involving the interplay of biological, chemical, and physical processes (Watson *et al*., 1990). Because the ocean contains about 60 times more carbon than the atmosphere (Sundquist and Broecker, 1985), variations in atmospheric CO_2 could result from even minor changes in the ocean's physicochemical and biogeochemical characteristics affecting carbon cycling in the sea. Among the proposed explanations for the variability of atmospheric CO_2 contents on these timescales are changes in ocean productivity (Sarnthein *et al*., 1988) and fluctuations in the quantity of carbon stored in the deep sea—which in turn, are related to changes in ocean circulation (Boyle and Keigwin, 1982; Curry *et al*., 1988).

The natural fluxes of the exchange of carbon dioxide among atmosphere, ocean, and land biota are much larger than anthropogenic perturbations (IPCC, 1994). Because of complex oceanic carbonate chemistry, the ocean—compared to its reservoir

Box 8-1. Ocean Conveyor Belt

The "conveyor belt" global thermohaline circulation is driven primarily by the formation and sinking of deep water (from 1500 m to the Antarctic bottom water overlying the bottom of the ocean) in the Norwegian Sea (Figure 8-1; Broecker, 1991). This circulation is thought to be responsible for the large flow of upper ocean water from the tropical Pacific to the Indian Ocean through the Indonesian Archipelago—the Indonesian Throughflow (e.g., Broecker, 1991).

Drop Holding Line
Figure 8-1: Ocean conveyor belt (after Broecker, 1991).

The global conveyor belt thermohaline circulation is controlled by two counteracting forcings operating in the North Atlantic. The *thermal forcing* (high-latitude cooling and low-latitude heating) drives a poleward surface flow, and the *haline forcing* (net high-latitude freshwater gain and low-latitude evaporation) moves in the opposite direction. In today's North Atlantic, the thermal forcing dominates. When the strength of the haline forcing increases due to excess precipitation, runoff, and/or ice melt, the conveyor belt will weaken (i.e., decrease in both poleward warm surface flow and deep-water formation) or even shut down. The variability in the strength of the conveyor belt will lead to climate change in Europe. Climatic variation in other parts of the global ocean also may be influenced by the variability of the conveyor belt (e.g., Gordon *et al.*, 1992; Lehman, 1993). Numerical simulations of global ocean circulation show that small changes in the external forcing at high latitudes can switch off the present conveyor belt and force the ocean to reach another equilibrium state, in which the Antarctic Circumpolar Front represents the sole deep-water source (e.g., Maier-Reimer *et al.*, 1993).

The North Atlantic atmosphere-ocean-cryosphere system appears to have natural cycles of many timescales in switching the conveyor belt. In these cycles, sea ice plays a pivotal role. Periodic movement of excessive sea ice from the Arctic into the Greenland Sea appears to be responsible for the interdecadal variability of the conveyor belt (Mysak *et al.*, 1990), characterized by the freshening of the intermediate water (Dickson *et al.*, 1988). There is no evidence yet that the influx of interdecadal switching extends beyond the North Atlantic Ocean.

Paleorecords show that 10,000 to 80,000 years ago there were millennial oscillations of several degrees of the sea-surface temperature in the North Atlantic (Bond *et al.*, 1993; Figure 8-2), with abrupt temperature shifts in decadal timescales (Taylor *et al.*, 1992). Interaction between the warm ocean surface current and the Scandinavian ice sheets is

Box 8-1 (continued)

Figure 8-2: Ocean surface temperature in the North Atlantic over the past 80,000 years as inferred from sediment cores (top). These variations may be related to the strength of the "conveyor belt." When the conveyor belt is strong, as in the present, the North Atlantic polar front (i.e., the circulation boundary between cold polar and warm boreal water masses) swings open, allowing warm subtropical water masses to flow on to the north (bottom left). During the last glacial period, the conveyor belt was rapidly weakened many times due to iceberg surges (triangles in bottom right). Then the polar front swung to the east, cutting off the northward flow of warm waters (after Bond *et al.*, 1993; Zahn, 1994).

thought to be the driving mechanism (Bond *et al.*, 1993). These millennial cycles, called Dansgaard-Oeschger cycles, appear to lump into long-term cooling cycles (Dansgaard *et al.*, 1993; Oeschger *et al.*, 1984). Each cooling cycle culminates in an enormous discharge of icebergs into the North Atlantic from massive collapses of Laurentinide ice sheets—called a Heinrich event—followed by an abrupt shift to a warmer climate. The Younger Dryas—an event that happened at the last glacial termination about 11,000 years ago, when there were abrupt temperature decreases in Greenland and Northern Europe—also was a Heinrich event. Similar observations also have been made in the Greenland ice-core record from the last interglacial period (GRIP Project Members, 1993). In as much as the last interglacial seems to have been slightly warmer than the present one, global warming may destabilize the relatively stable climate that the Earth has experienced over the past 8000 years (GRIP Project Members, 1993). There is some doubt, however, about the reliability of the Greenland ice-core record for the last interglacial (e.g., Broecker, 1994). If the last interglacial climate variability did exist, it could have been due to an origin different from fluctuations in the strength of the conveyor belt (e.g., Zahn, 1994).

size—is actually not an efficient sink for increases in atmospheric carbon dioxide concentrations (e.g., Siegenthaler and Sarmiento, 1993). Nevertheless, the ocean is estimated to have taken up about 30% of carbon dioxide emissions arising from fossil fuel use and tropical deforestation between 1980 and 1989 (Siegenthaler and Sarmiento, 1993), thus slowing the rate of greenhouse global warming. The same estimate also leaves about 25% of the emissions unaccounted for. This "missing sink" for carbon dioxide is thought to be located in the terrestrial biosphere (Tans *et al*., 1990), although Tsunogai *et al*. (1993) suggest that the oceanic intermediate waters are also significant sinks for carbon dioxide.

The global ocean also plays a major role in the global hydrological cycle. The cycling of the oceanic freshwater fraction through advection, evaporation (E), precipitation (P), and—in higher latitudes—the solid-ice phase will be affected by changes in wind systems and oceanic current systems. The freshwater budget of the ocean is still not well enough understood, primarily because of the lack of adequate data, although Schmitt *et al*. (1989) have given some preliminary assessments. Atmosphere-ocean interactions maintaining the overall E-P balance will be affected by changes in circulation, evaporation, precipitation, and the availability of precipitable water in the atmosphere over the ocean. A changing pattern of rainfall over the oceans will cause changes in the rainfall pattern over land, which will in turn have a considerable effect on the salinity of marginal seas.

8.2.2. *Resources and Products*

The oceans provide living and nonliving (minerals and water) resources, opportunities for unconventional energy sources, pharmaceuticals, and marine electronic instrumentation.

8.2.2.1. *Living Resources*

Living resources include fish and shellfish, marine mammals, and seaweeds. In 1990, the world's fish catch was 97 million tons (mt)—14 mt from inland sources and 83 mt from marine sources (FAO, 1992a). However, the annual rate of growth in world marine catch has been declining since 1972 (FAO, 1992b). This decline in the rate of growth, and decline in overall production experienced in 1990, is the combined result of uncontrolled growth in fishing effort and overfishing of important stocks in the Atlantic Ocean. Uncontrolled access to resources and growth in fishing effort supported by large national subsidies are major weaknesses in the world fisheries system as a whole (see Chapter 16). In contrast, the production trend in the world aquaculture industry is the opposite of that in the marine capture fisheries industry. Between 1984 and 1992, world aquaculture production increased 89% and amounted to 23% of the world marine catch with a value of $32.5 billion (in 1992 U.S.$) (Aquaculture Magazine Buyers Guide, 1995). This subject is considered in Chapter 16.

A combination of human activities (e.g., overfishing, pollution of estuaries and the coastal ocean, and the destruction of habitat, especially wetlands and seagrasses) currently exerts a far more powerful effect on world marine fisheries than is expected from climate change. However, fisheries are indeed sensitive to climate change as inferred from paleorecords. The Working Group I report concludes that because marine photosynthesis is limited by nitrogen rather than by carbon, increasing CO_2 contents in the upper ocean is unlikely to have a positive impact on net primary productivity. Rather, primary productivity should respond to changes in nutrient availability resulting from changes in ocean circulation, runoff input, or atmospheric deposition. Because there is substantial uncertainty about whether any of these factors will change with global warming, it is not clear if average primary productivity will be affected. Even if global average primary productivity is negatively affected, there are so many pathways and loops in the chain between primary productivity and upper trophic level species—including a significant microbial loop—and regional conditions vary so widely that it is difficult to say whether reductions in the average yield of commercial fisheries will result.

There are indications that the potential value of the marine pharmaceutical industry is large, although there is no comprehensive study of the market for this industry. The oceans are a potentially enormous source of biological tissue that can be refined and developed into pharmaceuticals, enzyme preparations, gene probes, immunological assays, and new materials. Some of these materials have commercial potential in medicine, agriculture, marine aquaculture, and materials science.

The cleaning and disinfection of contaminated areas using microorganisms (bioremediation) is of potential importance in the oceans, largely on fixed surfaces such as sediments (Bragg *et al*., 1994; Swannel and Head, 1994). Bioremediation of the marine water column may not be important, largely because most contaminants in the oceans are particle-associated (e.g., sediment particles). Possible exceptions include highly contaminated seawater close to terrestrial hazardous waste disposal sites. To date, efforts to deal with these areas have been few.

The newest class of marine organisms that appears to have considerable commercial potential in the biotechnology industry is the hyperthermophiles ($T_{opt} > 85°C$) (Kristjansson, 1989). These bacteria live at extremes of pH and temperature that make them attractive to industry because, among other characteristics, they can yield long shelf-lives and tolerate organic solvents and harsh purification processes. Large colonies of hyperthermophiles now have been found at spreading centers in mid-ocean ridges (Jannasch and Wirsen, 1979), in the deep North Sea, and in Alaskan oil reservoirs (Stetter *et al*., 1993). However, they are difficult to culture in the laboratory. Not surprisingly, the potential value and availability of these hyperthermophiles have stimulated serious efforts to harvest them for industrial applications by biotechnology firms (e.g., Myers and Anderson, 1992).

8.2.2.2.   *Nonliving Resources and Unconventional Energy*

The range of products in this category includes petroleum, placer and nearshore deposits (i.e., sand and gravel, sulfur, phosphorite), calcareous oozes including hot brines, manganese nodules, and polymetallic sulfides at spreading centers. The latter two are resources from the deep ocean bed, for which no large-scale commercial recovery has been attempted because it is presently uneconomic.

Petroleum hydrocarbons are by far the most significant contribution of the ocean to the world stock of nonliving (mineral) resources in both quantity and value. Offshore production is estimated to be approximately 26% of terrestrial production for oil, in amount and gross value, and 17% for natural gas (*Oil and Gas Journal*, 1993; *Offshore Journal*, 1993; Oil and Gas Journal Database, 1992).

Broadus (1987) estimates the annual gross value of all other extracted seabed minerals to be more than $600 million—of which tin is the most significant item and the only one that supplies more than 1% of its world market. Sand and gravel, calcium carbonate, sulfur, and other mineral placers are also among the seabed mineral resources that are actively extracted. The harvesting of precious coral, a combined living and mineral resource, supports an industry estimated to be worth more than $50 million a year (Broadus, 1987).

Other resources and products to be found in the ocean include water and unconventional energy resources. In the 1990s, more than 3,500 land-based desalination plants were in operation, producing more than 8 billion liters of water a day (Encyclopedia Britannica, 1993). Thirty percent of the total number of plants were located in the United States, and 20% were in the Middle East. Desalination of sea water is unlikely to be affected by global climate change.

Electricity from tidal power can be produced in only a few areas of the world (e.g., northern France and eastern Canada) where the tidal flux is sufficiently large. The total usable potential is estimated to be on the order of 200 million kW (Charlier and Justus, 1993). The potential for using temperature differentials in the tropical ocean between the surface and the water below the thermocline is quite large. This technique, called ocean thermal energy conversion (OTEC), theoretically can be applied in the latitude belt between 20°N and 20°S, but the area of greatest potential lies between 10°N and 10°S. Total potential electricity production from OTEC ranges between 10^8 and 10^{10} MW (Charlier and Justus, 1993). An upper limit per plant at the 10^7 MW level would amount to 299 quads per year [one quad = 10^{15} Btu (British thermal units)] of electric energy. So far, only two subsidized pilot plants have been in operation.

The oceans are an opaque, three-dimensional medium. The opacity derives from a limited capacity for penetration by either light or electromagnetic waves. The oceans also are characterized by storms, hazards to navigation, and currents of varying strength, so electronic means of sensing, communicating, and managing information are essential (Broadus *et al.*, 1989). The major products here include communication and navigation instruments, sensors, data management instruments, and services. Navies, offshore oil and gas firms, oceanographic research and environmental monitoring entities, commercial shipping and fishing companies, and recreational boaters are the consumers of these products (Broadus *et al.*, 1989). Initial estimates of the size of the world market for marine electronic instrumentation (Hoagland III and Kite-Powell, 1991) are in the range of $3–5 billion for the United States and roughly twice that size for the world (which includes the United States, Western Europe, and Japan).

8.2.3.   **Waste Reception and Recycling**

Due to their enormous volume of water, microbial communities, and sediments, the oceans have the capability to receive, dilute, transform, eliminate, store, and recycle massive quantities of wastes from human activities conducted on land and in the atmosphere, as well as on water (Izrael and Tsyban, 1983, 1989; GESAMP, 1986). This capability to accept contaminants, however, is not limitless, and negative consequences can occur—especially in coastal seas and estuaries. The major sources and pathways of pollutants into the oceans are runoff and river inputs of land-based discharges, which contribute an estimated 44% (GESAMP, 1990); atmospheric deposition of land-based pollutants over the oceans, which contributes an estimated 33%; and at sea-activities, including mineral production, maritime transportation, and ocean dumping, which contribute 23% of the total inputs (GESAMP, 1990).

8.2.4.   **Recreation and Tourism**

Recreation and tourism is an exceedingly large and rapidly growing market, which exceeded $2 trillion in 1986 (Miller and Auyong, 1991). Tourism accounts for more than 12% of the world's gross product and represents an important socioeconomic activity in the coastal environment (see Chapter 9). The organizational and operational facilities for the tourist industry—which include, for example, hotels, airports, ports, marinas, and the like—affect ecosystems such as estuaries, salt marshes, mangroves, seagrass beds, and other wetlands and coral reefs, all of which are already at risk due to pollution from human activities (Miller and Auyong, 1991). Maintaining a balance between developing tourism and recreation and preserving the aquatic environment is an issue affected by climate change because adverse human impacts on the coastal zone are likely to be amplified by the coastal effects of climate change (see Chapter 9).

8.2.5. *Transportation*

Transportation over water is by far the cheapest of all global transportation media available; consequently, more than 95% of world trade moves by ship. This medium is the least significant

contributor of CO_2 per amount of product shipped. The world fleet in 1990 consisted of 424 million gross tons (GT, a volumetric measure) or 667 million deadweight tons (dwt, a measure of carrying capacity). Of that amount, exclusively cargo-carrying ships accounted for 46%; fishing vessels (all types >100 GT) accounted for 19%; and passenger vessels accounted for 18% (Lloyds Register, l990). These three categories accounted for 83% of the world's fleet.

Marine transportation will be affected by climate change in three respects. First, in regions experiencing increased precipitation and runoff, increased dredging operations will be necessary in ports affected by increased sediment deposition. Second, if the frequency and uncertainty of tropical storms and hurricanes increases, shipping will be adversely affected, loss rates may increase, and freight and insurance rates will rise. Third, if the extent of sea ice is reduced by 20% in northern latitudes—which seems probable given that maximum warming is predicted to occur in high northern latitudes in winter (see the IPCC Working Group I volume, and Chapter 7)—then both the Northwest Passage and the Russian Northern Sea Route will become viable sea routes, thereby facilitating shipping and reducing costs between East Asia and Western Europe.

8.2.6. Information Function

In addition to the preceding functions and uses, the oceans represent a natural repository of genetic and biological information. One important effect of climate change is likely to be a net decrease in global biodiversity. In many cases, global warming will act in combination with other human factors—driving species to extinction, narrowing the genetic range within species, and transforming and simplifying ecosystems. Species that are rare, isolated on the edge of their tolerance, genetically impoverished, and in areas undergoing the most abrupt changes are likely to become extinct (Markham *et al*., 1993).

The biodiversity value of the ocean is particularly important because there are many groups of organisms, even at taxonomic levels above orders, that are exclusively marine. These animals and plants have special status in some ways related to biodiversity because the loss of these species represents a larger impact than the loss of species in widespread taxonomic groups.

8.3. Characteristics of Oceans and Their Responses to Climate Change

In this section we describe the major characteristics of oceans and their likely responses to global climate change scenarios.

8.3.1. Physical Characteristics

In the oceans, climate change will be accompanied by changes in temperature, circulation, sea level, ice coverage, wave climate, and extreme events. These changes are expected to have consequences for ecosystem structure and function, as well as for global biogeochemical cycles with feedbacks to the climate system.

8.3.1.1. Temperature

Studies of past climate changes show that sea surface temperature (SST) increases along with air temperature, although probably not as much as or as rapidly (IPCC, 1990a). Also, due to greater thermal inertia, changes in oceanic conditions will lag behind changes on the continents [e.g., by 10 years for the North Pacific (Wigley *et al*., 1985)]. The correlation between SST and land temperatures from a coupled ocean-atmosphere model suggests that SST will increase at a rate generally in line with the increase of mean land-temperature values (Manabe *et al*., 1991). Exceptions might occur in a belt around Antarctica and in the high-latitude North Atlantic. The modeled SST around Antarctica increases more slowly because of the upwelling deep-water masses. The predicted temperature increase in the high-latitude North Atlantic also is slower, apparently due to a weakening of the conveyor belt thermohaline circulation. The weakened conveyor belt could recover if atmospheric CO_2 concentration leveled off at double the present value but might never recover if it quadrupled (Manabe and Stouffer, 1993), driving the climate system into unknown directions. Exceptions also are expected to occur in arctic and subarctic regions, where the predicted warming may be higher than the global average.

8.3.1.2. Upwelling and ENSO Events

Divergence of wind-driven surface ocean currents induces upwelling of water from deeper layers. General circulation models (GCMs) predict a decrease of the meridional (north–south) gradients of sea-surface temperature due to significant warming in polar latitudes, which in turn would lead to a decrease in trade-wind intensity, the strength of the upper ocean currents (Mitchell, 1988), and the area and intensity of upwelling, such as in the equatorial eastern tropical Pacific. According to studies of paleoclimate, the productivity of open oceanic upwelling regions during glacial periods was much higher than during interglacial periods (e.g., Sarnthein *et al*., 1988; Lapenis *et al*., 1990). These studies indicate that global warming may be accompanied by a decrease in total productivity of the global ocean (Budyko and Izrael, 1987; Lapenis *et al*., 1990).

In contrast to model projections, however, observations over large parts of the tropical Atlantic between 1947 and 1986 have shown an increase in the trade winds (Bigg, 1993). Bakun (1990, 1993) suggests that the greenhouse effect will enhance the seasonal warming of continents—leading to a decrease in the pressure over land, an increase in the land–sea pressure difference, and increased alongshore winds. Binet (1988) has observed such effects along the coast of northwest Africa. It appears likely that the strength of both oceanic and coastal upwelling mechanisms could change under conditions of global warming, with profound impacts upon fish species and their

production as well as on the climate of the immediate coastal zone (see also Chapter 16).

The El Niño-Southern Oscillation (ENSO) results from fluctuations in the internal interactions within the Earth's ocean-atmosphere system and is the most significant source of interannual variability in weather and climate around the world. The Southern Oscillation (SO) component of ENSO is an atmospheric pattern that extends over most of the global tropics. It principally involves a seesaw in atmospheric mass between regions near Indonesia and the Pacific Ocean region centered near Easter Island. The El Niño component of ENSO is an anomalous warming of the eastern and central tropical Pacific Ocean. In major "warm events," warming extends over much of the tropical Pacific and becomes clearly linked to the atmospheric SO pattern. ENSO events occur every 3 to 10 years, although in recent years the frequency has increased. The influence of ENSO sometimes extends to higher latitudes and has far-reaching climatic and economic consequences around the world (Ropelewski and Halpert, 1987; Zuta, 1986).

Although ENSO is a natural part of the Earth's climate, a major question is whether the intensity or frequency of ENSO events might change as a result of global warming. Historical and paleorecords reveal that ENSO events have changed in frequency and intensity in the past on multidecadal to century timescales (Nicholls, 1992; Anderson *et al*., 1992; Thompson *et al*., 1984). It is unclear whether ENSO might change with long-term global warming. Studies of long-term variations in ENSO using models have just begun (Knutson and Manabe, 1994; Kumar *et al*., 1994), and it is still premature to project the behavior of ENSO events for different climate-change scenarios.

8.3.1.3.   *Changes in Sea Level*

The available estimates of sea-level changes under a changing climate are rather preliminary because of uncertainties both in the projections of climate change itself and in the assessment of the components that influence sea level. The latter include ocean thermal expansion, the effects of changing volumes of polar ice sheets and mountain glaciers, and dynamic effects resulting from ocean circulation, wind and weather patterns, and differences in regional ocean density (Box 8-2).

Revised projections, taking full account of both climate and sea-level components, are not yet available. However, indications are that both global warming and sea-level rise by the year 2100 may be 25–30% less than the IPCC 1990 projections (Wigley and Raper, 1992, 1993). Nonetheless, even the lower estimates of sea-level rise are about two to four times the rate of sea-level rise experienced in the last 100 years.

Rising sea level will have pervasive impacts for coastal zones and their ecosystems. A detailed analysis of the impacts of sea-level rise on the coastal zones may be found in Chapter 9.

8.3.1.4.   *Ice Cover*

Sea ice covers about 11% of the ocean, depending on the season. It affects albedo, salinity, and ocean-atmosphere thermal exchange. The latter determines the intensity of convection in the ocean and, consequently, the mean timescale of deep-ocean processes affecting CO_2 uptake and storage.

Projected changes in climate should produce large reductions in the extent, thickness, and duration of sea ice. Major areas that are now ice-bound throughout the year are likely to have major periods during which waters are open and navigable. Some models even predict an ice-free Arctic (IPCC, 1990b). Melting of snow and glaciers will lead to increased freshwater influx, changing the chemistry of those oceanic areas affected by the runoff. At present, however, there is no convincing evidence of changes in the extent of global sea ice (Gloersen *et al*., 1992). Studies on regional changes in the Arctic and Antarctic indicate trends of decadal length (e.g., Mysak and Manak, 1989; Parkinson, 1992), often with plausible mechanisms proposed for periodicities of a decade or more. Thus, longer data sets are needed to test whether a genuine long-term trend is developing (see Chapter 7).

8.3.1.5.   *Wave Climate and Vertical Mixing*

Winds and waves are the major forcing factors for vertical mixing; the degree of mixing depends on the vertical density structure. In the past 40 years, there has been an increase in the mean wave height over the whole of the North Atlantic, although it is not certain that global change is the cause of this phenomenon (Bacon and Carter, 1991).

In some permanently stratified anoxic basins, such as the Black Sea, climate change brings with it the possibility of turnover (Mee, 1992). The Black Sea has a very strong density gradient; the only risk of penetration of anoxic bottom waters to the surface would be by elevation of the oxic-anoxic boundary. Although this is controversial, Murray *et al*. (1989) have suggested that the oxic-anoxic boundary in the Black Sea has risen up to 30 m over the last 20 years in association with decreased river flows.

8.3.1.6.   *Extreme Events*

The catastrophic aspects of storms and storm surges are well known, particularly in exacerbating flooding in coastal areas and in erosion and restructuring of coastal formations (see Chapter 9 for details). The causal relationship between sea-surface temperature and the formation of tropical cyclones suggests that the intensity and frequency of tropical cyclones may increase in the future. However, the evidence inferred from models based on such relationships is conflicting (Ryan *et al*., 1992; Stein and Hense, 1994). A GCM analyzed by Haarsma *et al*. (1993) showed that a doubling of CO_2 concentration increased by about 50% the number of simulated tropical disturbances, as well as

Box 8-2. Changes in Sea Level

Model projections suggest that in the oceans, temperature increase due to climate change is largest in the thermocline (Stouffer *et al*., 1989) but that the warming signal there is masked by eddies and seasonal variability. However, Bindoff and Church (1992) also found significant warming in the South Pacific below the thermocline, where the signal-to-noise ratio is larger (Figure 8-3). The corresponding sea-level rise caused by the thermal expansion of seawater is 2–3 cm over 22 years—consistent with the estimates of global sea-level rise. Under the predicted global warming, sea-level rise also will be accelerated by both warming of the ocean and possible melting of ice. A 40-cm global mean sea-level rise is pro-

jected by 2050 (see the IPCC Working Group I volume). However, global warming also will alter the variations in sea surface caused by dynamic effects resulting from wind and atmospheric pressure patterns, regional ocean density differences, and oceanic circulation (Figure 8-4). Large regional differences in sea-level response can be expected due to the effects of ocean circulation in sea-surface topography (Mikolajewicz *et al*., 1990). Increases in sea level would be highest in the North Atlantic; in certain regions, such as the Ross Sea, sea level actually would fall (Mikolajewicz *et al*., 1990). Regional differences in sea-level change are to be expected (see also Church *et al*., 1991; Cubasch *et al*., 1994). Therefore, there also will be significant regional differences in sea-level rise with global warming. In addition, it should be emphasized that for coastal environments, it is the relative sea level that matters [i.e., the level of the sea in relation to that of the land (see Chapter 9)].

Figure 8-4: Global variations of sea-surface topography (in mm) due to dynamic effects relative to the global mean sea level, as obtained from a transient experiment of increasing carbon dioxide concentrations using a coupled ocean-atmosphere GCM. The results are for years 66–75 of the model run (but cannot be ascribed to a future calendar date). The stippled areas on the map show sea-level rises that are less than the global average (after Gregory, 1993).

the number of intense disturbances, whose maximum windspeed increased by about 20%. The low resolution of the GCM calls for caution in interpreting the simulated changes in the intensity of tropical disturbances (Haarsma *et al*., 1993). GCM results also indicate a change in cyclone tracks as a response to global warming. Bengtsson *et al*. (1994), on the other hand, report that with a doubling of CO_2 over the next 50 years, the global distribution of storms should be similar to the present geographical position and seasonal variability—although the number of storms is significantly reduced, particularly in the Southern Hemisphere. Tropical cyclone models require an initial disturbance to be present before a full-scale cyclone develops. A GCM, with its coarser horizontal resolution, cannot produce a better resolution than a cyclone model. Correlations also have been found between ENSO (as well as the southeast Asian monsoon) and the regional patterns of tropical cyclone activity (Nicholls, 1984; Evans and Allan, 1992). Unfortunately, it is not yet possible to say how ENSO, and thus tropical cyclones in these regions, will be affected by global warming (see also Section 8.3.1.2).

Although there is uncertainty, the extent of damage caused by great windstorm catastrophes has expanded in recent years. The concentrations of people living in high-risk coastal regions must be considered the main reason for this alarming trend (Berz, 1994). If storms intensify with rising temperatures, there will be adverse consequences for living and nonliving resource exploitation in the ocean and in coastal areas, for marine transportation, and for recreation and tourism. It must be noted, however, that scientific assessment of impacts in this context can differ from economic evaluation of loss because the methodologies used to assess loss are different. From a scientific perspective, damage or injury would be assessed in terms of the components and interrelationships in a particular ecosystem. From an economic perspective, however, loss is defined by value as determined by some market. It is therefore quite possible to get a scientific assessment of low injury to an ecosystem combined with high economic loss value, especially given that the value of waterfront real estate is normally high (see also Chapter 17). The reverse is also true: Major ecological damage might occur with little economic loss.

8.3.2. *Ecological Characteristics and Biodiversity*

Metabolic rates, enzyme kinetics, and other biological characteristics of aquatic plants and animals are highly dependent on external temperatures; for this reason alone, climate change that influences water temperature will have significant impacts on the ecology and biodiversity of aquatic systems (Fry, 1971). The capability of some species to adapt genetically to global warming will depend on existing genetic variation and the rapidity of change (Mathews and Zimmerman, 1990). Species remaining in suboptimal habitats should at least experience reductions in abundance and growth well before conditions become severe enough for extinctions to occur. The resilience of an ecosystem to climate change will be determined to a large extent by the degree to which it already has been impaired by other human activities.

Coastal ecosystems are especially vulnerable in this context. They are being subjected to habitat degradation; excessive nutrient loading, resulting in harmful algal blooms; fallout from aerosol contaminants; and emergent diseases. Human interventions also have led to losses of living marine resources and reductions in biodiversity from biomass removals at increasingly lower trophic levels (Sherman, 1994; Beddington, 1995; Pauly and Christiansen, 1995). The effects on biodiversity are likely to be much less severe in the open ocean than in estuaries and wetlands, where species in shallow, restricted impoundments would be affected long before deep-oceanic species (Bernal, 1991).

The chief biotic effects on individuals of an increase in mean water temperature would be increased growth and development rates (Sibley and Strickland, 1985). If surface temperatures were correlated positively with latitude, and temperature increased, one would expect a poleward shift of oceanic biota. While this may be the general case, there could be important regional variations due to shifts in atmospheric and oceanic circulation. The resulting changes in predator-prey abundance and poleward shifts in species' ranges and migration patterns could, in the case of marine fisheries, lead to increased survival of economically valuable species and increased yield. Such cases have been observed by Wooster and Fluharty (1985) as a result of the large and intense 1983 El Niño.

In high latitudes, higher mean water temperature could lead to an increase in the duration of the growing period and ultimately in increased bioproductivity in these regions. On the other hand, the probability of nutrient loss resulting from reduced deep-water exchange could result in reduced productivity in the long term—again highlighting the importance of changes in temperature on patterns of circulation. Global warming could have especially strong impacts on the regions of oceanic subpolar fronts (Roots, 1989), where the temperature increase in deep water could lead to a substantial redistribution of pelagic and benthic communities, including commercially important fish species.

For tropical latitudes, GCMs predict temperature increases that are half of those predicted for high latitudes, and the impacts in tropical latitudes are less clear. A 1.5°C increase would raise the summertime mean temperature to 30.5°C over much of the tropical and subtropical regions. Most migratory organisms are expected to be able to tolerate such a change, but the fate of sedentary species will be highly dependent on local climate changes. Some corals would be affected (as in the 1983 and 1987 bleaching events), but it is expected that other environmental stresses (e.g., pollution, sedimentation, or nutrient influx) may remain more important factors (e.g., Maul, 1993; Milliman, 1993). Intertidal plants and animals, such as mangroves and barnacles, are adapted to withstand high temperature, and unless the 1.5°C increase affects reproduction, it will have no effect. Similarly, only seagrass beds already located in thermal-stress situations (i.e., in shallow lagoons or near power plant effluents) are expected to be negatively affected by the projected temperature rise. One cannot rule out, however, the

possibility of significantly greater tropical warming than 1.5°C. For example, some investigators argue that tropical warming was approximately 5°C from the last glacial maximum to today (Beck *et al*., 1992). If this value is correct, current GCMs probably underestimate tropical sensitivity.

Some algal species that are growing at the upper limit of their acceptable temperature range may be eliminated by a temperature increase of a few degrees in oceanic surface waters. There is no evidence that such increases will stimulate toxic algal blooms. Other factors, including competition for micro- and macronutrients, predation by zooplankton, and light-limitation, are of much greater significance to the growth rate and survival of marine algae. High levels of nutrients released into the coastal ocean from anthropogenic sources appear to increase the incidence and growth rates of many types of algae, including some toxic species (GESAMP, 1990). For instance, the toxic algae *Heterosigma spp*., which are responsible for fish kills in net-pen operations, have been linked to nutrient inputs in coastal waters in Japan (Insuka, 1985; Honjo, 1992).

Changes in temperature and salinity are expected to alter the survivorship of exotic organisms introduced through ballast water in ships, especially those species with pelagic larval forms. Introduction of exotic species is a form of biological pollution because, from a human perspective, they can have adverse impacts on ecosystems into which they are introduced and in some cases pose hazards to public health (International Maritime Organizations [IMO], 1991). A classic recent example of the spread of an introduced exotic species is that of the zebra mussel (*Dressena polymorpha*), which was transported to the Great Lakes via transatlantic shipping from the Baltic sea (Mills *et al*., 1993). Another recent example is that of the ctenophore, *Mnemiopsis leidyi*, which appears to have been introduced to the Black Sea from the east coast of the United States and has experienced explosive development since 1988 (Mee, 1992). Changes in temperature could enhance the potential for the survival and proliferation of exotic species in environments that are presently unfavorable.

Changes also can be expected in the growth rates of biofouling organisms that settle on means of transport, conduits for waste, maritime equipment, navigational aids, and almost any other artificial structure in the aquatic environment. Their species distributions often are limited by thermal and salinity boundaries, which are expected to change with regional changes in temperature and precipitation. Areas that experience warming and reduced precipitation (i.e., salinity increases) likely will have increased problems with biofouling.

Predicted climate change also may have important impacts on marine mammals such as whales, dolphins, and seals, and seabirds such as cormorants, penguins, storm petrels, and albatross. However, it is presently impossible to predict the magnitude and significance of these impacts. The principal effects of climate change on marine mammals and seabirds are expected from areal shifts in centers of food production and changes in underlying primary productivity due to changes in upwelling, loss of ice-edge effects, and ocean temperatures; changes in critical habitats such as sea ice (due to climate warming) and nesting and rearing beaches (due to sea-level rise); and increases in diseases and production of oceanic biotoxins due to warming temperatures and shifts in coastal currents.

Ice plays an important role in the development and sustenance of temperate to polar ecosystems because it creates conditions conducive to ice-edge primary production, which provides the primary food source in polar ecosystems; it supports the activity of organisms that ensure energy transfer from primary producers (algae and phytoplankton) to higher trophic levels (fish, marine birds, and mammals); and, as a consequence, it maintains and supports abundant biological communities (Izrael *et al*., 1992).

One of the possible beneficial consequences of global warming might be a reduction in the extent and stability of marine ice, which would directly affect the productivity of polar ecosystems. For example, the absence of ice over the continental shelf of the Arctic Ocean would produce a sharp rise in the productivity of this region (Izrael *et al*., 1992), provided that a sufficient supply of nutrients is maintained. Changes in water temperature and wind regimes as a result of global warming also could affect the distribution and characteristics of polynyas (ice-free areas), which are vital to polar marine ecosystems. In addition, changes in the extent and duration of ice, combined with changes in characteristics of currents—for example, the circumpolar current in southern latitudes—may affect the distribution, abundance, and harvesting of krill. Krill are an important link in the ocean fauna in the Southern Ocean. It is important to understand how, when, and where productivity in the Southern Ocean will change with global warming.

A number of marine organisms depend explicitly on ice cover. For example, the extent of the polar bear's habitat is determined by the maximum seasonal surface area of marine ice in a given year. The disappearance of ice would threaten the very survival of the polar bear, as well as certain marine seals. Similarly, a reduction in ice cover would reduce food supplies for seals and walruses and increase their vulnerability to natural predators and human hunters and poachers. Other animals, such as the otter, could benefit by moving into new territories with reduced ice. Some species of marine mammals will be able to take advantage of increases in prey abundance and spatial/temporal shifts in prey distribution toward or within their primary habitats (e.g., Fraser *et al*., 1992; Montevecchi and Myers, 1995), whereas some populations of birds and seals will be adversely affected by climatic changes if food sources decline (Polovina *et al*., 1994) or are displaced away from regions suitable for breeding or rearing of young (Schrieber and Schrieber, 1984).

Animals that migrate great distances, as do most of the great whales and seabirds, are subject to possible disruptions in the distribution and timing of their food sources during migration. For example, it remains unclear how the contraction of ice cover would affect the migration routes of animals (such as whales) that follow the ice front (Izrael *et al*., 1992). At least

some migrating species may respond rapidly to new situations; for example, migrating ducks have altered their routes to take advantage of the recent exploding population of zebra mussels in the Great Lakes (Worthington and Leach, 1992).

While the impacts of these ecological changes are likely to be significant, they cannot be reliably forecast or evaluated. Climate change may have both positive and negative impacts, even on the same species. Positive effects such as extended feeding areas and seasons in higher latitudes, more-productive high latitudes, and lower winter mortality may be offset by negative factors that alter established reproductive patterns, breeding habitat, disease vectors, migration routes, and ecosystem relationships.

8.3.3.   *Biogeochemical Cycles*

8.3.3.1.   *CO_2 Uptake and Biological Productivity*

Climate change is expected to have an impact on processes controlling biogeochemical cycling of elements in the oceans, with potential feedbacks on various components of the carbon cycle. These impacts include the uptake of and storage capacity for CO_2 by physicochemical and biological processes. These aspects are considered in Chapter 6, *Climate Models—Projections of Future Climate*, and Chapter 10, *Marine Biotic Responses to Environmental Change and Feedbacks to Climate*, of the Working Group I volume.

Changes in sea-surface temperature can be expected to affect carbon chemistry both directly and indirectly. Changes will occur in the solubility of CO_2 and the remineralization of dissolved organic carbon. However, these changes are not expected to significantly affect atmospheric CO_2 concentrations (IPCC, 1994). Less certain, however, is the role of biological processes in sequestering carbon in the ocean and the potential impact of climate change on these processes.

The major process by which marine biota sequester CO_2 is thought to be controlled by nutrients, not by the concentration of dissolved inorganic carbon. A weakening of vertical and horizontal circulation as a result of warming (e.g., Manabe and Stouffer, 1993) could result in fewer nutrients in surface water, leading to a reduction of biological CO_2 uptake and storage (Volk and Hoffert, 1985). At the same time, less carbon-enriched deep water would be carried to the surface where the CO_2 is released to the atmosphere. The two effects result from the same process but affect the storage of carbon in opposite directions; they dominate models that use constant carbon-to-nutrient ratios to describe the marine biosphere (e.g., Bacastow and Maier-Reimer, 1990). These models project that a reduction of ocean circulation and vertical mixing will increase oceanic carbon storage slightly. A reduction in vertical mixing in the ocean also leads to a reduced downward transport of excess CO_2. It reduces the capacity of the oceans to store excess CO_2 because progressively less water is in contact with the surface over the period of atmospheric perturbation.

Current model results suggest that the effects of predicted changes in circulation on the oceanic carbon cycle will not be large (Paillard *et al.*, 1993). However, extrapolation of the long-term impacts of warming on circulation patterns has just begun; hence, the analyses of impacts on the carbon cycle must be viewed as preliminary.

Riebesell *et al.* (1993) claimed recently that phytoplankton growth rates are dependent on the availability of dissolved CO_2 and that this process could have been one of the factors responsible for changes in atmospheric CO_2 contents observed in the ice-core record. Their conclusions have been contested by other researchers who suggest that CO_2-limited photosynthesis cannot be equated with CO_2-limited growth rates (e.g., Turpin, 1993). Further research will be needed to ascertain whether increased CO_2 concentrations are likely to have the effects suggested by Riebesell *et al.* (1993).

Climate change also can affect the role of marine biota in other ways. Shifts may occur in the structure of biological communities in the upper ocean—for example, from coccolithophorids to diatoms—as a result of increased freshwater influx from melting ice and river runoff. This change will alter the ratio of organic carbon to carbonate carbon in the material settling out of the surface layers of the sea (Berger and Keir, 1984; Ittekkot *et al.*, 1991). Biologically mediated carbon storage in the ocean is determined by the rate of transfer of organic matter from the surface layers, which exchange gases with the atmosphere, to the deep ocean, which remains isolated from the atmosphere for up to hundreds of years. The role of this transfer in the context of deep-sea carbon storage has not been adequately addressed in the scientific literature. Recent studies suggest that eolian dust and river-derived mineral matter can enhance carbon fixation at the sea surface by providing essential trace constituents such as iron (e.g., Martin and Fitzwater, 1987; Murray *et al.*, 1994). Furthermore, this material can accelerate the transfer of organic matter to the deep sea by providing "ballast" material for rapidly sinking organic aggregates (Figure 8-5; Ittekkot, 1993). Thus, the efficiency of carbon storage in the deep sea may be affected by a changing climate and associated changes in atmospheric and ocean circulation and nutrient availability, combined with other global changes such as desertification. The magnitude and the direction of these changes remain unclear. Major national and international activities within the framework of JGOFS (Joint Global Ocean Flux Study) and GLOBEC (Global Ocean Ecosystem Dynamics) are expected to provide data to assess the role of biological processes in the removal of CO_2 from the atmosphere into the depths of the oceans.

Most of the organic-carbon burial in modern marine sediments on a global basis occurs in deltas and continental-margin environments (Berner, 1992) that are characterized by inputs from high primary productivity and terrigenous material discharged by the rivers. Both inputs are likely to be influenced by climate change affecting carbon cycling in these regions, with feedbacks to the carbon cycle and hence climate. It is difficult at present to assess the nature and extent of such an influence because other factors such as nutrient loading and river runoff
Figure 8-5: Schematic of processes that control organic-matter production and removal to the deep sea ("the abiotically driven organic carbon pump" in the ocean). Dust particles deposited at the sea surface not only introduce essential trace nutrients such as iron (stimulating primary productivity), but also become incorporated into organic aggregates that form high-density particles (the ballast effect) with faster sinking rates—thus accelerating the transfer of newly fixed carbon dioxide to the deep sea. Strong winds enhance the effect as well. The efficiency of this transfer—therefore of carbon storage in the deep sea—is expected to be affected by global warming (after Ittekkot, 1993).

already have a strong impact in these areas and because the role of coastal oceans in the global carbon cycle is poorly understood (Smith and MacKenzie, 1991).

Marine aerosol formation is associated with the production of dimethyl sulfide (DMS) by specific phytoplankton species in the ocean (Charlson *et al.*, 1987). DMS is the most important source of cloud condensation nuclei (CCN). Changes in phytoplankton species due to predicted global warming can have other feedbacks in the climate system, although the direction and quantitative significance of such feedbacks have to be assessed. The role of the oceans in the contribution of other greenhouse gases to the atmosphere—such as, for example, methane and nitrous oxide—is just beginning to be assessed, and the impact of climate change is still uncertain (see Chapter 10, *Marine Biotic Responses to Environmental Change and Feedbacks to Climate*, of the Working Group I volume).

8.3.3.2. Contaminant Distribution and Degradation

Contaminant distribution in the ocean will be especially sensitive to climate change because two major pathways of

pollutants into the oceans will be affected: river runoff and atmospheric transport. The impacts of global warming on coastal and ocean pollution can be expected to depend on the way global warming will affect the nature and concentrations of pollutants in question, as well as on changes in their persistence in the environment. Changes in the cycling and distribution between phases (dissolved versus sedimentary) could occur under a global warming scenario for sewage, organics, organochlorines, and heavy metals (e.g., Tsyban *et al.*, 1990). In most cases, phase transitions can be expected. A rise in temperature also may result in accelerated biodegradation of global organic pollutants (petroleum and chlorinated hydrocarbons, etc.). This process would promote their removal from the biologically active surface layers of the ocean (Izrael and Tsyban, 1989; Tanabe, 1985). However, the fate of degradation products is less well-known, and there also is the possibility of an increase in the toxicity of at least some of the pollutants under such conditions and with higher temperature. Further, the impact of climate change can be expected to be more severe in coastal seas and landlocked marine basins—such as, for example, the Baltic Sea and the Black Sea, which are already seriously impacted by pollution from human activities.

8.3.4. Socioeconomic Systems

The institutional structure of socioeconomic systems is an extremely important determinant of behavior, and it accounts for relative success or failure in system performance (Ostrom, 1990; Haas *et al.*, 1993; Lee, 1993; Putnam, 1993). Institutional structure includes, among other characteristics, patterns of social organization and the distribution of authority.

A survey of the patterns of current social organization on a global basis, however, shows that present patterns and system capabilities are inadequate to respond to climate change. The major drawback is a lack of integrative capacity even at national levels concerning the use of the coastal ocean and even more so with reference to the exclusive economic zone (EEZ) as a whole (Underdal, 1980; Miles, 1989, 1992). This lack of integrative capacity arises because patterns of ocean use have developed largely in isolation from each other and because different technologies have given rise to separate networks, communities, and ways of thinking and doing. These communities have matured into almost fully autonomous sectors, with only weak or no links among them. These sectors are still needed for specialization. What is missing, however, is an integrative overlay in the institutional structure to assess a country's interest in the ocean as a whole and to make judgments about long- and short-term priorities and responses.

8.4.   Impacts of Climate Changes on Resources and Products

The potential effects of climate change on resources and products range from significantly negative to significantly positive. These effects and the probability of their occurrences are listed below:

- **Significantly Negative**
  - A predicted 2°C average global atmospheric temperature increase by 2050 will result in increased coral bleaching, which in turn will result in a reduction in coral production. *Rating*: Very probable.
  - Increased precipitation, river runoff, and atmospheric deposition from land-based activities will lead to increased loading of pollutants in coastal waters and an adverse impact on fisheries, coral production, and recreation and tourism. *Rating*: Very probable.
  - If the frequency of tropical storms and hurricanes increases, there will be adverse impacts on offshore oil and gas activities in certain locations and on marine transportation. *Rating*: Uncertain.
- **Mildly Negative**
  - There will be problems in the operation of low-head tidal power plants due to increased sedimentation from increased precipitation and runoff in the Northern Hemisphere. There also will be reduced potential for OTEC in certain locations due to a reduction in differential between surface temperature and temperature below the thermocline. *Rating*: Very probable.

- There will be increased costs generated by the need to expand dredging operations to keep major ports open in particular locations. *Rating*: Very probable.
  - There will be reduced fisheries yield if average primary productivity decreases. *Rating*: Uncertain. This effect probably will be dwarfed by the combined adverse impacts of overfishing, marine coastal pollution, and habitat destruction. *Rating*: Virtually certain.
- **Neutral**
  - Marine pharmaceutical and biotechnology industries are unlikely to be affected by climate change. *Rating*: Very probable.
  - Nonliving resource exploitation other than petroleum hydrocarbons will not be affected by climate change. *Rating*: Very probable.
- **Mildly Positive**
  - There will be growth in the marine instrumentation industry to facilitate research and monitoring of climate change through expanding capabilities for automatic sensing. *Rating*: Virtually certain.
- **Significantly Positive**
  - There will be increased growth and yield of upper-trophic-level species in commercial fisheries, but this effect will be dwarfed by current overfishing, marine pollution, and habitat destruction. *Rating*: Uncertain.
  - The Northwest Passage and the Northern Sea Route of Russia will be opened for routine shipping, reducing freight rates between East Asia and Western Europe. *Rating*: Very probable.

8.5.   Evaluation of the Impacts of Climate Change

8.5.1.   Resources and Products

In this chapter, the notion of mitigating impacts includes techniques of prevention or reduction in the scope or intensity of predicted effects. Adaptation means coping with or compensating for the rate of damage.

8.5.1.1.   Significantly Negative Impacts

Reported incidences of coral bleaching appear to be increasing in association with more-frequent ENSO events since 1982–83 (Glynn, 1989; Brown and Ogden, 1993). Coral mortality is positively correlated with the intensity and length of warming episodes (Glynn, 1989; Glynn and Croz, 1990), and recent paleoclimatic investigations of ENSO phenomena show that the coral record can be read as a proxy for increased SSTs, potentially over several thousand years (Cole *et al.*, 1992; Shen, 1993). Corals thrive in a temperature range of 25–28°C, but experimental and observed evidence indicates that mortality can be induced with even a 5°C increase in SST if exposure is prolonged beyond six months (Glynn and Croz, 1990). The

time required to induce mortality decreases as SST increases along a gradient of 1–4°C (Glynn, 1989).

Therefore, assuming a 2°C increase in average global temperature by 2050—as predicted by Working Group I—it is doubtful that either mitigation or adaptation would be possible. The magnitude of such an increase, in addition to the rapid rate of change, leaves virtually no margin for corrective action. If maximum temperatures in the tropics exceed an increase of 3°C for extended periods, the impact will be severe. Moreover, corals are already at risk from a wide variety of human activities on land and at sea. This additional risk severely compounds the problem.

Independent of coral bleaching, increased loading of land-based pollutants in the coastal ocean as a result of increased precipitation and atmospheric transport can be mitigated by significantly reducing current loading of land-based pollutants in the marine environment. This very difficult problem has received some scientific and legal attention at global and regional levels since the Stockholm Conference in 1972 and a great deal more since the UN Conference on Environment and Development in Rio de Janeiro in 1992. Indeed, a major international conference on land-based pollution of the marine environment was convened by the United Nations Environment Program (UNEP) in October 1995.

The legal infrastructure at the global level for combating land-based pollution of the marine environment appears to be adequate. The problems to be solved are increasing compliance with existing legal obligations and developing scientifically based policies that effectively respond to the land-based pollution problem (GESAMP, 1990). Effective regulation must be based on an understanding of the fate and transport of contaminants over space and time and the damage caused by these pollutants to the structure and function of aquatic ecosystems. Significant issues include the persistence of contaminants in the aquatic environments, their uptake by commercially important fish and shellfish, the nature of sublethal effects to marine and freshwater organisms, and the risk to humans (Capuzzo, l990).

In addition, competing legislative and institutional structures at national, regional, and global levels need to be harmonized and rationalized in order to avoid the inconsistencies in policy derived from piecemeal attempts to solve problems. In the formulation of policies, priority must be given to the most-toxic waste streams in order to curtail long-term damage. In this connection, it is important to focus particularly on nonpoint sources of pollution, especially agricultural and urban runoff, and to avoid placing the greatest burdens on estuaries and the coastal ocean. Policy formulation might most effectively emphasize risk assessment and risk management—in support of which the development of long-term monitoring capabilities and standardized databases will be particularly important (GESAMP, 1991).

If the frequency of tropical storms and hurricanes increases, there are no mitigating options available for either the offshore oil and gas industry or the shipping industry. The former will have to adapt by improving the design standards for offshore structures. For marine transportation, the issue of whether the frequency of storms increases is an important question that will affect ship operations, equipment, maintenance, and insurance. One possible adaptation may be in national regulations to avoid areas that are too dangerous or will put biological communities at risk—along with the technological means to provide early warning at sea. If the occurrence of extreme events increases, governments have the option of increasing the attention given to issues of institutional design to respond to disasters and acute emergencies, planning for such responses, and introducing effective training of personnel (Drabek, 1985, 1989).

8.5.1.2. *Mildly Negative Impacts*

Mitigation and adaptation options are available for the mildly negative impacts. Because the minimum temperature differential required for OTEC plants is 20°C (Charlier and Justus, 1993), the crucial question is to what extent the intermediate water will warm relative to the surface. Should the temperature differential become unfavorable, two corrective measures are at least theoretically possible for floating power plants: relocate the plant, or increase the depth of the cold-water pipe. However, both of these options are seriously constrained by cost, and increasing the depth of the pipe imposes maintenance requirements that are severe below about 450 m (Charlier and Justus, 1993). For marine transportation, if major ports experience significant increases in sediment deposition via river runoff, dredging is the obvious option—with associated increases in the costs of operation.

There is uncertainty with respect to the impact of increased global average temperature of magnitude 2°C on primary productivity, but much less so on the growth and development of species at higher trophic levels. However, the impact of global warming can be swamped by the combined effects of overfishing, increased marine pollution, and habitat degradation/destruction. Again, in this case both mitigation and adaptation options are available.

As detailed in Chapter 16, changes must be made in approaches to management so that fishing effort is controlled and sized to available resources. Control over land-based pollution of the marine environment, combined with control over habitat degradation/destruction, also will go a long way toward creating an environment in which fisheries can prosper.

Moreover, in marine ecosystems where the fish community has been altered through excessive fishing effort—causing cascading effects up the food chain to top predators and down to first and second trophic levels—it is possible to facilitate recovery of depleted species through the introduction of adaptive management techniques (e.g., Sherman, 1994).

8.5.1.3. *Neutral Impacts*

Except for hydrocarbon extraction in polar areas, marine mineral extraction will be largely insensitive to an increase in average global temperature on the order of 2°C. Hence, mitigation

and adaptation options are not required. Similarly, the source material for biotechnological/biomedical uses will not be affected by global warming, because most marine organisms living in the upper layers of the ocean can and do tolerate some degree of seasonal variations in temperature. Those living in the more-constant temperature depths are unlikely to be affected. Global warming will not have an effect on bioremediation applications. The most likely response to higher temperatures will be an increase in growth rate (hence, clean-up rate) of the organisms involved. It must be noted, however, that the changes in biodiversity due to global warming can be expected to have a certain degree of impact on these industries.

8.5.1.4.   *Mildly Positive Impacts*

There is no need for mitigation of the mildly positive impacts of global warming; the market-driven need will create its own adaptation, to which the marine instrumentation industry will respond. Growth within the marine instrumentation industry generated by the need to monitor climate change will be reflected in the design of new sensors to facilitate observation, measurement, and monitoring, as well as the adaptation of existing platforms to perform new functions. For instance, offshore oil and gas platforms are now seen as having value for monitoring dimensions of climatic change (MTSJ, 1993). The U.S. National Oceanic and Atmospheric Administration (NOAA) has organized the cooperation of platform operators into a network to provide time-series measurements for the Global Ocean Observation System (GOOS) program in the Gulf of Mexico. Such adaptation appears to be extremely cost-effective.

8.5.1.5.   *Significantly Positive Impacts*

Existing human-induced problems will swamp the significantly positive impacts of global warming on fisheries, and the same mitigation options outlined in Sections 8.5.1.1 and 8.5.1.2 relative to negative impacts on fisheries will apply in this case.

On the other hand, opening up the Northwest Passage and the Russian Northern Sea route for routine shipping for as much as 100 days a year (see Chapter 7) will provide significant benefits to many countries in terms of efficiency and speed of service and cost reduction that could translate into lower freight rates. At the same time, because both transportation and hydrocarbon exploitation will be facilitated by the reduction in ice cover in polar seas, the development of these regions for transportation and resource exploitation should be approached with great care. Stringent controls on pollution of these newly accessible regions will be necessary because ice will still retard clean-up possibilities for more than 200 days per year.

8.5.2.   *Ecology and Biodiversity*

In some cases, no reliable adaptation is possible for changes in ecology and biodiversity. For example, for large mammals

affected by the loss of ice cover, such as polar bears, no adaptation at all will be possible because of the loss of territory and loss of prey. In cases where adaptation options are available, they will vary according to the scale of the changes. If, for example, there is extirpation of a species, then carefully planned reintroductions may work. Survival of the species will then depend on the elimination of the stress factors that caused their extirpation. In the case of global extinctions, there is no adaptation possible. The consequences of an artificial restructuring of an ecosystem or community are at present unpredictable.

In the case of increases in species, eliminating successful exotics is rarely possible. Although the introduction of exotic predators is one possible option, our ability to predict the effects of such introductions is lacking. Depending on management goals, there could be successful introduction of exotics that make the system more useful to humans.

8.5.3.   *The Issue of Costs*

Critical to any discussion of adaptation options is the issue of costs. However, at present we do not have sufficiently detailed knowledge of the costs of the most important impacts of climate change on the human uses of the oceans and the available options to mitigate and adapt. Some of the impacts of global climate change are beneficial, some are neutral, and some are adverse. The costs and benefits will be transferred and/or apportioned either by governments or by markets, or by some combination thereof. Such transfers will have price effects, which could affect the competitiveness of ocean industries in relation to each other and their competitors on land. In some cases (e.g., the impacts of sea-level rise), the total burden of cost transfers is likely to be greatest on those least able to bear them (i.e., the poorest countries). It is likely that costs will vary in a nonlinear fashion, sometimes rising much more steeply than the temperature increase with time, especially for flood damages or agricultural impacts.

The point about the competitiveness of ocean industries in relation to their competitors on land requires further elaboration. By and large, it is more costly to work on the ocean than it is on land, and the risk is generally higher. Whether one is dealing with nonliving resources or any other kind of product, the critical issues are relative scarcity, substitutability of materials/products, extension of available resources as a result of technological innovation, or location and exploitation of previously uneconomic resources (Broadus, 1987). Increasing reliance on more costly resources tends to raise the price of extracted materials—prompting substitution, conservation, recycling, and exploration (Broadus, 1987).

Increasing or decreasing scarcity of resources is best reflected in the long-term market price (Broadus, 1987). However, if the practical utilization of a marine resource lies more than two decades into the future, the net present value of that resource is essentially zero because firms will consider that they do not have sufficient control over the relevant factors controlling the

cost of production and therefore price. The market's reluctance to act in these circumstances does not mean that nothing will be done. For strategic reasons, some governments may wish to subsidize exploration and even exploitation for varying lengths of time in some of these cases.

8.6. Multistress Factors

We have made the point that the coastal ocean is already under stress as a result of a combination of factors (e.g., increased population pressure in coastal areas, habitat destruction, increased land-based pollution, and increased river inputs of nutrients and other pollutants). In addition, increased UV-B radiation due to stratospheric ozone depletion is expected to impair the resilience of aquatic ecosystems to climate change. Smith *et al*. (1992) demonstrate that increased UV-B radiation has the effect of causing an estimated 6–12% reduction in primary productivity in the surface waters of the Southern Ocean during Austral spring. McMinn *et al*. (1994) conclude, on the other hand, that thick ice cover and the timing of the phytoplankton bloom in the Southern Ocean protect the phytoplankton from the adverse effects of increased UV-B radiation. A more comprehensive treatment of the subject is given by the Ozone Trends Panel (OTP).

Also of importance in the context of the impact of global warming is the debate about whether the phenomenon of coral bleaching is an effect solely of increased water temperature or increased UV-B radiation in the 280–400 nm band. Recent results suggest that bleaching of corals by increased UV-B radiation and by the temperature of surface waters appears to be independent of each other (Gleason and Wellington, 1993). These results are challenged, however, by Dunne (1994), who argues that the experimental controls do not conclusively rule out other factors such as the impact of photosynthetically active radiation (PAR) or synergistic effects between PAR and UV-B radiation on bleaching.

The effects of global climate change therefore will constitute a mixed series of impacts on an already overstressed context, with attendant opportunities for synergistic relationships between the stresses where the climate-change impacts are adverse. Synergy will accelerate the adverse impacts of these stresses. These burdens present a challenge and increase the urgency for the development of integrated coastal management responses at regional and global levels.

These multistress factors also make coastal areas much more vulnerable than the open ocean. Coastal states therefore may wish to consider controlling population density, habitat destruction, and land-based pollution. In this connection, the combination of existing trends of human-induced stress on the coastal environment with potential stresses generated by global climate change requires building the capability for planners and analysts to provide cumulative, integrated impact assessments (Gable *et al*., 1991). Databases to facilitate such assessments do not yet exist and need to be built. The criteria for designing such

databases include the need to "evaluate the exposure, response, risk, and vulnerability of cultural, economic, social, biological, and physiographical implications of global change and its local, basin-wide, regional, and interregional manifestations"; the cumulative effects of environmental variability on various time and space scales; the effects of minor but collectively significant events occurring over long timescales; and the potential for synergistic effects of interacting combinations superimposed on direct effects (Gable *et al*., 1991).

8.7. Research and Monitoring Needs and Strategies

In this section, we consider research and monitoring needs that will allow better understanding of the characteristics and functions of oceans that are most likely to be affected by a projected climate change; development of methodologies to assess the sensitivity of oceans to climate change; and formulation of pilot studies on potential impacts, thresholds and sensitivities, and mitigation/adaptation strategies:

- *Research activities to better understand processes in the oceans*, in particular the role of the oceans in the natural variability of the climate system at seasonal, interannual, and decadal to century timescales; the role of the Atlantic Ocean in climate variability; the role of the ocean in the hydrological cycle; the role of biological and biogeochemical processes in transient— decades to centuries—carbon storage in the deep sea

- *Long-term monitoring and mapping of*: water-level changes, ice coverage, and thermal expansion of the oceans; sea-surface temperature and surface air temperature; extratropical storms and tropical cyclones; changes in upwelling regimes along the coasts of California, Peru, and West Africa; UV-B radiation, particularly in polar regions, and its impact on aquatic ecosystems; regional effects on distribution of species and their sensitivity to environmental factors; changes in ocean biogeochemical cycles. These activities allow for better understanding of the processes that affect the stability and vulnerability of marine ecosystems and their spatial and temporal variability. They also allow for better assessment of climate change-induced rates and the direction of changes and processes in oceans that already are impacted by other factors.

- *Socioeconomic research activities* to document human responses to global environmental change, such as the establishment of databases on patterns of human responses to global and regional environmental changes; the assessment of the transfer costs and economic effects of global and regional climate change; the development of alternative approaches to mitigation and adaptation, as well as policy design; and assessment of the synergistic effects of sectoral approaches to policy implementation

- *Strategies for implementation* of these monitoring and research needs could include national and international environmental and climate research programs to

consider research and monitoring components specifically designed to investigate the impact of climate change, taking into account the specific regional and national needs based on the pattern of the respective human response to global and environmental changes; and formal coordination between IPCC and other international environmental and climate research and monitoring activities organized by, for example, the International Geosphere-Biosphere Programme (IGBP) and the World Climate Research Programme (WCRP), to pool expertise and efforts to better monitor aspects of climate change and its impacts, as well as to formulate policy options. Because modeling and monitoring depend on actual knowledge and technological capabilities, there also is considerable room for improvement in the level of communication between modelers and monitors in order to improve the state of the art and prediction capabilities.

It must be noted that research programs, by definition, are focused on a topic or problem, have an underlying approach, and promise results in a given time and funding frame. Furthermore, research topics change over longer times. In contrast, monitoring must be protected from such changes because the use of time series depends on the absence of changes in data-collection methods. Institutional research or scientific establishments with a longer breadth, such as government research laboratories, need to be encouraged to get their particular expertise rolled out: long-term maintenance of monitoring and research programs. Especially in view of the need to support long-term observations (observing systems such as GOOS, GCOS, GTOS, etc.) and the complex nature of the issues at hand, it will be necessary to pool the expertise and efforts of individual research institutions and governmental research laboratories actively and intimately.

CONTENTS

EXECUTIVE SUMMARY

Coastal zones and small islands are characterized by highly diverse ecosystems that are important as a source of food and as habitat for many species. They also support a variety of economic activities—which, in many places, has led to a high rate of population growth and economic development. Many studies indicate that overexploitation of resources, pollution, sediment starvation, and urbanization have:

- Led to a decrease in the resilience of coastal systems to cope with natural climate variability (High Confidence)
- Adversely affected the natural capability of these systems to adapt to changes in climate, sea level, and human activities (High Confidence)
- Led to increased hazard potential for coastal populations, infrastructure, and investment (High Confidence).

As demands on coastal resources continue to increase with a growing population and expanding economic activity, coastal systems continue to face increasing pressures, which often lead to the degradation of these systems. In many parts of the world, for example, coastal wetlands are presently disappearing due to human activities.

Since the IPCC First Assessment Report (1990) and its supplement (1992), the interrelationships between the impacts of climate change and human activities have become better understood. Although the potential impacts of climate change by itself may not always be the largest threat to *natural coastal systems*, in conjunction with other stresses they can become a serious issue for *coastal societies*, particularly in those places where the resilience of natural coastal systems has been reduced. Taking into account the potential impacts of climate change and associated sea-level rise can assist in making future development more sustainable. A proactive approach to enhance resilience and reduce vulnerability would be beneficial to coastal zones and small islands both from an environmental and from an economic perspective. It is also in line with the recommendations of the UN Conference on Environment and Development (UNCED) Agenda 21. Failure to act expeditiously could increase future costs, reduce future options, and lead to irreversible changes.

Important findings by Working Group I that are of relevance to coastal impact assessment include the following:

- Current estimates of global sea-level rise represent a rate that is two to five times higher than what has been experienced over the last 100 years (High Confidence).

- Locally and regionally, the rate, magnitude, and direction of sea-level changes will vary substantially due to changes in ocean conditions and vertical movements of the land (High Confidence).
- It is not possible to say if the intensity, frequency, or locations of cyclone occurrence would change in a warmer world (High Confidence).

Since 1990, there has been a large increase in research effort directed at understanding the biogeophysical effects of climate change and particularly sea-level rise on coastal zones and small islands. Studies have confirmed that low-lying deltaic and barrier coasts and low-elevation reef islands and coral atolls are especially sensitive to a rising sea level, as well as changes in rainfall, storm frequency, and intensity. Impacts could include inundation, flooding, erosion, and saline intrusion. However, it has also been shown that such responses will be highly variable among and within these areas; impacts are likely to be greatest where local environments are already under stress as a result of human activities.

Studies of natural systems have demonstrated, among other things, that:

- The coast is not a passive system but will respond dynamically to sea-level and climate changes (High Confidence).
- A range of coastal responses can be expected, depending on local circumstances and climatic conditions (High Confidence).
- In the past, estuaries and coastal wetlands could often cope with sea-level rise, although usually by migration landward. Human infrastructure, however, has diminished this possibility in many places (High Confidence).
- Survival of salt marshes and mangroves appears likely where the rate of sedimentation will approximate the rate of local sea-level rise (High Confidence).
- Generally, coral reefs have the capacity to keep pace with projected sea-level rise but may suffer from increases in seawater temperature (Medium Confidence).

The assessment of the latest scientific information regarding socioeconomic impacts of climate change on coastal zones and small islands is derived primarily from vulnerability assessments based on the IPCC Common Methodology. Since 1990, many national case studies have been completed, embracing examples of small islands, deltas, and continental shorelines from around the world. These studies mainly utilize a scenario

of a 1-m rise in sea level and generally assume the present socioeconomic situation, with little or no consideration of coastal dynamics. There is concern that these studies understate nonmarket values and stress a protection-orientated response perspective. Despite these limitations, these studies provide some important insights into the socioeconomic implications of sea-level rise, including:

- Sea-level rise would have negative impacts on a number of sectors, including tourism, freshwater supply and quality, fisheries and aquaculture, agriculture, human settlements, financial services, and human health (High Confidence).
- Based on first-order estimates of population distribution, storm-surge probabilities, and existing levels of protection, more than 40 million people are estimated to experience flooding due to storm surge in an average year under present climate and sea-level conditions. Most of these people reside in the developing world. Ignoring possible adaptation and likely population growth, these numbers could roughly double or triple due to sea-level rise in the next century (Medium Confidence).
- Protection of many low-lying island states (e.g., the Marshall Islands, the Maldives) and nations with large deltaic areas (e.g., Bangladesh, Nigeria, Egypt, China) is likely to be very costly (High Confidence).
- Adaptation to sea-level rise and climate change will involve important tradeoffs, which could include environmental, economic, social, and cultural values (High Confidence).

Until recently, the assessment of possible response strategies focused mainly on protection. There is a need to identify better the full range of options within the adaptive response strategies: protect, accommodate, and (planned) retreat. Identifying the most appropriate options and their relative costs, and implementing these options while taking into account contemporary conditions as well as future problems such as climate change and sea-level rise, will be a great challenge in both developing and industrialized countries. It is envisaged that the most suitable range of options will vary among and within countries. An appropriate mechanism for coastal planning under these varying conditions is integrated coastal zone management. There is no single recipe for integrated coastal zone management; rather, it constitutes a portfolio of sociocultural dimensions and structural, legal, financial, economic, and institutional measures.

Integrated coastal zone management, which has already started in many coastal countries, is a continuous and evolutionary process that identifies and implements options to attain sustainable development and adaptation to climate change in coastal zones and small islands. Constraints that could hinder its successful implementation include, but are not limited to:

- Technology and human resources capability
- Financial limitations
- Cultural and social acceptability
- Political and legal frameworks.

Continued exchange of information and experience on the inclusion of climate change and sea-level rise within integrated coastal zone management at local, regional, and international levels would help to overcome some of these constraints. In addition, more research is required on the *process* of integrated coastal zone management to improve the understanding and modeling capability of the implications of climate change and sea-level rise on coastal zones and small islands, including biogeophysical effects, the local interaction of sea-level rise with other aspects of climate change, and more complete assessment of socioeconomic and cultural impacts.

9.1.   Introduction

Coastal zones and small islands contain some of the world's most diverse and productive resources. They include extensive areas of complex and specialized ecosystems, such as mangroves, coral reefs, and seagrasses, which are highly sensitive to human intervention. These ecosystems are the source of a significant proportion of global food production. Moreover, they support a variety of economic activities, including fisheries and aquaculture, tourism, recreation, and transportation. In recent decades, many coastal areas have been heavily modified and intensively developed, which has significantly increased their vulnerability to natural coastal dynamics and the anticipated impacts of global climate change.

Many attempts have been made to define the "coastal zone" and its land and seaward boundaries. Some definitions are based on physiographic characteristics, such as the extent of tidal influence on the land or the geomorphology of the continental shelf; others simply use a fixed distance from the shoreline. In the case of small islands, the coastal zone could include the entire island. While the boundaries of the coastal zone may or may not coincide with political or administrative boundaries, they rarely coincide with those of areas from which demands on the resources of the coastal area are derived (Ehler, 1993).

Irrespective of how coastal zones are defined, the following characteristics, which are strongly interrelated, often make them distinctive from other areas:

- A high rate of dynamic changes in the natural environment
- A high biological productivity and diversity
- A high rate of human population growth and economic development
- A high rate of degradation of natural resources
- Exposure to natural hazards such as cyclones and severe storms
- The need for management regimes that address both terrestrial and marine issues.

The global importance of coastal zones and small islands in terms of both ecological and socioeconomic values is widely recognized. Many international organizations, including IPCC, have called for action to implement strategies toward better planning and management of coastal areas and resources to prevent them from being degraded and becoming progressively more vulnerable to the potential impacts of climate change and associated sea-level rise. The World Coast Conference, partly held under the auspices of IPCC, has supported the Framework Convention on Climate Change (UNCED, 1992a) and Agenda 21, Chapter 17 (UNCED, 1992b), requiring action on coastal zone management planning, among many other initiatives, by all signatories (WCC'93, 1993).

This chapter presents an assessment of the latest scientific information on the impacts of climate change on coastal zones and small islands and on strategies that countries may wish to apply in response to these impacts. It builds on the previous IPCC assessments carried out in 1990 and 1992 and on the work of the former Coastal Zone Management Subgroup (CZMS) of IPCC. The chapter concentrates on the scientific work completed since 1990, although earlier work is acknowledged where appropriate.

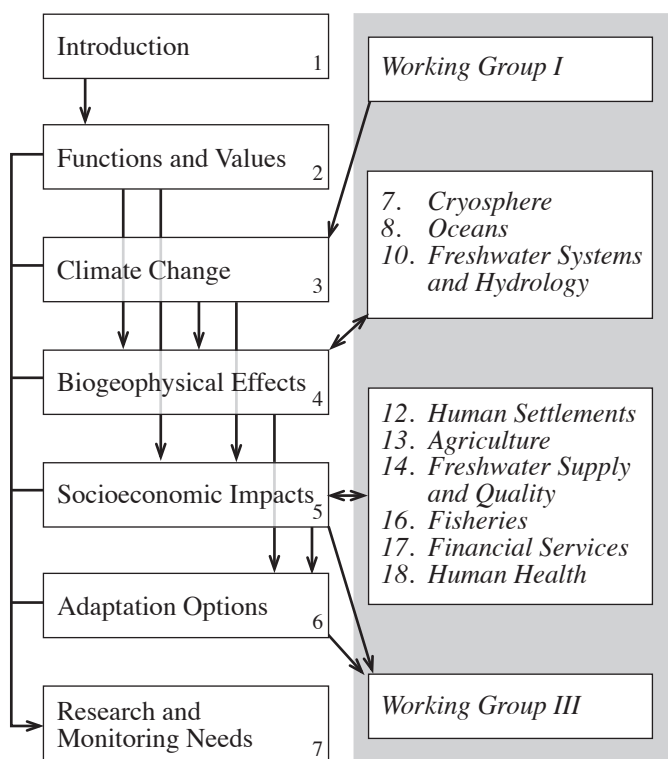
The structure of this chapter is schematically depicted in Figure 9-1. This figure also shows how this chapter relates to other chapters and Working Group reports of this IPCC Second Assessment Report. In Section 9.2, the functions and values of coastal zones and small islands are discussed. Special emphasis is put on the importance of maintaining the proper functioning of coastal systems with regard to sustainable development and their resilience to climate change. Section 9.3 then discusses the likely consequences of climate change on sea-level rise, sea-surface temperatures, and tropical cyclones in the context of coastal zones and small islands. On this basis, Section 9.4 addresses the effects of climate change on biogeophysical systems, and Section 9.5 examines the socioeconomic impacts. Section 9.6 considers response strategies to climate change and the need to integrate them with other coastal management activities. Finally, Section 9.7 identifies needs and opportunities for future research and monitoring that would help nations to respond more appropriately to the likely impacts of climate change on coastal zones and small islands.


Figure 9-1: Structure of this chapter and interrelationships with other chapters and Working Group volumes of the IPCC Second Assessment Report.

9.2. Functions and Values of Coastal Zones and Small Islands

In large measure, human social and economic well-being depends directly or indirectly on the availability of environmental goods and services provided by marine and coastal systems. Coastal zones and small islands are characterized by highly diverse ecosystems, and a great number of functions are performed over a relatively small area. This concentration of functions, together with their spatial location, makes coastal zones and small islands highly attractive areas for people to live and work in. Coastal human populations in many countries have been growing at double the national rate due to migration to urban coastal centers; it is estimated that 50–70% of the global human population lives in the coastal zone, although there are great variations among countries. The existing rate of socioeconomic development in coastal zones also is unprecedented (WCC'93, 1994).

9.2.1. Functions and Values

The total economic value of coastal systems is more than simply the financial value of the coastal resources that they produce. It also includes their role in regulating the environment, their satisfaction of subsistence needs, and their satisfaction of human intellectual and emotional needs. De Groot (1992a) and Vellinga *et al.* (1994) have categorized the environmental functions performed by natural systems as regulation functions, user and production functions, and information functions. *Regulation functions* are crucial in safeguarding environmental

quality. They include regulation of erosion and sedimentation patterns, regulation of the chemical composition of the atmosphere and oceans, flood prevention, waste assimilation, maintenance of migration and nursery habitats, and maintenance of biological diversity. Many natural and seminatural coastal systems thus play a fundamental part in the regulation of essential biospheric processes that contribute to the maintenance of a healthy environment and the long-term stability of the biosphere, including the climate system. *User and production functions* are essential in providing many living and nonliving resources that are utilized by human society. These functions include the provision of space and a suitable substrate for human habitation and a variety of socioeconomic activities. Important socioeconomic activities in coastal zones and small islands include tourism and recreation, exploitation of living and nonliving resources (e.g., fisheries and aquaculture; agriculture; extraction of water, oil, and gas), industry and commerce, infrastructure development (e.g., harbors, ports, bridges, roads, sea-defense works), and nature conservation. *Information functions* relate to the part that nature plays in meeting human intellectual and emotional needs. For example, coastal systems can be a source for cultural inspiration, but they also serve as a storehouse for genetic information. Also, scientific understanding of coastal processes and evolution depends on the geological and biological information that coastal systems contain.

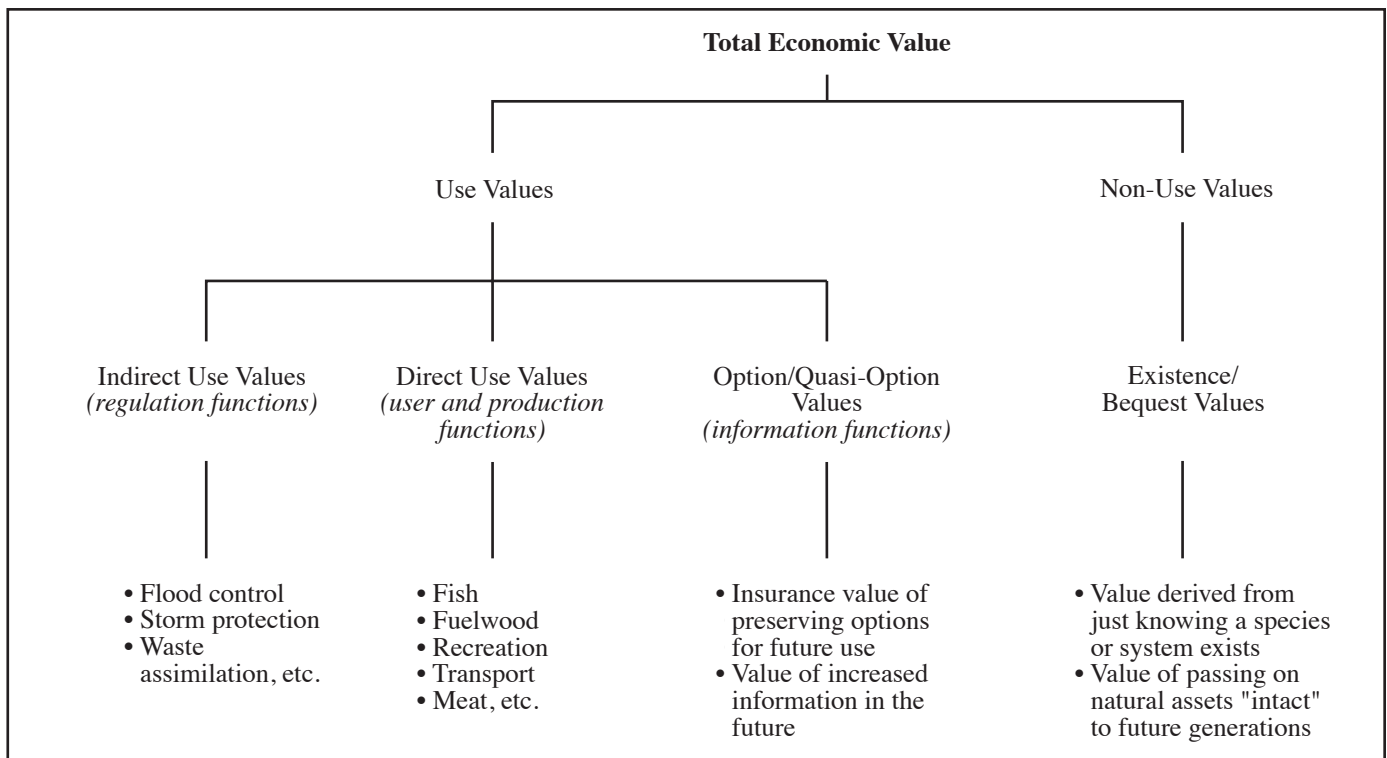
Any coastal system can yield values related to the direct, indirect, and future use of the functions described above, as well as non-use, or intrinsic, values (Turner, 1988, 1991; Barbier, 1994). This is illustrated by Figure 9-2. Empirical


Figure 9-2: Values of coastal systems (adapted from Barbier, 1989).

studies confirm that coastal systems possess significant economic value, in terms of both use and non-use outputs. Mangrove forests, for example, have been shown to sustain more than 70 direct human activities, ranging from fuelwood collection to artisinal fisheries (Dixon, 1989). However, some uses preclude others, so some caution is necessary when the total economic value of such a system is estimated. This caution is also justified by the fact that many functions provide nonmarket goods and services and therefore do not carry appropriate market prices and value. Moreover, individuals and communities may find that nature has a value of its own, independent of human use or perception. They would therefore value nature purely because it exists and would feel a loss if it was damaged or destroyed.

Nonetheless, some studies are available that have produced estimates of the monetary value of coastal functions, using a variety of techniques. For example, recreation and amenity benefits provided by the Broadlands coastal wetland in England are estimated to be around $5 million per year (Bateman *et al.*, 1995). The storm buffering function of the Terrebonne coastal wetlands in Louisiana (United States) has been valued in terms of storm damage avoided. If the wetlands continue to recede at their present rate (3–4 m/yr), the present discounted value of increased expected property damage lies between $2.1–3.1 million (Constanza *et al.*, 1989). The total monetary value of all functions performed in the Ecuadorian Galápagos National Park amounts to $138 million per year (De Groot, 1992a).

9.2.2. *Sustainable Development*

In most coastal nations, a considerable part of gross national product (GNP) is derived from activities that are directly or indirectly connected with coastal zones. Therefore, maintaining the proper functioning of marine and coastal systems is of significant concern to a country's economy. In the shorter term, however, large financial benefits may be available at the expense of longer-term sustainability. Many coastal problems that are currently being encountered worldwide can be attributed to the unsustainable use and unrestricted development of coastal areas and resources. These problems include the accumulation of contaminants in coastal areas, erosion, and the rapid decline of habitats and natural resources. Great care must therefore be taken in planning to avoid overdevelopment and degrading or destroying the very environment that attracted coastal development in the first place.

Nonetheless, increasingly large areas of coasts and small islands have been managed with the aim of maximizing the financial "resource take" provided by the user and production functions performed by coastal systems. However, when one particular function is overexploited, this may not only result in the depletion of the resources that this function provides; it can also reduce the performance of other functions below their full potential. For example, when mangroves are logged and cleared in an unsustainable way, it can be at the expense of functions that enable fish to breed and be caught in the same area or that protect the coast from being eroded. The same applies when the capacity of regulation functions is exceeded—for example, when coastal waters are polluted beyond their waste-assimilative capacity. The maintenance of all functions at a sustainable level would provide higher economic returns over a longer period of time.

One can state that sustainable development in coastal zones and small islands is realized only when it enables the coastal system to self-organize—that is, to perform all its potential functions without adversely affecting other natural or human systems. Climate change could pose an additional threat to the full performance of these functions, compounding the pressures that present-day development activities already place on coastal zone capacities. Overexploitation of resources, pollution, sediment starvation, and urbanization may inhibit or destroy the working of functions that are essential to the provision of goods and services that are difficult to value in monetary terms, or in maintaining the resilience of coastal ecosystems to external stresses, such as climate change. For instance, one important regulation function of natural systems in coastal zones and small islands is the provision of a buffering capacity, protecting the land against the dynamics of the sea. As climate changes and sea level rises, this function will become even more important than it is today, preventing coastal areas from being eroded and inundated as much as they would without this natural protection. Nevertheless, although present-day human activities often result in large financial payoffs in the short term, they may also lead to environmental degradation. Such degradation results in the loss of functions, may increase coastal vulnerability to climate change, and has adverse economic effects on tourism, fishing, and other aspects of the coastal economy. In some cases, the long-term costs of these environmental disruptions may be greater than the long-term benefits of the human activity that caused them.

9.3. Aspects of Climate Change of Concern to Coastal Zones and Small Islands

Sea-level rise and possible changes in the frequency and/or intensity of extreme events, such as temperature and precipitation extremes, cyclones, and storm surges, constitute the components of climate change that are of most concern to coastal zones and small islands. Short-term extreme events are superimposed on long-term changes in CO_2 concentrations, climate, and sea level, and all aspects work in concert to bring about environmental change at regional and local levels. In order to understand fully their interactive effects on the coast, it is paramount to know how the means, variability, and extremes of the range of relevant climatic elements will change at local and regional scales. At such scales—with possibly a few exceptions—the predictive capability of models is currently very low, and knowledge about possible future changes in variability and extremes is meager. This section summarizes the main findings regarding sea-level and climate change that pertain to coastal zones (see the IPCC Working Group I volume for a full discussion).

9.3.1.   Sea-Level Rise

9.3.1.1.   Global Projections

In 1990, IPCC provided a best estimate and a range of uncertainty of sea-level rise, based on a "business-as-usual" projection of greenhouse-gas emissions for the period 1990–2100. It was estimated that sea level would, on average, rise by about 6 mm/yr, within a range of uncertainty of 3–10 mm/yr (Warrick and Oerlemans, 1990). Subsequent to IPCC90, projections of sea-level rise have been lower, largely as a result of downward revisions in the rate of global warming, which drives sea-level rise (see Section 9.3.2).

Present estimates of sea-level rise have been presented in Chapter 7, *Changes in Sea Level*, of the IPCC Working Group I volume. For a forcing scenario (IS92a) comparable to that of the IPCC 1990 assessment, it is estimated that sea level would, on average, rise by about 5 mm/yr, within a range of uncertainty of 2–9 mm/yr (see Figure 9-3). An important point to bear in mind is that the current best estimates represent a rate of sea-level rise that is about two to five times the rate experienced over the last 100 years (i.e., 1.0–2.5 mm/yr). The current projections of sea-level rise should therefore be of major concern in the context of coastal zones and small islands. Furthermore, model projections show that sea level will continue to rise beyond the year 2100 due to lags in climate response, even with assumed stabilization of global greenhouse-gas emissions (Wigley, 1995).

9.3.1.2.   Regional Implications

One cannot assume that changes in sea level at regional and local levels will necessarily be the same as the global-average change, for two broad reasons. First, vertical land movements affect sea level. With respect to the coastal environment, it is relative sea level that is most important—that is, the level of the sea in relation to that of the land. Regionally and locally, vertical land movements can be quite large, even on the decadal time scale. For example, parts of Scandinavia experience uplift (and thus a relative sea-level decline) of about 1 m per century due to the continuing "glacial rebound" following the contraction of the large continental ice sheets at the end of the last Ice Age some 10,000 years ago (Aubrey and Emery, 1993). In contrast, the Mississippi delta is experiencing subsidence (a relative sea-level rise) of about 1 m per century due to consolidation by sediment loading and the diminished supply of additional sediments to the delta required for accretion (Day *et al.*, 1993; Boesch *et al.*, 1994). Locally, tectonic activity, groundwater pumping, and petroleum extraction can cause large and sometimes abrupt changes in relative sea level (Milliman *et al.*, 1989; Han *et al.*, 1995b). Subsidence of urban areas due to groundwater withdrawal has been a significant problem in many locations. In Japan, for example, 2.1 million people live in protected areas below high water due to this cause. Box 9-1 includes four examples of observed sea-level change. Emery and Aubrey (1991) have provided a comprehensive discussion of the
Figure 9-3: 1990–2100 sea-level rise for scenario IS92a (see Chapter 7, *Changes in Sea Level*, of the Working Group I volume).

Box 9-1. Four Examples of Observed Sea-Level Change

Figure 9-4 shows tide-gauge measurements of sea-level changes in Stockholm (Sweden), Fort Phrachula (Bangkok, Thailand), Honolulu (Hawaii, United States), and Nezugaseki (Japan). In a period of rising global sea levels, these four places show different trends in sea-level change due to their being situated in different geological settings. This illustrates the importance of local conditions on relative sea level. In Stockholm, glacial rebound is causing the land to rise out of the sea, resulting in a sea-level fall relative to the land of ~4 mm/yr. In Bangkok, human influence is apparent: Although over the period 1940–1994 relative sea-level rise averages 13.19 ± 0.73 mm/yr, two separate trends can be distinguished; the first, until about 1960, averages ~3 mm/yr, and the second, from 1960 onward, is ~20 mm/yr. The latter trend reflects the increased effort in groundwater pumping since 1960 (Emery and Aubrey, 1991). Nezugaseki shows the dramatic effects of an earthquake, which caused a 15-cm land submergence in 1964, along a coast generally dominated by emergence (Emery and Aubrey, 1991). The Honolulu record is believed to reflect a stable site and it is the only one of the four examples that approximates the global trend.

Figure 9-4:   Relative sea-level records for Stockholm, Fort Phrachula (Bangkok), Honolulu, and Nezugaseki, indicating the geological settings and observed trends of the four sites (data provided by the Permanent Service for Mean Sea Level, Bidston).
effects of vertical land movements on relative sea level. In assessing coastal impacts, such vertical land movements must be considered in conjunction with climate-related changes in sea level.

Second, there are dynamic effects resulting from oceanic circulation, wind and pressure patterns, and ocean-water density that cause variations in the level of the sea surface with respect to the geoid—that is, the surface that the ocean would describe in the absence of currents, winds, and so forth. These variations have been observed to be on the order of 1 m for major current systems such as the Gulf Stream, Kuroshio, and the Antarctic Circumpolar Current (Pugh, 1987; Levitus, 1982). Climate change may affect ocean circulation, which can result in regional changes of this sea-surface "topography." Recent advances in ocean-atmosphere modeling offer some idea of the possible magnitude of such changes (e.g., Mikolajewicz *et al.*, 1990; Gregory, 1993; Murphy, 1992; Church *et al.*, 1991; Cubasch *et al.*, 1992). Model results show ranges of regional sea-level change that are on the order of two to three times the global-average change (see Box 8-2 in Chapter 8). However, it should be emphasized that confidence in coupled ocean-atmosphere model predictions of regional sea-level changes still must be considered low, as reliable regional scenarios of this effect are not yet available for impact analysis.

9.3.2.   Climate Changes

One of the certainties regarding global climate change is that the *atmospheric concentration of carbon dioxide* (the major player among the greenhouse gases), now about 360 ppmv, has increased by about 29% over the preindustrial concentration and will continue to increase in the future, even if rather stringent policies on CO_2 emissions were adopted. Although controversial, there is some evidence that increased CO_2 would lead to significant increases in net primary productivity through enhanced photosynthesis (Melillo *et al.*, 1993), which could potentially have far-reaching implications for coastal vegetation and the coastal environment.

Recent projections of *global warming* (Mitchell and Gregory, 1992; Wigley and Raper, 1992; see also Chapter 6, *Climate Models—Projections of Future Climate*, of the IPCC Working Group I volume) are somewhat lower than those presented in IPCC90 (about 0.2°C per decade, as compared to 0.3°C per decade averaged over the next century). Nonetheless, the best-estimate projection still falls within a very large range of uncertainty. Thus, such projections are plausible scenarios of what could occur, not necessarily of what will occur. This caution should be applied even more emphatically to regional details of climate change as they are derived from general circulation models (GCMs). While refinements have been made since

IPCC90, the overall judgment is that confidence in the predicted patterns of climate change at spatial scales relevant to coastal zones and small islands must still be regarded as low (Gates *et al*., 1992, 1990; Mitchell *et al*., 1990; McGregor and Walsh, 1993). Nonetheless, there are some broad regional results that are consistently produced by equilibrium and transient GCM experiments that have relevance to the coastal zone. These results include (Mitchell *et al*., 1990; Gates *et al*., 1992):

- The mean surface air temperature increases more over land than over oceans (by about a factor of two), and at higher latitudes during winter. The climate of the coastal zone tends to be moderated by ocean temperature and will thus be strongly influenced by sea-surface temperature changes. Northern Hemisphere warming is greater than Southern Hemisphere warming because of the larger extent of land.
- In general, global models show increases in precipitation throughout the year in the high latitudes and during the winter in mid-latitudes. Most models show some increase in Asian monsoon rainfall.
- At scales relevant to coastal zones and small islands, predictions of changes in other climate elements, such as windiness, storminess or radiation, cannot yet be considered reliable.

Although changes in *sea-surface temperatures* (SSTs) are projected to be less than those on land, they are not necessarily less significant. As Edwards (1995) has pointed out, a 2°C change in SST in the tropical and subtropical oceans is considered to be anomalous, but is on the order of temperature changes associated with strong El Niño/Southern Oscillation (ENSO) events. In comparison, the projected change in mean sea-surface temperature for these regions is on the order of 1–2°C by the year 2100. Thus, by 2100, SSTs that are now considered anomalous could well be normal occurrences. Such warming would be unprecedented in the recent geological past.

Tropical cyclones (also known as hurricanes or typhoons, depending on region) affect vast coastal areas in tropical and subtropical countries. Tropical cyclones and associated storm surges can cause enormous loss of life and have devastating impacts on coastal ecosystems and morphology. It is therefore of critical importance to know how the frequency, magnitude, and areal occurrence of such storms will change in a warmer world, if at all. Unfortunately, the evidence from theoretical and numerical models and from observational data is, as yet, inconclusive. While current GCMs provide some indication of possible tropical cyclone formation, identifying "tropical disturbances" (e.g., see Broccoli and Manabe, 1990; Haarsma *et al*., 1993), they cannot explicitly model such storms at the present grid-scale resolution (Mitchell *et al*., 1990). However, recent work has been moving in this direction (e.g., Bengtsson *et al*., 1994). Alternatively, theoretical storm models have been used to examine the maximum storm intensity in relation to SSTs (Emanuel, 1987) but cannot easily be extended to address questions of regional changes in tropical storm intensity or frequency under conditions of climate change (Schlesinger, 1993; Lighthill *et al*., 1994).

At present, there is no evidence of any systematic shift in *storm tracks*. The tracks are governed by the location of cyclogenesis and prevailing meteorological conditions; thus far, there is no evidence of shift in the preferred locations of cyclogenesis. Empirical studies have found correlations between ENSO and the regional patterns of tropical cyclone activity (as well as the Southeast Asian monsoon, Atlantic hurricanes, Pacific precipitation patterns, and other phenomena) (Nicholls, 1984; Evans and Allan, 1992; see also Chapter 3, *Observed Climate Variability and Change*, of the IPCC Working Group I volume). Progress is being made on model simulations of the present features of ENSO-like events (e.g., Philander *et al*., 1992), which could lead to a predictive capability for the future. Recent coupled-model simulations under enhanced CO_2 show a tendency toward ENSO-like patterns in the Pacific, with accompanying temperature and precipitation variability (see Chapter 6, *Climate Models—Projections of Future Climate*, of the IPCC Working Group I volume), but realistic simulations of ENSO are not yet possible. The behavior of ENSO is critical in understanding the future coastal effects of both climate change and sea-level rise in the Pacific region and elsewhere (Pittock and Flather, 1993; Pittock, 1993). In short, it is not yet possible to say whether either the intensity or frequency of tropical cyclones (or ENSO) would increase or the areas of occurrence would shift in a warmer world.

Despite the often repeated assertion that *climate variability* could increase in a warmer world, there is little evidence from climate models to support this notion (Gates *et al*., 1992). However, Working Group I has identified at least one exception that has potentially large implications for coastal areas: Various GCMs consistently predict a higher frequency of convective precipitation in mid- to high-latitude regions of the world. This anticipated change may imply more intense local rainfall, with a decrease in the return period of extreme rainfall events (e.g., Gordon *et al*., 1992). This could interact with sea-level rise to further increase the likelihood of flooding in low-lying coastal areas (Titus *et al*., 1987; Nicholls *et al*., 1995).

Without any change in variability, however, a change in mean value still implies a change in the frequency of *extreme events*. Because such events by definition are at the tails of the probability distribution, the change in return periods can be quite large relative to the change in mean value. In the absence of information about changes in variability, this simple concept has been employed to create scenarios of changes in extremes—for example, for temperature in Britain (Warrick and Barrow, 1991), rainfall in Australia (Pittock *et al*., 1991), and storm surges in the United States (Stakhiv *et al*., 1991). As has been pointed out at the beginning of this section, in most cases it is the combination of climate extremes—temperature, precipitation, winds, sea levels—and how they are affected by longer-term changes in climatic means that are especially important for considering the future effects of global warming on coastal zones and small islands. Yet little understanding of the possible interaction of different aspects of climate change in the coastal zone exists.

9.4. Biogeophysical Effects

In the 1990 IPCC Impacts Assessment, Tsyban *et al.* (1990) suggested that the most important aspects of climate change on the coastal zone would be the impact of sea-level rise on coastal residents and marine ecosystems. They argued that a rise in sea level would:

* Inundate and displace wetlands and lowlands
* Erode shorelines
* Exacerbate coastal storm flooding
* Increase the salinity of estuaries, threaten freshwater aquifers, and otherwise impair water quality
* Alter tidal ranges in rivers and bays
* Alter sediment depositional patterns
* Decrease the amount of light reaching water bottoms.

It was recognized then—and highlighted again in the IPCC 1992 supplement (Tsyban *et al.*, 1992) and at the meeting *The Rising Challenge of the Sea* (IPCC CZMS, 1992; O'Callahan, 1994)—that such effects would not be uniform around the world and that certain coastal environments would be especially at risk. These included tidal deltas and low-lying coastal plains, sandy beaches and barrier islands, coastal wetlands, estuaries and lagoons, mangroves, and coral reefs. Small islands became a major focus of concern because some of the more extreme predictions foreshadowed that low atoll and reef islands would completely disappear or become uninhabitable, with the total displacement of populations of several small island nations (Roy and Connell, 1991).

Many of the early studies on the effects of climate change emphasized sea-level rise and were based on a simple inundation model that vertically shifted the land-sea boundary landward by the amount of the projected global rise. However, it has become increasingly clear from recent studies that the geomorphological and ecological responses to a rising sea level will be complex and will also reflect a large number of other factors, including other aspects of climate change. No longer can effects be defined simply in terms of inundation of the sea upon the land, nor by just shifting the land-sea contour by an amount corresponding to the projected vertical increase in global sea level. Biogeophysical effects will vary greatly in different coastal zones around the world because coastal landforms and ecosystems are dynamic and both respond to and modify the variety of external and internal processes that affect them. Effects will depend not only on the local pattern of sea-level rise and climate change (as shown in Section 9.3) but also on the nature of the local coastal environment and on the human, ecological, and physical responsiveness of the particular coastal system being considered (J.R. French *et al.*, 1995).

Since the IPCC 1990 assessment, considerable progress has been made in understanding the effects of sea-level rise and climate change on coastal geomorphological and ecological systems. Studies have shifted from the use of simple, monothematic approaches to more complex yet pragmatic methods (Woodroffe, 1994). Three groups of approaches can be distinguished:

* Retrospective studies concerned with reconstructing past geomorphological and ecological responses to sea-level change in the Holocene, particularly during its rising stage
* Contemporary studies of geomorphological and ecological trends over the past several decades
* Mathematical and simulation modeling of coastal geomorphological and ecological systems using simplified sea-level rise scenarios and process assumptions.

In all three cases, emphasis has been on sea-level rise, with little consideration of other climate-change aspects, although sometimes increased seawater temperatures and storminess have been included. Invariably, global sea-level rise scenarios have been applied, irrespective of their appropriateness at the local or regional level. Further, several authors (e.g., Bird, 1993a; J.R. French *et al.*, 1995) have argued that it is not always appropriate to employ Holocene stratigraphical reconstructions as analogues for the future behavior of coastal systems, primarily because of the modern complications of human impacts that may now have an overriding effect on geomorphological and ecological responses.

In spite of the increased research effort, there is still no generally accepted global typology of coastal types relating to the potential effects of sea-level rise and climate change. There have been some attempts based on the resistance of the coast to environmental forces (e.g., Van der Weide, 1993), some based on both natural and socioeconomic features and processes (Pernetta and Milliman, 1995), and some through the development of a coastal vulnerability index that captures the different characteristics of a coastal region (e.g., Gornitz, 1991). The development of such a typology is clearly an area for substantial international research in the future. Moreover, the emphasis of recent studies on coastal types has been quite uneven. For instance, there has been little research on the potential effects of sea-level rise and climate change on high-latitude coasts, bold coasts, rocky shores, coastal cliffs, coarse clastic coasts, gravel barriers, coastal sand dunes, and seagrass beds. This lack of emphasis, however, does not necessarily imply that anticipated effects on these coastal types are less serious. Studies that show a strong correlation between sea-level rise and erosion of, for example, coastal cliffs, gravel barriers, and sand dunes include Griggs and Trenhaile (1994), Carter and Orford (1993), and Van der Meulen *et al.* (1991), respectively.

There are several comprehensive reviews on the biogeophysical effects of climate and sea-level change on coastal environments (e.g., Bird, 1993b; Oude Essink *et al.*, 1993; Wolff *et al.*, 1993). In addition to these general reviews there is a series of regional summaries covering a large area of the world—including the Mediterranean (Jeftic *et al.*, 1992), European coastal lowlands (Tooley and Jelgersma, 1992), Southeast Asia (Bird, 1993a), the South Pacific (Hay and Kaluwin, 1993), wider Caribbean (Maul, 1993), the Western Hemisphere

(Ehler, 1993), and the Eastern Hemisphere (McLean and Mimura, 1993)—as well as some edited volumes on specific themes, including geomorphic response (J.R. French *et al.*, 1995), coastal wetlands (Parkinson, 1994), and developing countries (Nicholls and Leatherman, 1995a). This section assesses first the biogeophysical effects of climate change on three distinct coastal geomorphic systems, then the effects on two important ecological systems, and finally the effects on coastal biodiversity.

9.4.1. Sedimentary Coasts, Sandy Beaches, Barriers, and Dunes

Open coasts, primarily made up of unconsolidated sands and gravels and exposed to wind and wave action, are common on all inhabited continents and islands of all sizes. About 20% of the world's coast is sandy and backed by beach ridges, dunes, or other sandy deposits. International studies reported by Bird (1985, 1993b) indicate that over the last 100 years about 70% of the world's sandy shorelines have been retreating; about 20–30% have been stable and less than 10% advancing. He has listed at least twenty possible reasons for the prevalence of erosion and has indicated that sea-level rise is only one possibility. Although Stive *et al.* (1990), Leatherman (1991), and others have recognized a causal relationship between erosion and sea-level rise, many attempts to correlate accelerated coastal erosion with global sea-level rise over the last 100 years have not been convincing because of the difficulties in excluding other factors, including human impacts. Analyses of erosional trends on sandy shorelines over the past several decades indicate a predominance of local rather than common explanations—suggesting that, if sea-level rise has been a contributor, its contribution may have been masked by other mechanisms.

Two other approaches have been used to gauge the effect of sea-level rise on sedimentary coasts. First, models have been used to predict beach-profile changes that will result from a rise in water level. Model studies have been reviewed by international expert committees such as the Scientific Committee on Oceanic Research (SCOR, 1991), as well as by individuals (e.g., Healy, 1991; Leatherman, 1991). The best-known model is that of Bruun (1962), who formulated a two-dimensional relationship between rising sea level and the rate of shoreline recession based on the concept of profile equilibrium, which has been the subject of much evaluation (e.g., Dubois, 1992). SCOR (1991) has noted that testing and application of the models for beach response to a long-term rise in sea level have been hampered by significant lag times of beach changes—amounting to months or years—and the importance of other elements of the sediment budget that produce shoreline erosion or accretion irrespective of any sea-level rise. Profile changes assumed by the models have been reasonably well-verified by laboratory and field studies, but the predictive equations are found to yield poor results when the effects of profile lag times and complete sediment budgets are not included in the analysis. One solution to these uncertainties is to determine a range of beach-recession scenarios rather than a single estimate—

although SCOR (1991) has concluded that the status of models for the beach response to elevated water levels is far from satisfactory; predictions of the associated shoreline recession rates yield uncertain results; and there is clear need for substantial research efforts (field and laboratory) in this area. A new generation of shoreface-profile evolution models is presently being developed (e.g., Stive and De Vriend, 1995).

Second, morphostratigraphic studies, particularly of sandy barriers, have been undertaken, although frequently these studies predate the recent interest in attempting to predict future coastal response to climate change and sea-level rise. Nevertheless, sandy-barrier responses to rises in sea level in the Holocene can be used as historical analogues. Although transgressive sedimentary sequences, where coastal barriers migrate landward as a result of shoreface erosion and washover, are widespread in North America, Europe, and Australia, other responses to sea-level rise include *in situ* growth (the stationary barrier) and even seaward advance (the regressive sequence). As with other approaches, field-based evolutionary morphostratigraphic models do not yield a consistent response to sea-level rise. Rate of sediment supply and coastal configuration are just two of the other factors that influence how sandy shorelines will respond. In addition to field-based studies, some indication of the complex way that sand barriers have responded to post-glacial sea-level rise has been shown through computer-simulation techniques (Cowell and Thom, 1994; Roy *et al.*, 1994).

Collectively, all of these results suggest that with future sea-level rise there will be tendencies for currently eroding shorelines to erode further, stable shorelines to begin to erode, and accreting coasts to wane or stabilize. Locally, changes in coastal conditions and particularly sediment supply may modify these tendencies (Bird, 1985, 1993b).

9.4.2. Deltaic Coasts, Estuaries, and Lagoons

Deltas form where terrigenous sediment brought down to the coast by rivers accumulates more rapidly than can be removed by waves, tides, and currents. Although there is a wide spectrum of delta types around the world, all are the result of the interaction between fluvial and marine processes. Since ancient times, deltas have been of fundamental importance to civilizations due to the presence of highly productive agricultural lands, fisheries, and human settlement. Many modern delta regions, with their dense populations and intensive economic activities, are now in crisis because of past management practices such as dam, dyke, and canal construction and habitat destruction, which have led to problems such as enhanced subsidence and reduced accretion, salinity intrusion, water quality deterioration, and decreased biological production (Day *et al.*, 1993; Boesch *et al.*, 1994).

Deltaic coasts are particularly susceptible to any acceleration in the rate of sea-level rise (as well as storm frequency or intensity). As Baumann *et al.* (1984) have recognized, delta survival

is a battle of sedimentation versus coastal submergence. Most deltas are subsiding under the weight of accumulating sediment, a process that often is enhanced by artificial groundwater withdrawal. Any global sea-level rise will exacerbate existing problems of local submergence. Bird (1993b) has argued that a rising sea level will have two major effects on low-lying deltaic areas: First, it is likely to cause extensive submergence, especially where there is little prospect of compensating sediment accretion. Second, progradation of most deltaic coastlines will be curbed, with erosion becoming more extensive and more rapid.

Similar conclusions have come from a host of case studies around the world, including those reported from Europe and the Mediterranean in Jeftic *et al*. (1992), Tooley and Jelgersma (1992), Poulos *et al*. (1994), and Woodroffe (1994); from the Americas in Day *et al*. (1993, 1994); and from Southeast Asia in McLean and Mimura (1993). While there appears to be general agreement among all of the studies on the implications of reduced sediment discharge, subsidence, and rising sea level, there have been few attempts to determine the relative vulnerability of deltaic regions or to model the effects of sea-level rise on deltas. Exceptions to the former include Ren's (1994) study of the Chinese coast, in which six variables (relief, land subsidence, shoreline displacement, storm surge, tidal range, and coastal defenses) have been used to evaluate risk classes of eight vulnerable areas. Exceptions to the latter include the conceptual model of general deltaic functioning developed by Day *et al*. (1994) and their two-state variable model, which simulates height in sea level and land elevation over time as a function of varying rates of sea-level rise, subsidence, and vertical accretion. Model results of the "date of immersion" (i.e., when sea level equals land elevation) have been produced for several sites in the Mississippi, Camargue, and Ebro deltas. Intradelta variations have been highlighted in the model results. In natural situations, such variations commonly result from variations in subsidence and/or changes in active and passive distributary positions across deltas, as demonstrated for the Nile (Stanley and Warne, 1993) and Rhine-Meuse (Tornqvist, 1993) deltas, respectively.

Studies on the physical response of tidal rivers and estuaries to predicted sea-level rise have covered two main areas—geomorphic changes and saltwater penetration—although the American Society of Civil Engineers (ASCE) Task Committee (1992) has indicated that several hydraulic processes such as tidal range, prism and currents, and sedimentation would also be modified. Bird (1993b) has suggested that estuaries will tend to widen and deepen. This may enhance their role as sediment sinks, causing greater erosion of the neighboring open coast (Stive *et al*., 1990). However, Pethick (1993) has shown that along the southeast coast of Britain, where relative sea-level rise is already 4–5 mm/yr due to local subsidence, estuarine channels are becoming wider and shallower by local redistribution of sediment as the intertidal profile shifts both upward and shoreward. In some areas, these effects may be offset by increased catchment runoff, greater soil erosion, and increased sediment yield as a result of climate changes.

However, as with deltas, critical factors will be relative sea-level change, including local subsidence (e.g., Belperio, 1993), and sediment availability (e.g., Chappell, 1990; Parkinson *et al*., 1994). In macrotidal estuaries in Northern Australia, channel widening initiated by rising sea level will contribute sediment to the adjacent estuarine plains, which may offset the effect of flooding and lead to steady vertical accretion. One consequence of this would be to endanger backwater swamps and freshwater ecosystems on the estuarine plains (Chappell and Woodroffe, 1994).

The effects of sea-level rise on saltwater penetration in rivers and estuaries have recently been reviewed by Oude Essink *et al*. (1993) and Van Dam (1993), who have suggested that saline water will gradually extend further upstream in the future. More serious is the accelerated effect of saline water intruding into groundwater aquifers in deltaic regions and coastal plains. In these areas, the effect of sea-level rise can be exacerbated by the withdrawal of freshwater, which may result in either subsidence and/or replacement by seawater. Subsidence and landward migration of saltwater are already serious problems in many coastal deltaic areas around the world. Two examples are Myanmar (Aung, 1993) and China (Han *et al*., 1995b).

9.4.3. Coral Atolls and Reef Islands

Coral atolls and reef islands appear especially susceptible to climate change and sea-level rise. Based on the sea-level rise scenarios of the 1980s and the application of simple models, Pernetta (1988) developed an index of island susceptibility for the South Pacific region and concluded that the most susceptible nations included those "composed entirely of atolls and raised coral islands, which will be devastated if projected rises occur," and consequently "such states may cease to contain habitable islands." Three related effects were envisaged: erosion of the coastline, inundation and increased flooding of low-lying areas, and seawater intrusion into the groundwater lens, which would cause reductions in island size, freeboard, and water quality, respectively.

Since that time, a series of vulnerability assessments of atolls and reef islands have been carried out. Studies include the atoll states and territories of Tuvalu, Kiribati, Tokelau, and the Marshall Islands in the Pacific and the Maldives and Cocos (Keeling) Islands in the Indian Ocean (Aalbersberg and Hay, 1993; Woodroffe and McLean, 1992; McLean and D'Aubert, 1993; Holthus *et al*., 1992; Connell and Maata, 1992; Pernetta, 1992; McLean and Woodroffe, 1993). Generally, these studies have documented the likelihood of more complex and variable responses than initially suggested, recognizing that the balance between reef growth, island accumulation or destruction, and sea-level rise will be locally important. Differences in response can be further expected between islands within and beyond storm belts, between those composed primarily of sand and those of coral rubble, and between those that are or are not anchored to emergent rock platforms. The presence or absence of natural physical shore-protection structures in the form of

beachrock or conglomerate outcrops and biotic protection in the form of mangrove or other strand vegetation will also result in different responses between islands.

It is not clear to what extent reef islands will erode or whether sediment from the adjacent reef or lagoon will contribute to the continued growth of islands. McLean and Woodroffe (1993) have envisaged at least three possible responses in the face of sea-level rise: the Bruun response, the equilibrium response, and continued growth, which would result in shoreline erosion, redistribution of sediment, and shoreline accretion, respectively. Each of these processes can be observed on many reef islands today, as well as in the stratigraphic record, suggesting that the factors identified above are significant determinants of island stability. Moreover, as Spencer (1995) has pointed out, coral-island responses to future sea-level rise will vary as a result of constraints on the development of modern reefs and the varying inherited topographies upon which future sea-level will be superimposed.

On small islands, the freshwater lens is an important resource and often is the primary source of potable water on atolls. Recent studies suggest that the first approximation of the response of the freshwater lens to sea-level rise (the Ghyben-Herzberg principle) is not appropriate on small coral islands. The layered-aquifer model—which, among other things, considers geological structure and distinguishes between Pleistocene and Holocene stratigraphic units—is considered more appropriate for assessing freshwater inventories on such islands. If recharge and island width remain constant or expand, freshwater lenses may actually increase in size with a rise in sea level because of the larger volume of freshwater that can be stored in the less-permeable upper (Holocene) aquifer (Buddemeier and Oberdorfer, 1990). On the other hand, if recharge or island width are reduced, a diminution in both freshwater quantity and quality can be expected. In many places, increasing demand and recharge contamination are likely to be more serious issues than freshwater inventory *per se*.

Although recent reviews on coral islands have emphasized their variability and resilience (e.g., Hopley, 1993; McLean and Woodroffe, 1993), such islands remain among the most sensitive environments to long-term climate change and sea-level rise, especially where these effects are superimposed on destructive short-term events such as hurricanes, damaging human activities, and declining environmental quality. In spite of a more optimistic outlook in recent years, Wilkinson and Buddemeier (1994) have maintained that coral-reef islands may be rendered uninhabitable by climate change, especially sea-level rise, and that will necessitate relocation of any remaining human populations (see also Section 9.5).

9.4.4.   *Coastal Wetlands*

Coastal wetlands are frequently associated with deltas, tidal rivers, estuaries, and sheltered bays. Geomorphic and hydrologic changes resulting from sea-level rise will have important effects on these biological communities, as well as on unvegetated tidal flats. The survival of the latter is dependent very much on sediment supply from adjacent river catchments—which, if not provided, will result in substantial loss of such areas. Although Woodroffe (1993) has commented that research on coastal wetlands has concentrated upon reconstructing their development under conditions of sea-level rise during the Holocene, there also have been assessments of contemporary trends and processes and simulation modeling of environmental changes.

Historical studies of temperate salt marshes include those of Allen (1991) and Reed (1990), whereas Pethick (1993) and French (1993) have used current trends and numerical simulation, respectively. Pethick (1993) has shown that salt marshes in southeast England appear to be migrating inland along the estuary but that the natural changes are interrupted by the presence of flood embankments. The result is that loss of the seaward boundaries of these wetlands will continue without compensating landward migration—a process known as coastal squeeze in the United Kingdom. Wolff *et al.* (1993) have concluded that salt marshes have the ability to respond quickly to sea-level rise as long as sedimentation and internal biomass production processes keep pace and as long as the entire marsh can move to higher shore levels or further inland. Provided that it is not constrained by infrastructure, protection works, or other barriers, vertical accretion is likely to neutralize sea-level rise as long as sediment supply is sufficient and horizontal erosion is absent or can be compensated. If not, salt marshes will progressively decline and ultimately disappear. Pethick (1992) has also shown that salt marshes under stable sea level undergo cyclical changes to their seaward boundaries; infrequent high-magnitude storm events erode the edges, while intervening lower-magnitude events allow depositional recovery. An increase in the frequency of storm events as a response to sea-level rise would result in the replacement of such cyclical change by progressive erosion. The sensitivity of certain salt-marsh species to waterlogging and soil-chemical changes also could result in a change in species composition or the migration of vegetation zones (Reed, 1995).

Mangroves grow largely in tidal forests and are characterized by adaptations to unconsolidated, periodically inundated saline coastal habitats. They fringe about 25% of shorelines in the tropics and extend into the subtropics as far north as Bermuda and as far south as North Island, New Zealand. Studies on the effects of sea-level rise on tropical mangrove ecosystems have been primarily of historical nature (reviewed by Woodroffe, 1990; UNEP-UNESCO Task Team, 1993; Edwards, 1995). These studies have shown that extensive mangrove ecosystems became reestablished when sea level stabilized around 6,000 years BP. During the prior rise, mangroves probably survived as narrow coastal fringes, shifting landward with the migrating shoreline. Ellison and Stoddart (1991) and Ellison (1993) have indicated that mangroves in areas of low sediment input in both low-island and high-island settings appear to be unable to accrete vertically as fast as the projected rate of sea-level rise. However, recent evidence from the Florida Keys (Snedaker *et*

al., 1994) has shown that low-island mangroves may be resilient to rates of sea-level rise about twice those suggested as upper limits by Ellison and Stoddart (1991) from their study in Bermuda. It is also apparent that mangrove communities are more likely to survive in macrotidal, sediment-rich environments such as Northern Australia, where strong tidal currents redistribute sediment (Semeniuk, 1994; Woodroffe, 1995), than in microtidal sediment-starved environments such as around the Caribbean (Parkinson *et al*., 1994).

If the rate of shoreline erosion increases, mangrove stands may tend to become compressed and suffer reductions in species diversity. On the other hand, extensive mangroves in deltaic settings with continuing large inputs of terrigenous sediment are likely to be more resilient to sea-level rise (Edwards, 1995). Thus, different responses can be envisaged in different mangrove settings. Additionally, certain species are likely to be more robust in the face of sea-level rise than others (Ellison and Stoddart, 1991; Aksornkaoe and Paphavasit, 1993).

It is now becoming increasingly clear, as Woodroffe (1993, 1994) and Edwards (1995) have observed, that coastal wetlands (marshes and mangroves) can undergo a number of responses to sea-level rise. Responses may be different in muddy, tide-dominated systems than in more organic systems, in areas of high or low tide range, and in areas of high or low sediment and freshwater input. Thus, the balance between accretion and submergence will be complex, and a range of morphological responses is likely for different coastal types and coastal settings. Although some marshes and mangroves may be under threat from sea-level rise over the next century, human impact has been the major threat up to the present and may be far more important locally than climate change in the long term (Bird, 1993a; WCC'93, 1994). In the case of mangroves, afforestation programs may be one way to compensate for natural or human-induced losses, although experiences in Bangladesh have indicated the difficulties in such a program (Saenger and Siddigi, 1993). There also is some evidence that coastal wetlands may experience loss due to short-term (decadal) acceleration in the rate of sea-level rise (Boesch *et al*., 1994; Downs *et al*., 1994).

Whereas mangroves are restricted to the intertidal zone, and salt marsh extends landward into supratidal areas, seagrasses extend subtidally to maximum depths of several tens of meters. Relatively little appears to have been published on the possible effects of climate change and sea-level rise on seagrasses (used here generically to include eelgrasses, turtlegrasses, etc.), although their biology and biogeography have been studied extensively (e.g., Larkum *et al*., 1989; Mukai, 1993). Edwards (1995) has provided a brief but comprehensive analysis, noting the economic importance of seagrasses, and their ability to trap sediment, accrete vertically, stabilize unconsolidated sediment, slow water movement, and generally serve as natural coastal protection agents. Edwards (1995) has argued that intertidal and shallow seagrass beds (<5 m depth) are most likely to be affected by climate change, particularly by any sustained elevations in sea temperature or increases in freshwater runoff

from land. However, the main threat to seagrass habitats is likely to come from increased anthropogenic disturbances, including dredging, overfishing, water pollution, and reclamation. In some parts of the world, seagrass beds are already severely threatened (Fortes, 1988), although elsewhere they have expanded due to eutrophication of estuarine waters.

9.4.5. Coral Reefs

Coral reefs are estimated to cover about 600,000 km² of the Earth's surface (Smith, 1978). They are dominated by calcifying organisms that are depositing about 0.6 to 0.9 Gt of calcium carbonate ($CaCO_3$) globally each year (Kinsey and Hopley, 1991). Intuitively, one would think that coral reefs—by precipitating $CaCO_3$ and sequestering carbon—would act as sinks for CO_2, but on the decade to century timescale this is not the case (Smith and Buddemeier, 1992). The calcification process actually generates CO_2 (Ware *et al*., 1992), and over periods of decades reefs may contribute about 0.02 to 0.08 Gt C/yr as CO_2 to the atmosphere.

The effects of climate change on coral reefs, as well as nonclimatic anthropogenic disturbances, have recently been reviewed by Smith and Buddemeier (1992), Wilkinson and Buddemeier (1994) and Edwards (1995). The global climate-change effects of significance to coral reefs are likely to be increases in seawater temperature and sea-level rise; locally or regionally, changes in storm patterns and coastal currents, as well as changes in rainfall patterns, may have effects on coral communities—for example, through increases in sedimentation.

Coral reefs are particularly sensitive to increases in seawater temperature (Brown, 1987) and increased irradiance (Brown *et al*., 1994). They respond to the combined effect of irradiance and temperature elevations by paling in color, or bleaching (Brown and Ogden, 1993). Corals do not generally bleach in response to rapid fluctuations in seawater temperature but rather to departures in temperature above their seasonal maximum. If the temperature elevation involves a substantial increase in seawater temperature (3–4°C) for an extended period (>6 months), considerable coral mortality can ensue (Brown and Suharsono, 1990). If, however, the temperature increase is only on the order of 1–2°C and for a limited period, bleached corals may recover but show reduced growth and impaired reproductive capabilities (Brown and Ogden, 1993).

Projected increases in seawater temperatures thus appear to be a major threat to coral reefs. In Indonesia, where severe bleaching took place as a result of seawater warming during an ENSO event in 1983, coral reefs have failed to show continued recovery beyond the initial recovery noted in 1988 (Brown and Suharsono, 1990). Such results have been mirrored in studies in the Galápagos and eastern Panama, where little recovery has been noted since major bleaching in 1982–1983. At sites in the East Pacific, reefs subsequently have shown rapid bioerosion from the destructive grazing activities of sea urchins, and destabilization of reef substrates is anticipated. Full community

restoration probably will not occur for several hundred years (Glynn, 1993).

Reef accretion rates—calculated from community calcification rates, growth rates of calcifying organisms, and radiocarbon dating of cores through reefs—range from less than 1 mm/yr to a maximum slightly in excess of 10 mm/yr (Buddemeier and Smith, 1988; Hopley and Kinsey, 1988; Kinsey, 1991). A rate of 10 mm/yr is commonly taken as the consensus value for the maximum sustained vertical reef accretion rate (Buddemeier and Smith, 1988). The present best estimates for global sea-level rise over the next century (see Section 9.3) are well within the range of typical reef accretion rates. Even slowly accreting reef flats should, on average, be able to keep up with this rate of sea-level rise after a lag, provided that other factors such as increased seawater temperatures and damaging anthropogenic influences are not acting simultaneously (Edwards, 1995). Widespread warming of seawater, however, will clearly limit the accretion rates of coral reefs—as exemplified by the Panamanian reef, which before suffering 50% coral mortality as a result of sea-surface warming during an ENSO event was depositing about 10 tonnes $CaCO_3$/ha/yr and now is eroding at a rate of approximately 2.5 tonnes $CaCO_3$/yr, equivalent to vertical erosion of 6 mm/yr (Eakin, 1995).

Smith and Buddemeier (1992) have expected shifts in zonation and community structure associated with the interaction between wave-energy regime and sea level, although far too little is known about the physiological and physical constraints to reef growth (Spencer, 1995). Wilkinson and Buddemeier (1994) have shown that coral reefs have come through episodes of severe climate change in the past and have the necessary resilience to cope with current scenarios of climate change. However, coral reefs near land masses and near large population centers will come under greater human pressure in the future and are likely to be damaged beyond repair.

9.4.6.   *Coastal Biodiversity*

Through the biogeophysical effects on coastal geomorphic and ecological systems described in Sections 9.4.1 through 9.4.5, climate change has the potential to significantly affect coastal biological diversity. It could cause changes in the population sizes and distributions of species, alter the species composition and geographical extent of habitats and ecosystems, and increase the rate of species extinction (Reid and Miller, 1989). Coral reefs have the highest biodiversity of any marine ecosystem, with enormous numbers of different species packed into small areas (Norris, 1993). Despite the known and potential value of reef communities and the threats to their health and vigor, the total biodiversity of coral reefs is not known, nor is the fraction of the diversity that is described versus undiscovered. Reaka-Kudla (1995) has estimated that there are about 91,000 described species of coral-reef taxa but argues that undocumented diversity is likely to be much higher. Nonetheless, coral-reef macrobiota represent about 4–5% of the described global biota, although they occupy less than 1% of the Earth's surface. Coral-reef biodiversity is centered around the archipelagos of the Philippines and Indonesia; diversity decreases away from this core. For example, the number of coral species in French Polynesia drops to less than 10% of that in the core area (Wilkinson and Buddemeier, 1994). Similar geographical variations in species richness occur in mangroves and tropical seagrasses (Woodroffe, 1990; Mukai, 1993).

In addition to marine systems such as coral reefs, coastal zones also comprise the adjacent terrestrial environments. Although scientists have long studied the interactions between marine and terrestrial systems and have seen the coastal zone as a discrete entity, it is poorly understood ecologically (Ray, 1991). Among all macroscopic organisms, there are 43 marine phyla and 28 terrestrial phyla; 90% of all known classes are marine (Reaka-Kudla, 1995). Ray (1991) has estimated that 80% of marine phyla occur in the coastal zone, which occupies only 8% of the Earth's surface, and argues that the marine portion of the coastal zone is the most biologically diverse realm on the planet. For example, of the 13,200 species of marine fish, almost 80% are coastal. Tropical coastal zones are particularly rich, with about 182,000 described species (Reaka-Kudla, 1995); they are about twice as rich as temperate coasts.

Coastal zones are sharply subdivided by gradients in geomorphic structure and habitat diversity; this enables them to perform many of the regulation functions and user and production functions outlined in Section 9.2.1. Ray (1991) has identified a nexus between physical processes and ecological pattern and diversity; he suggests that if global warming accelerates during the next few decades, the extent of coastal lagoons, marshes, and so forth will be affected and that these changes will strongly influence the fate of associated biota. In addition, intensive habitat modification on land and deterioration of coastal areas will clearly result in a decline of global biodiversity. Similarly, the capacity of species and ecosystems such as mangroves to shift their ranges and locations in response to climate change will be hindered by human land-use practices that have fragmented existing habitats. The establishment of nature reserves is seen as an option to arrest the decline of coastal biodiversity (Ray and Gregg, 1991; De Groot, 1992b).

9.5.   **Socioeconomic Impacts**

Section 9.4 outlines how the coastal environment can be altered by climate change and sea-level rise; such alterations could have significant effects on functions and values in coastal zones and small islands. This section presents an overview of the related socioeconomic impacts and their evaluation, with an emphasis on the problems of sea-level rise. It highlights the particularly vulnerable situation of low-lying small islands and deltas. The emphasis on sea-level rise reflects a bias of existing studies. A discussion of the human activities in coastal zones that increase vulnerability to climate change also is included.

9.5.1. Pressures and Management Problems in Coastal Zones and Small Islands

During the twentieth century, urbanized coastal populations have been increasing because of the many economic opportunities and environmental amenities that coastal zones can provide. The need to protect and enhance the wealth-creation potential of coastal zones has led to widespread coastal construction and modification of natural coastal processes, resulting in losses of coastal habitats, changes in circulation and material flux, and reductions in biological productivity and biodiversity. These pressures are expected to increase substantially in the coming decades (WCC'93, 1994).

Of particular concern is the worldwide destruction and degradation of coral reefs, mangroves, sea grasses, and salt marshes—which, among other things, act as natural barriers against marine erosion processes. The natural response of salt marshes and mangroves to sea-level rise—an upward and landward migration of the intertidal profiles (see Section 9.4)—is inhibited by flood embankments and other human constructions. The result is that erosion of the seaward boundaries of these wetlands will continue without a compensating landward migration, leading to loss of wetland area. Deltaic processes also are being modified. In the United States, for example, the Mississippi River delta was roughly in a state of dynamic balance before the twentieth century, but since then human intervention in the form of large-scale engineering works, levees, dams, canals, and water diversions has effectively starved the wetlands of needed freshwater and sediments and radically altered wetland hydrology. Relative sea level is rising at a rate of up to 1 m per 100 years in this region; up to 100 km^2 of wetlands were lost each year during the 1970s, falling to 50 km^2/yr in the 1980s (Boesch *et al.*, 1994). In Bangladesh, flood defense systems and/or human activities in the Ganges-Bramaputra-Meghna river system may have affected runoff, sediment flow, and deposition rates, with detrimental effects on coastlines, fisheries, and the frequency and severity of inland flooding (Warrick and Rahman, 1992; see also Ives and Messerli, 1989). Small island states (many of which are low-lying) face particularly severe threats, and pollution and mining of coral will further serve to inhibit the capabilities of these countries to respond to sea-level rise.

Human interference in the dynamic processes that affect coastal zones is not restricted to activities within the coastal zone itself. Activities upstream in catchment areas may also play a part. For example, effluent discharging from sewage plants and industrial plants and agricultural runoff can lead to eutrophication, and water-resource schemes (e.g., dams and irrigation systems) can restrict the supply of water, sediment, and nutrients to coastal systems. Sewage and siltation are among the most significant causes of coral-reef and other natural coastal system degradation in the Philippines, Singapore, Malaysia, Indonesia, Sri Lanka, the Pacific islands, Hawaii, the Persian Gulf, the Caribbean, parts of the South American coast, and Cuba (Lundin and Linden, 1993).

The message is clear: Climate-related changes such as accelerated sea-level rise and possibly altered patterns of storm frequency and intensity represent potential *additional* stresses on systems that are already under intense and growing pressure. In addition, there are complex interrelationships and feedbacks between human and environmental driving forces and impacts on the one hand and climate-induced changes and effects on the other. These relationships require considerably more study (Turner *et al.*, 1995b).

9.5.2. Assessment of Impacts

Of direct relevance when analyzing socioeconomic impacts is the evaluation of the potential loss of environmental values. As discussed in Section 9.2, a coastal system can yield a number of different values related to the functions and services it provides. A range of methods is available to evaluate these (see Table 9-1).

Table 9-1: *Environmental evaluation methods showing—from left to right—increasing complexity and scale of analysis (adapted from Pearce and Turner, 1992).*

Least Complicated				Most Complicated
Financial Analysis	**Economic Cost-Benefit Analysis**	**Extended Cost-Benefit Analysis**	**Environmental Impact Assessment**	**Multi-Criteria Decision Methods**
• Financial profitability criterion • Private costs and revenues • Monetary valuation	• Economic efficiency criterion • Social costs and benefits • Monetary valuation	• Sustainable development principles • Economic efficiency and equity tradeoff environmental standards as constraints • Partial monetary valuation	• Quantification of a diverse set of effects on a common scale, but no evaluation	• Multiple decision criteria • Monetary and nonmonetary evaluation

The more comprehensive the technique, the greater the diversity of information that will be required and yielded to assist the appraisal of policy options from a societal perspective. Therefore, assessing the value of climate-change impacts is not a straightforward issue. More robust techniques are available for deriving use values than for non-use values. Moreover, monetary valuation is not always appropriate when cultural and heritage assets are threatened by climate change and sea-level rise. Small islands often are particularly threatened, including their distinct ways of life and possibly even their distinct cultures. The same applies to heritage and other culturally significant sites on the coast. The core project Land-Ocean Interactions in the Coastal Zone (LOICZ) of the International Geosphere-Biosphere Program (IGBP) (see also Sections 9.6.4 and 9.7) is currently preparing comprehensive guidelines for evaluating coastal functions and services.

Coastal zones and small islands support a range of socioeconomic sectoral activities that can be affected by climate change and sea-level rise. Most of these sectors are covered in separate chapters in this report. Table 9-2 reflects the results of these sectoral assessments as they pertain to direct impacts specifically related to climate change in coastal zones and small islands. The reader is referred to the chapters listed in the table for more detailed discussions of the impacts and vulnerability of each sector.

Tourism also is of great importance to coastal zones and small islands, although it is not covered as a separate sector in this report. Tourism helps to support the economies of many coastal countries (Miller and Auyong, 1991). For many small islands in particular, tourism is the largest contributor to the country's GNP. Coastal tourism can be affected by climate change directly through coastal erosion and changes in weather patterns (e.g., storminess, precipitation, cloud cover). Indirect effects, however, may be just as important. Adverse impacts on freshwater supply and quality, human settlements, and human health will severely affect tourism, as will overdevelopment leading to environmental degradation.

Many efforts have been made in the last few years to assess the implications of climate change and associated sea-level rise on the coastal zone. As part of these efforts, the former Coastal Zone Management Subgroup of IPCC has published a methodology for assessing the vulnerability of coastal areas to sea-level rise (IPCC CZMS, 1991). The framework, called the Common Methodology, has been widely applied as the basis of vulnerability assessment studies. These studies have aimed to identify populations and resources at risk and the costs and feasibility of possible responses to adverse impacts. The vulnerability of many more coastal countries to sea-level rise has been reviewed using other approaches. Examples of assessments of the possible impacts and responses to sea-level rise and climate change can be found in Tobor and Ibe (1990), Parry *et al.* (1992), Bijlsma *et al.* (1993), Warrick *et al.* (1993), Ehler (1993), McLean and Mimura (1993), Qureshi and Hobbie (1994), O'Callahan (1994), WCC'93 (1995), and Nicholls and Leatherman (1995a). A series of studies on Pacific islands has been conducted by the South Pacific Regional Environment Programme, including Holthus *et al.* (1992), Aalbersberg and Hay (1993), McLean and D'Aubert (1993), and Nunn *et al.* (1994a, 1994b).

This section summarizes a number of these vulnerability case studies, with an emphasis on the strengths and weaknesses of those conducted using the Common Methodology or similar approaches.

9.5.2.1. Vulnerability Assessment and the IPCC Common Methodology

Vulnerability to impacts is a multidimensional concept, encompassing biogeophysical, socioeconomic, and political factors. The Common Methodology defines vulnerability as "the degree of incapability to cope with the consequences of climate change and accelerated sea-level rise" (IPCC CZMS, 1991). Therefore, analysis of the vulnerability of a coastal area or small island to climate change includes some notion of its *susceptibility* to the biogeophysical effects of climate change and sea-level rise (see Section 9.4), as well as of its natural *resilience*—which is greatly influenced by past, current, and future population and settlement patterns and rates of socioeconomic change. Susceptibility and resilience together determine the natural system's *sensitivity* to anticipated changes. Socioeconomic *vulnerability* is further determined by a country's technical, institutional, economic, and cultural capabilities to cope with or manage the

anticipated biogeophysical effects and their consequent socioeconomic impacts (Turner *et al*., 1995a).

The IPCC Common Methodology has aimed to identify "*the types of problems that a country will have to face and, if necessary, the types of assistance that are most needed to overcome these problems*." Assessments are to "*serve as preparatory studies, identifying priority regions and priority sectors and to provide a first reconnaissance and screening of possible measures*" (IPCC CZMS, 1991). Three boundary conditions and scenarios have been specified in the methodology: the impacts on the natural coastal systems, the impacts on socioeconomic developments, and the implications of possible response strategies for adaptation. The methodology includes consideration of the reference (or present) situation and a rise in sea level of 30 cm to 1 m by the year 2100. These scenarios approximate the low and high estimates of the 1990 IPCC Scientific Assessment. It considers socioeconomic developments by extrapolating 30 years from the present situation. The Common Methodology recommends considering a full range of adaptation options, including at least the extreme options of complete retreat and total protection. To simplify analysis, the method does not consider coastal evolution other than that caused by climate change, nor does it assess the effects of progressive adaptation at the local scale, such as the raising of dikes.

The Common Methodology has helped to focus the attention of many coastal nations on climate change and has contributed to long-term thinking about the coastal zone. On the other hand, a number of problems have been raised concerning the Common Methodology through the experiences of vulnerability assessment case studies (WCC'93, 1994):

- Many case studies have faced a shortage of accurate and complete data necessary for impact analysis. In particular, it often has proven difficult to determine accurately the impact zone in many countries due to the lack of basic data, such as the coastal topography.

- Many studies have found the use of a single global scenario of sea-level rise (1 m by 2100) inappropriate to their respective areas, often due to the lack of more detailed data on coastal elevations; most studies have ignored the spatial distribution of relative sea-level rise and other coastal implications of climate change, largely due to a lack of regional climate scenarios. Future vulnerability assessment would be greatly improved by the availability of regional scenarios for climate change and sea-level rise, including reference, low, and high scenarios.

- Although the Common Methodology has encouraged researchers to take into account the biogeophysical response of the coastal system to sea-level rise, lack of data and models for describing local coastal processes and responses have hindered detailed, quantitative impact assessment. Many case studies have carried out a simple first-order assessment by horizontally shifting the coastline landward by an amount corresponding with the sea-level rise scenario.

- While vulnerability profiles have yielded some useful relative guidance on potential impacts, the Common Methodology has been less effective in assessing the wide range of technical, institutional, economic, and cultural elements present in different localities.

- There has been concern that the methodology stresses a protection-orientated response, rather than considering a full range of adaptation options.

- Market-evaluation assessment frameworks have proved inappropriate in many subsistence economies and traditional land-tenure systems. More attention should be paid to broader socioeconomic evaluation techniques, which include traditional, aesthetic, and cultural values (see Box 9-2).

9.5.2.2. Vulnerability Assessment Case Studies

At least 23 country case studies have produced quantitative results that can be interpreted in terms of the IPCC Common

---

Box 9-2. Cultural Impacts and Alternative Assessments

Conventional impact evaluation techniques and indicators, such as GNP and population at loss, protection costs, and cost-benefit analysis, reflect only one (largely Western) approach for assessing potential damages from climate-related events. This has led to the development of alternative methodologies that seek to assess changes in culture, community, and habitat. In a study of coastal vulnerability and resilience to sea-level rise and climate change, Fiji is considered (Nunn *et al*., 1994a). The methodology (Yamada *et al*., 1995) computes a Sustainable Capacity Index based on the sum of ratings of vulnerability and resilience for many categories of cultural, social, agricultural, and industrial impacts at the local, regional, and national levels. Areas with higher concentrations of assets are judged to be more vulnerable, whereas areas with diversity and flexibility in the system—whether natural or managerial—tend to be viewed as more resilient in this analysis. The study has evaluated potential impacts to subsistence economies according to the view that communities in which people feed and clothe themselves with little cash exchange are more vulnerable but that subsistence economies in which staples can be replaced with other crops tend to be more resilient. In addition, cultural sites have been ranked according to the level of national interest in their preservation. The study concludes that subsistence economies and cultural assets are more vulnerable in Fiji and that conventional analyses of relatively high-lying islands such as Fiji would tend to underestimate the potential vulnerability of these areas, given that most people live in the low-lying coastal plain and the majority of cash and subsistence economic activities take place in the low-lying areas.

Methodology. Some results are summarized in Table 9-3, and these show considerable variation in possible impacts from country to country, reflecting that certain settings are more vulnerable than others. This conclusion is widely supported by all of the country studies that are available. Small islands, deltaic settings, and coastal ecosystems appear particularly vulnerable. In addition, developed sandy shores may be vulnerable because of the large investment and significant sand resources required to maintain beaches and protect adjoining infrastructure in the face of sea-level rise (Nicholls and Leatherman, 1995a).

Several caveats are in order so that the following impact estimates can be put into proper perspective (following Section 9.5.2.1). First, the impacts presented assume a 1-m rise in sea level by 2100—which is the high estimate of the IPCC90 business-as-usual sea-level rise scenario—and no other climate change. The latest scientific information, however, suggests a lower global mean sea-level rise (see Section 9.3.1.1). For a number of nations, the impacts of a 50-cm or smaller rise have been examined, including Argentina (Dennis *et al.*, 1995a), parts of north China (Han *et al.*, 1993), Japan (Mimura *et al.*, 1994), Nigeria (G.T. French *et al.*, 1995), Senegal (Dennis *et*

Table 9-3: *Synthesized results of country case studies. Results are for existing development and a 1-m rise in sea level. People affected, capital value at loss, land at loss, and wetland at loss assume no measures (i.e., no human response), whereas adaptation assumes protection except in areas with low population density. All costs have been adjusted to 1990 US$ (adapted from Nicholls, 1995).*

[6]Minimum estimates—number reflects estimated people displaced.

[7]Minimum estimates—capital value at loss does not include ports.

[8]Best estimate is that 20,000 km² of dry land are lost, but about 5,400 km² are converted to coastal wetlands.

[9]Adaptation only provides protection against a 1-in-20 year event.

[10]Adaptation costs are linearly extrapolated from a 0.5-m sea-level rise scenario.

[11]Adaptation costs include 30-year development scenarios.

al., 1995b), parts of the United Kingdom (Turner *et al*., 1995a), the United States (Titus *et al*., 1991), Uruguay (Volonté and Nicholls, 1995), and Venezuela (Volonté and Arismendi, 1995). Second, all of the country studies have assumed that the socioeconomic situation is constant until 2100. This is unrealistic and ignores the rapid coastal development that is occurring with little regard for existing problems, let alone tomorrow's (WCC'93, 1994). However, the mere threat of extensive loss of land and other assets may stimulate macroeconomic effects within national economies. Some assets may be relocated and others may be adapted to reduce the damage implications of climate change. On the other hand, the damage-cost estimates may represent underestimates because they neglect some nonmarket asset values and factors such as the cost of resettlement of coastal populations that cannot be easily protected. Finally, it has been assumed that the rise in sea level will be a slow, gradual process, which may not be the case for all regions. Scientific uncertainties are compounded by the socioeconomic adaptation uncertainties referred to above and by the fact that economic cost estimates are very sensitive to changes in discount rates.

Despite these limitations, these studies have offered some important insights into potential impacts and possible responses to climate change and sea-level rise. Many of the vulnerability assessments emphasize the severe nature of existing coastal problems such as beach erosion, waterlogging, and pollution (e.g., El-Raey *et al*., 1995; Han *et al*., 1995b). For many small islands, population pressure and urbanization, coastal pollution, and overexploitation of resources already are critical problems. For deltas and estuaries, changes in sediment supply and distribution are often already causing significant changes in the coastal zone. This reinforces the message that climate change will act on coastal systems that are already under stress.

In addition to accelerated sea-level rise, there is widespread concern about the coastal implications of other aspects of climate change such as changing rainfall and runoff in the catchment area, as well as the effects of changes in storminess and storm surges (e.g., Warrick *et al*., 1993; McLean and Mimura, 1993). One quantitative vulnerability assessment study exists; it shows that in The Netherlands the costs of avoiding damage related to an adverse 10% change in the direction and intensity of storms may be worse than those of a 60-cm rise in sea level (Peerbolte *et al*., 1991). This storm-change scenario is arbitrary, but shows that concern is justified and that there is a need for more widespread analysis.

All of the 23 national case studies shown in Table 9-3 project land loss as the sum of dry-land and wetland loss, assuming no protective measures are taken. The estimated losses range from 0.05% of the national land area in Uruguay (Volonté and Nicholls, 1995) to more than 12% of Tarawa, Kiribati (Woodroffe and McLean, 1992); more than 17% of Bangladesh (Huq *et al*., 1995); and 80% of Majuro atoll, Marshall Islands (Holthus *et al*., 1992). From fifteen case studies, 63,000 km^2 of wetlands are estimated to be lost. Most of these assessments are based on first-order analyses, and key parameters such as

limiting vertical accretion rates and potential for wetland migration often are poorly defined (Nicholls, 1995). The study of the United States has considered wetland migration, estimating that a 50-cm rise in sea level would erode or inundate 38% to 61% of existing coastal wetlands. Assuming that dikes or bulkheads were not built to impede inland migration, new wetland formation on formerly upland areas would reduce the total loss to 17% to 43% (Titus *et al*., 1991). Therefore, wetland migration is not projected to compensate for losses, even under the most ideal circumstances. Many studies, however, have found that direct human reclamation of wetlands for a range of purposes at present is a much bigger threat than sea-level rise (Nicholls and Leatherman, 1995a).

Fifteen case studies have provided estimates of undiscounted capital value potentially at loss, assuming no protection. Nearly half of the studies have concluded that capital value at loss could exceed 50% of present GNP, illustrating the concentration of infrastructure and economic activity in the coastal zones of many of the countries studied. To counter these impacts, adaptation would be expected (see Section 9.6). Table 9-3 stresses the cost of total protection rather than other possible adaptation options, which may have lower costs. Assuming that costs will accrue uniformly over 100 years, the annual protection costs—as a percentage of present GNP—are highest for the Marshall Islands at 7% (Holthus *et al*., 1992) and St. Kitts-Nevis at 2.7% (Cambers, 1994). This supports the conclusion that some small islands have a high vulnerability to sea-level rise. However, Kiribati has a similar setting to the Marshall Islands, yet the estimates of protection costs are much smaller, at 0.1% of present GNP (Woodroffe and McLean, 1992). This reflects important differences in assumptions about the meaning of total protection. In Kiribati, local engineers have selected existing low-technology, low-cost gabions to protect the atoll, whereas in the Marshall Islands large and expensive sea walls have been utilized to determine the costs. This comparison shows one of the weaknesses of the Common Methodology and the need to assess a wider range of response options in future vulnerability assessment studies.

In many locations, beaches are likely to require nourishment to protect tourist infrastructure because existing urban and tourist infrastructure could be damaged and destroyed. The amount of sand required to maintain a beach in the face of long-term sea-level rise is uncertain (Stive *et al*., 1991); in some case studies, the costs of beach nourishment could dominate basic response costs if countries invest in such an adaptation option (Dennis *et al*., 1995b; Nicholls and Leatherman, 1995a; Volonté and Nicholls, 1995). There is also the question of the availability of sufficient sand resources. The usual source is suitable-grade nearshore deposits, if available. However, the implication of the removal of such deposits must be carefully considered in terms of its effect on the coastal sediment budget and the nearshore wave climate.

In many industrialized countries, the main potential loss from sea-level rise seems to be coastal wetlands, as well as sandy beaches in some countries (e.g., Mimura *et al*., 1994).

Box 9-3. The Vulnerable Situation of Small Islands

Many small island countries could lose a significant part of their land area with a sea-level rise of 50 cm to 1 m. The Maldives, for example, have average elevations of 1 to 1.5 m above existing sea level (Pernetta, 1992). Although bio-geophysical processes may counter land losses (see Section 9.4), the threat of submergence and erosion remains; this could convert many small islands to sandbars and significantly reduce the usable dry land on the larger, more populated islands. Saltwater intrusion and loss of the freshwater lens may be an equally binding constraint on human habitation in some islands, particularly smaller atolls (Leatherman, 1994).

The available case studies have shown that small islands—most particularly, coral atolls such as the Marshall Islands (Holthus *et al*., 1992)—are heavily oriented toward coastal activities and hence are vulnerable to sea-level rise (e.g., Cambers, 1994; Fifita *et al*., 1994). At the same time, their relatively small economies may make the costs of adaptation prohibitive. In global terms, the population of small islands is relatively small, but a number of distinct societies and cultures are threatened with drastic changes in lifestyle and possibly forced abandonment from ancestral homelands if sea level rises significantly (Roy and Connell, 1991).

Even the less-vulnerable small islands would suffer significant economic effects from the loss of beach tourism and recreation areas because of sea-level rise and, possibly, more storms leading to increased beach and reef erosion. In 1988, among the Caribbean islands, income from tourism as a percentage of GNP was 69% for Antigua and Barbuda and 53% for the Bahamas; for a dozen other Caribbean islands, tourism revenues make up more than 10% of the GNP (Hameed, 1993). The Indian Ocean islands of the Seychelles and the Maldives also have seen a steady growth in tourism. In 1991, total receipts from tourism generated foreign exchange earnings of $94 million in the Maldives. This represented some 74% of the country's total foreign exchange earnings. Since 1985, tourism has been the single biggest contributor to the GNP of the Maldives. Tourism to developing countries has increased significantly in recent years, and small island developing states have experienced a particularly rapid increase. Tourist numbers to Mauritius, for example, have increased from 1,800 visitors in 1968 to 180,000 in 1988 (UNEP, 1991).

Given accelerated sea-level rise, first-order estimates suggest that substantial investment would be required in some developing countries in order to protect urban areas and maintain related activities such as beach tourism. Nine small island states appear in the list of countries facing the highest coastal protection costs as a percentage of their GNP. The global average percentage required annually for coastal protection is 0.037%; however, for many small islands it is significantly higher—up to 34% for the Maldives (OECD, 1991). To explore the full range of potential responses, more comprehensive assessment of the available adaptation options in these vulnerable settings is urgently required.

However, a change in the frequency, intensity, or distribution of extreme weather events could have implications for urban areas and related capital assets in countries such as Japan, Australia, the United States, and some countries bordering the North Sea.

From the above it is clear that all coastal zones of the world are vulnerable to the range of possible impacts from sea-level rise and other climate-induced impacts, although to different degrees. Studies using other approaches than the Common Methodology support this conclusion. Small island developing states are often judged to be among the most vulnerable countries. In Box 9-3, case material is presented for small islands, centering chiefly on threats to small economies dominated by tourism.

9.5.2.3. *Global Vulnerability Assessment*

In addition to local and country vulnerability assessments, a Global Vulnerability Assessment (GVA), which provides a worldwide estimate of the socioeconomic and ecological implications of accelerated sea-level rise (Hoozemans *et al*., 1993) has been conducted, using the same scenarios as the Common Methodology. The GVA has provided estimates of the following impacts: *population at risk*, the average number of people per year subject to flooding by storm surge on a global scale; *wetlands at loss*, the ecologically valuable coastal wetland area under serious threat of loss on a global scale; and *rice production at change*, the changes in coastal rice yields as a result of less-favorable conditions due to sea-level rise in South, Southeast, and East Asia.

Recently, an extension of the GVA has been prepared using a more refined approach to estimate flooding probabilities (Baarse, 1995). Sea-level rise scenarios of both 50 cm and 1 m have been considered. The data sets available for global-scale analysis are limited, and important assumptions are necessary with regard to storm-surge probability and population distribution. Also, increases in wave height and wave run-up have not been taken into account in these analyses, and neither have socioeconomic changes such as population growth. Therefore, the results of both studies must be considered as first-order estimates.

Some conclusions drawn from Hoozemans *et al*. (1993) and Baarse (1995) include:

- Presently, some 200 million people are estimated to live below the "maximum" storm-surge level (the once-per-1000-years storm-surge level). Based on this population estimate, as well as on first-order estimates of storm-surge probabilities and existing levels of protection, 46 million people are estimated to experience flooding due to storm surge in an average year under present conditions. Most of these people live in the developing world.

- The present number of people at risk will double if sea level rises 50 cm (92 million people/yr) and almost triple if it rises 1 m (118 million people/yr).

- The average number of people who will experience coastal flooding more than once per year will increase considerably under both scenarios (80–90% of the respective populations at risk). This estimate underlines that many people will have to adapt to sea-level rise by moving to higher ground, increasing protection efforts or other adaptation options (see Section 9.6).

- Because of regional differences in storm-surge regimes, the increase of flood risk due to sea-level rise is greater than average for the Asian region (especially the Indian Ocean coast), the south Mediterranean coast, the African Atlantic and Indian Ocean coasts, Caribbean coasts, and many of the small islands.

- All over the world, coastal wetlands are presently being lost at an increasingly rapid rate, averaging 0.5–1.5% per year. These losses are closely connected with human activities such as shoreline protection, blocking of sediment sources, and development activities such as land reclamation, aquaculture development, and oil, gas, and water extraction.

- Sea-level rise would increase the rate of net coastal wetland loss. Losses of coastal wetlands of international importance are expected to be greater than average for the coasts of the United States, the Mediterranean Sea, the African Atlantic coast, the coast of East Asia, and the Australian and Papua New Guinean coast.

- Approximately 85% of the world's rice production takes place in South, Southeast, and East Asia. About 10% of this production is located in areas that are considered to be vulnerable to sea-level rise, thereby endangering the food supply of more than 200 million people.

- Less-favorable hydraulic conditions may cause lower rice production yields if no adaptive measures are taken, especially in the large deltas of Vietnam, Bangladesh, and Myanmar.

In summary, the GVA confirms that sea-level rise will have global impacts and reinforces the need for more refined vulnerability assessments at regional and local scales.

9.5.2.4.   Overview of Impact Assessment

Vulnerability assessment has demonstrated that certain settings are more vulnerable to sea-level rise, including small islands (particularly coral atolls), nations with large deltaic areas, coastal wetlands, and developed sandy shores. However, vulnerability assessment has been less successful in assessing the range of response options to deal with the problems of climate change. Therefore, vulnerability analysis has further utility for countries and areas where none has yet been carried out or where only preliminary studies are available. Even in many areas with a completed vulnerability assessment, an assessment of additional sea-level rise scenarios, scenarios of other impacts of climate change, and a wider range of response options remains necessary. This entails a greater emphasis on local conditions and careful evaluation of progressive adaptation options.

Problems and deficiencies with the Common Methodology have been indicated in several papers in O'Callahan (1994) and McLean and Mimura (1993) [e.g., Kay and Waterman (1993)], and recommendations have been made for integrating vulnerability assessments into the process of coastal zone management (WCC'93, 1994). In order to continue vulnerability assessment studies in a more complete form, approaches should be developed that more readily meet biogeophysical, socioeconomic, and cultural conditions, as well as governmental and jurisdictional arrangements (e.g., Yamada *et al*., 1995). Common approaches or frameworks that are tailored to the geographic circumstances and needs of each nation should be consistent with the IPCC Technical Guidelines for Assessing Climate Change Impacts and Adaptation (Carter *et al*., 1994) and need to take into account and correct the weaknesses found with the Common Methodology (McLean and Mimura, 1993; WCC'93, 1994).

9.6.   Response Strategies

There is no doubt that the threat of climate change and sea-level rise has focused attention on coastal zones and small islands and awakened awareness of the vulnerability of the world's coastal regions in general—and to low-lying coasts, tidal deltas, and small islands in particular. IPCC CZMS (1990, 1992) have distinguished three groups of response strategies: (planned) retreat, accommodate, and protect. The first involves strategic retreat from or the prevention of future major developments in coastal areas that may be impacted. The second includes adaptive responses such as elevation of buildings, modification of drainage systems, and land-use changes. Both strategies are based on the premise that increases in land loss and coastal flooding will be allowed to occur and that some coastal functions and values will change or be lost. On the other hand, these strategies help to maintain the dynamic nature of coastal ecosystems and thus allow them to adapt naturally. The third strategy involves defensive measures and seeks to maintain shorelines at their present position by either building or strengthening protective structures or by artificially nourishing

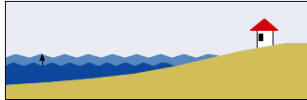
or maintaining beaches and dunes. This strategy could involve the loss of natural functions and values.

As discussed in Section 9.5, vulnerability assessment of various forms provides a range of procedures for a first overview of the consequences of climate change to coastal nations. These procedures also include guidance to a survey of response strategies and a country's capacity to implement those strategies in the context of management and planning of coastal areas. For the majority of coastal nations surveyed, the typical problems posed by sea-level rise (i.e., increased coastal erosion, inundation, flooding, saltwater intrusion) are not uniformly threatening. This does not imply that serious problems will not arise—only that there may be feasible, cost-effective adaptation options.

From Section 9.5, four major areas of concern regarding sea-level rise have emerged: inundation and increased flooding of low-lying islands, inundation and increased flooding of large parts of densely populated deltaic areas, loss of coastal wetlands, and erosion of developed sandy coasts. Each of these areas may require different options to reduce or prevent the prospective adverse impacts associated with biogeophysical changes caused by climate change and sea-level rise. In addition, strategies to reduce the vulnerability of coastal zones and small islands to climate change and sea-level rise should not be seen independently of the resolution of short-term problems arising primarily from human activities. Effective adaptation to climate change and sea-level rise therefore requires a flexible coastal management strategy at all timescales, that incorporates and integrates both short-term and long-term goals.

Although one may argue that there is still a considerable amount of time to implement a response strategy, present-day coastal development often adversely influences the effectiveness of long-term adaptation options (WCC'93, 1994). Moreover, considerable time lags are often involved between the planning and implementation of adaptation options (Vellinga and Leatherman, 1989). The World Coast Conference therefore has concluded that strengthening planning and management capabilities for coastal areas should be delayed no further (WCC'93, 1993, 1994).

Assessing the full social costs of adaptation to climate change is a complicated, often controversial, issue, for which a range of techniques will be required. Apart from estimates of protection costs for a number of countries (see also Table 9-3), this chapter does not offer a comprehensive assessment of these full social costs. This has been done in Chapter 6, *The Social Costs of Climate Change: Greenhouse Damage and the Benefits of Control*, and Chapter 7, *A Generic Assessment of Response Options*, of the IPCC Working Group III volume, which also discuss the techniques available for assessing adaptation costs. A number of cost–benefit studies have been undertaken that attempt to determine optimal response strategies in the face of sea-level rise. Studies include Titus (1991), Nijkamp (1991), Fankhauser (1995), and Turner *et al*. (1995a).

9.6.1. Adaptation Options


There is a wide array of adaptation options that can be employed to retreat, accommodate, and protect. Table 9-4 outlines the options within these three strategies, as listed in the IPCC First Assessment Report (IPCC, 1990).

Box 9-4. Approaches to Coastal Adaptation to Climate Change: Two Examples

West and Central Africa: The coastal nations of West and Central Africa (e.g., Senegal, Gambia, Sierra Leone, Nigeria, Cameroon, Gabon, Angola) have mostly low-lying lagoonal, erosive coasts—and hence are likely to be threatened by sea-level rise, particularly since most of the countries in this area have major, rapidly expanding cities on the coast (Tobor and Ibe, 1990; Adam, 1995; Dennis *et al*., 1995b; G.T. French *et al*., 1995). Ibe (1990) has found that large-scale protective engineering measures are impractical in the region because of the high costs to those countries. Instead, low-cost, low-technology, but effective measures—such as permeable nonconcrete floating breakwaters; artificial raising of beach elevations; installation of riprap; timber groins; and so forth—are considered to be more sensible. Ibe (1990) has noted that "fortunately, outside the urbanized centers, the coasts are almost in pristine condition and largely uninhabited. Where coasts are deemed highly vulnerable, total ban of new development is absolutely necessary."

The Netherlands: The Dutch Impacts of Sea-Level Rise on Society (ISOS) study has assessed consequences and the possible responses for water management and flood protection in the Netherlands (Peerbolte *et al*., 1991). Various scenarios of climate change have been considered, including sea-level rise, changes in river discharges, and changes in storm patterns (i.e., wind direction, storm frequency and intensity). Possible adaptation options, including investments in infrastructure and soft measures such as beach and dune nourishment, have been evaluated and optimized in time for the different sets of scenarios. If sea level were to rise by 60 cm over the next century, $3.5 billion would have to be spent on raising dikes and other safety infrastructure, $500 million on preserving the dune areas, $900 million on adapting flood-prone residential and industrial areas and harbors, and $800 million on adapting water-management facilities. An unfavorable change in storm pattern alone would have the same magnitude of impacts. The occurrence of sea-level rise in combination with the implementation of protective measures will further lead to losses of wetland and intertidal area. These losses cannot be prevented by any realistic additional measures.

Table 9-4: *Response strategies to sea-level rise (IPCC, 1990).*

Present Situation

(Planned) Retreat

*Emphasis on abandonment of land and structures in highly
vulnerable areas and resettlement of inhabitants*

- Preventing development in areas near the coast
- Conditional phased-out development
- Withdrawal of government subsidies

Accommodate

*Emphasis on conservation of ecosystems harmonized with the continued
occupancy and use of vulnerable areas and adaptive management responses*

- Advanced planning to avoid worst impacts
- Modification of land use, building codes
- Protection of threatened ecosystems
- Strict regulation of hazard zones
- Hazard insurance

Protect

*Emphasis on defense of vulnerable areas, population centers, economic
activities, and natural resources*

- Hard structural options
  - Dikes, levees, and floodwalls
  - Sea walls, revetments, and bulkheads
  - Groins
  - Detached breakwaters
  - Floodgates and tidal barriers
  - Saltwater intrusion barriers
- Soft structural options
  - Periodic beach nourishment (beach fill)
  - Dune restoration
  - Wetland creation
  - Littoral drift replenishment
  - Afforestation

Traditionally, the emphasis has been on engineering responses to coastal erosion and protection against flooding, with action often being triggered in response to an extreme event. Now the range of options has expanded to include nonstructural adaptation consisting primarily of zoning, building codes, land-use regulation, and flood-damage insurance, with more emphasis on a precautionary approach. Two different approaches to adaptation to anticipated climate change are discussed in Box 9-4.

IPCC CZMS (1990) has identified the environmental, economic, cultural, legal, and institutional implications of the three response strategies. Vulnerability assessments have since made clear that the extreme options of retreat and full protection highlight the negative effects and overestimate the potential costs and losses from climate change and sea-level rise. Yet adaptation options in low-lying island states (e.g., the Marshall Islands, the Maldives) and for nations with large deltaic areas

(e.g., Bangladesh, Nigeria, Egypt, China), which have been identified as especially vulnerable, are problematic because the options have not been fully evaluated but appear limited and potentially very costly. Even without climate change and associated sea-level rise, these nations will continue to experience rapidly increasing vulnerability to natural coastal hazards due to high rates of population growth, increased demands, continued unsustainable exploitation of resources in the coastal zone, and development in upstream catchment areas. Continued natural and possible anthropogenic subsidence (relative sea-level rise) of large river deltas will increase the risk from storm surges. Strategies must be devised to reduce the economic damages and social hazards well before climate change and associated sea-level rise become a significant factor (Han *et al*., 1995b; Boesch *et al*., 1994). For these situations, conventional adaptation options will have to be enacted as a first step, while innovative or radical solutions—for example, controlled

flooding and sedimentation to harness the natural capability of a delta to respond to sea-level rise—are examined for their effectiveness, environmental impact, social acceptability, and economic efficiency.

Heavily populated areas are primary candidates for structural protection measures such as dikes, sea walls, breakwaters, and beach groins. Because these are expensive options, the use of economic evaluation principles—especially risk assessment and benefit-cost analysis—can provide useful tools in deciding whether to protect or retreat, as well as where such infrastructure investments ought to be placed in order to maximize national or regional social and economic welfare (Carter *et al*., 1994).

Some of the more detailed recent studies of response strategies to sea-level rise have been accomplished for coastal urban areas. In all instances, the problems of sea-level rise are considered to be serious. Many examples can be found in Frassetto (1991) and Nicholls and Leatherman (1995a), including Venice, Hamburg, London, Osaka, St. Petersburg, Shanghai, Hong Kong, Lagos, Alexandria, Recife, and Tianjin. However, Devine (1992) has argued that the shantytown areas found in many coastal cities may be particularly vulnerable to climate change, and adaptation options are uncertain. Chapter 12 further discusses impacts of and adaptation options to climate change in human settlements, including coastal cities.

Kitajima *et al*. (1993) have undertaken a comprehensive analysis of the range of likely structural measures that would be required to respond to a 1-m sea-level rise at 1,100 Japanese ports, harbors, and neighboring areas, as well as their estimated costs. The cumulative undiscounted costs have been estimated at $92 billion. Of that sum, about $63 billion is for raising port facilities and $29 billion is for adjoining shore protection structures (e.g., breakwaters, jetties, embankments). This cost estimate covers about 25% of Japan's coastline; other residential areas would also have to be protected, if that were the most cost-effective option. Further costs would be incurred to maintain existing standards of protection for populated areas as sea level rises (Mimura *et al*., 1994). For a rise of 1 m, total costs would exceed $150 million. Further, natural shores could be largely lost from Japan's coast. It should be noted that, on an average annual basis, the costs constitute a small fraction of the GNP.

Adaptation can exploit the fact that coastal infrastructure is not static. There is a turnover of many coastal facilities through major rehabilitation, construction, and technological changes in ports, harbors, and urbanized areas, averaging roughly 25–30 years. Therefore, there will be recurring opportunities to adapt to sea-level rise, especially if the rate is relatively slow and construction and maintenance plans can be taken into account in land-use planning, management, and engineering design criteria (Stakhiv *et al*., 1991; Yim, 1995). Moreover, experience with allowances for accelerated sea-level rise is limited but growing (e.g., Nicholls and Leatherman, 1995b). The interaction of different aspects of climate change should be considered. For instance, given the likelihood of both sea-level rise and a decrease in the return period of intense rainfall

events (see Section 9.3), more consideration of future drainage capacity requirements in low-lying coastal areas may be prudent (Titus *et al*., 1987; Nicholls *et al*., 1995).

Some structural examples of proactive adaptation include:

- In the early 1990s, design standards for new seawalls in The Netherlands and eastern England were raised 66 cm and 25 cm, respectively, to allow for accelerated sea-level rise. This has been in response to the IPCC90 best estimate for future sea-level rise; the different magnitudes reflect a 100-year and 50-year planning horizon, respectively.
- The Massachusetts Water Resources Authority has included an additional 46 cm of height in the Deer Island sewage treatment plant. This is a safety factor to maintain gravity-based flows under higher sea levels without the additional costs of pumping.
- In Hong Kong, the West Kowloon reclamation is being built 80 cm above earlier design levels to allow for sea-level rise and/or unanticipated subsidence (Yim, 1995). In this case, costs have increased by less than 1%; future reclamations are expected to be similarly raised, and existing reclamations may be raised as part of the redevelopment cycle.

Enlarged setbacks to allow for expected shoreline recession, most notably in some states in Australia (Caton and Eliot, 1993), would enable planned retreat to accommodate climate change impacts. A variant on fixed setbacks is presumed mobility—whereby coastal residents are allowed to live at the shore but give up their right to protect the shore if it retreats in response to climate change or other causes (Titus, 1991). To counter the coastal squeeze of wetlands and maintain their habitat and flood-buffering functions, managed retreat on estuarine shorelines is increasingly favored in the United Kingdom (Burd, 1995). This involves setting back the line of actively maintained defense to a new line inland of the original and promoting the creation of intertidal habitat on the land between the old and new defenses.

9.6.2. *Implementation Considerations*

To date, the assessment of possible response strategies has focused mainly on protection. There is a need to better identify the full range of options within the adaptive response strategies: protect, accommodate, and retreat. Identifying the most appropriate options and their relative costs and implementing these options while taking into account contemporary conditions as well as future problems such as climate change and sea-level rise will be a great challenge in both developing and industrialized countries. The range of options will vary among and within countries, and different socioeconomic sectors may prefer competing adaptation options for the same areas. Experience shows that intersectoral conflicts are a major barrier to improved coastal management (WCC'93, 1994). In the present context, they could also be a major barrier to adaptation to climate change. An appropriate mechanism for coastal

---

Box 9-5. Integrated Coastal Zone Management

ICZM involves comprehensive assessment, setting of objectives, planning, and management of coastal systems and resources, while taking into account traditional, cultural, and historical perspectives and conflicting interests and uses. It is an iterative and evolutionary process for achieving sustainable development by developing and implementing a continuous management capability that can respond to changing conditions, including the effects of climate change. ICZM includes the following:

- Integration of programs and plans for economic development, environmental quality management, and land use
- Integration of programs for sectors such as food production (including agriculture and fishing), energy, transportation, water resources, waste disposal, and tourism
- Integration of all the tasks of coastal management—from planning and analysis through implementation, operation and maintenance, monitoring, and evaluation—performed continuously over time
- Integration of responsibilities for various tasks of management among levels of government—local, state/provincial, regional, national, international—and between the public and private sectors
- Integration of available resources for management (i.e., personnel, funds, materials, equipment)
- Integration among disciplines [e.g., sciences such as ecology, geomorphology, marine biology; economics; engineering (technology); political science (institutions); and law].

---

planning under these varying conditions is integrated coastal zone management (ICZM) (see Box 9-5).

There is no single recipe for ICZM; rather it constitutes a portfolio of sociocultural dimensions and structural, legal, financial, economic, and institutional measures. There are many approaches as well as diverse institutional arrangements that can be tailored to the particular culture and style of governance. Yet a number of essential prerequisites can be identified (WCC'93, 1994). The first of these is the need for *initial leadership* for the planning process. The initiative may consist of a centrally led "top-down" approach, a community-based "bottom-up" approach, or something in between. The second necessary element of ICZM is the provision of *institutional arrangements*. This may involve creating new institutions but more commonly will involve improving horizontal and vertical linkages between existing ones. Third, *technical capacity* (both technological and human capacities) is necessary for compiling inventories in the planning phase and during the implementation of the program, and for monitoring the changes. The final necessary element of ICZM is *management instruments*. These include tools ranging from directive to incentive-based, all with the aim of encouraging stakeholders to comply with the goals and objectives of the given ICZM program.

At both UNCED and at the World Coast Conference, ICZM has been recognized as the most appropriate process to deal with current and long-term coastal problems, including degradation of coastal water quality, habitat loss, depletion of coastal resources, changes in hydrological cycles, and, in the longer run, adaptation to sea-level rise and other effects of climate change.

The goal of ICZM is not only to address current and future coastal problems but also to enable coastal societies to benefit from a more efficient and effective way of handling coastal development. Most coastal areas are called on to provide multiple products and services. As demands on coastal resources continue to grow with increasing population and economic development, conflicts could become more common and apparent. ICZM should resolve these conflicts and implement decisions on the mix of uses that best serve the needs of society now and in the future. Also, ICZM is important in the context of the increasingly expressed concern for sustainable development. Sustainable use of any natural resource can be achieved only by having in place a set of integrated management tasks that are financed and carried out continuously (WCC'93, 1994).

There is a persuasive case for taking action about climate change now—to institute or expand ICZM and thus comply with the precautionary approach. Although the time lag between planning and investment in integrated (cross-sectoral) management is longer than that for single-sector management, the returns are significantly greater. A proactive approach to ICZM, in order to enhance the resilience of natural coastal systems and reduce vulnerability, would be beneficial from both an environmental and an economic perspective (Jansen *et al.*, 1995). In addition to reducing vulnerability and enhancing the resilience of developed coastal regions, such initiatives also can encompass the large lengths of shorelines that are presently undeveloped but may be subject to significant pressures in the coming decades. By acting now, future development may be designed to be sustainable and to accommodate the potential impacts of climate change and sea-level rise.

9.6.3. *Constraints to Implementation*

It is important for governments and policymakers to recognize that although a particular response strategy may appear initially to be appropriate, there are constraining factors that can determine how successfully that option can be implemented (SDSIDS, 1994).

The applicability of any option must be evaluated against (among other things) a background of a country's technology and human resources capability, financial resources, cultural and social acceptability, and the political and legal framework. This is not to suggest that these constraints are insurmountable but that decisionmakers must be realistic when considering the range of options available to them.

9.6.3.1.   Technology and Human Resources Capability

For many countries, scarcity of (or lack of access to) appropriate technology and trained personnel will impose limits on the adaptation options realistically available. For example, the design, implementation, and maintenance of "state-of-the-art" civil works may be beyond the immediate reach of many developing nations unless there is technical assistance to provide the required technology and human skills. This is highlighted in vulnerability assessments for a number of countries, such as Tonga (Fifita *et al*., 1994), Bangladesh (Khan *et al*., 1994), and Belize (Pernetta and Elder, 1993).

Specifically in the case of protection and accommodation, there will be a need for ongoing maintenance and periodic replacement and upgrade. These activities will also require access to the relevant technology and skills to remain effective.

9.6.3.2.   Financial Limitations

The implementation of any adaptation option—whether retreat, accommodate, or protect—will necessitate certain financial commitments from governments, although the level of required funding may vary widely from one option to another. In the case of planned retreat, substantial infrastructure would have to be rebuilt and settlements relocated to less-vulnerable areas, at high reinvestment costs. Adjustment strategies might entail acceptance of less-than-ideal circumstances, while simultaneously increasing the costs of reducing flood risks. Protection strategies almost always involve "hard" engineering structures, which are costly both to construct and to maintain. In the Maldives, for example, the present costs of shoreline protection are close to $13,000 per m; in Senegal, Benin, Antigua, Egypt, Guyana, the Marshall Islands, St. Kitts-Nevis, and Uruguay, maintenance of the existing shoreline against a 1-m rise in sea level could require substantial funding compared with the nation's GNP (Nicholls, 1995). However, it should be noted that national responses to climate change will more likely comprise a variable combination of planned retreat, accommodation, and protection; hence, lower-cost responses probably are available in some areas (e.g., Turner *et al*., 1995a; Volonté and Nicholls, 1995).

Clearly, any combination of response strategies will be largely influenced by monetary considerations, necessitating both short-term investment and a commitment to longer-term maintenance and replacement costs. Many developing countries will find it especially difficult to meet such costs and will increasingly have to turn to donor countries and international agencies for assistance. In Kiribati, for instance, it has been demonstrated that implementation of protection measures especially will almost certainly require external assistance (Abete, 1993). Lack of adequate financial resources will also circumscribe a country's capacity to "purchase" appropriate technology and human skills required for the implementation of various options. Countries should therefore consider designing efficient, least-cost response plans, based on some realistic assessment of what their economies will be able to sustain (WCC'93, 1994).

9.6.3.3.   Cultural and Social Acceptability

Although certain options may be technically and financially possible in a given set of circumstances, they may, at the same time, be culturally and socially disruptive. In some societies, resettlement, for example, would lead to dislocation of social and cultural groups and might even involve the loss of cultural norms and values and the assimilation of new ones. Additionally, an option involving planned retreat could mean the loss of access to communally owned resources and land entitlements, which might undermine the entire economic, social, and cultural base of some communities. Other adaptive measures, such as the construction of "hard" engineering structures, could cause the partial or total elimination of access to traditional fishing, hunting, and culturally important sites.

9.6.3.4.   Political and Legal Framework

The extent to which a given response strategy can be successfully employed may well be influenced by political and legal considerations (Freestone and Pethick, 1990). Retreat options, for example, might prove infeasible given the policy and legal structures of the "receiving" area. Where international resettlement is indicated, these issues can become even more complex—as demonstrated by the plight of refugees worldwide. Further, some options will be incompatible with existing systems of land tenure and ownership and in some societies would necessitate a fundamental change in arrangements prior to implementation to avoid violating certain rights. Failing this, governments could be called upon to provide substantial compensation to communities for loss of property and resource-use rights.

Strategies that lead to coastal land loss might also have an undesirable impact on a country's Exclusive Economic Zone (e.g., Aparicio-Castro *et al*., 1990). This could lead to international legal disputes concerning ownership and use of resources. In those circumstances, such options might not only be considered legally unacceptable but politically infeasible as well.

9.6.4.   Overcoming the Constraints

As a step toward overcoming these constraints, the World Coast Conference was organized with the objective of bringing

together coastal experts and policymakers to identify actions that can be taken to strengthen capabilities for progressive sustainable development and integrated coastal zone management. The conference participants acknowledged that there is an urgent need for coastal states to strengthen their capabilities, in particular with regard to the exchange of information, education and training; the development of concepts and tools; research, monitoring, and evaluation; and funding (WCC'93, 1993). The following are examples of measures that could improve capabilities for developing, implementing, and strengthening national programs for ICZM (WCC'93, 1993):

- Multidisciplinary studies and assessments to determine the potential importance of the coastal zone and its vulnerabilities, particularly those that limit its ability to achieve sustainable development
- An institutional body or mechanism to investigate the need and potential benefits and costs of developing an ICZM program
- A long-term and effective body or mechanism to prepare, recommend, and coordinate the implementation of a permanent ICZM program
- A continuing monitoring and assessment program to collect data, assess results, and identify the need for change or improvement
- An ongoing research program, including an investigation of the potential effects of global climate change, to improve the analytical foundation for the decision-making process
- A policy to increase the availability and accessibility of information to all interested parties
- Active support for local initiatives, exchange of practical and indigenous experiences, and enhancement of public participation
- Education, training, and public-awareness efforts to increase the constituency for ICZM
- Coordination of financial support for relevant activities and investigation of innovative sources for additional support.

Effective ICZM can be achieved by coordination among national, regional, and international organizations and institutions. This will help to avoid unnecessary duplication and develop the concepts, tools, and networks needed to facilitate the development and implementation of national programs, which is a complex process that can be accelerated and enhanced through international cooperation. Regional approaches can complement and strengthen activities at the national and international levels.

Various international initiatives have been undertaken to encourage and facilitate coordination and cooperation in both policy and research. Several United Nations organizations and other international governmental and nongovernmental organizations have developed programs aimed at strengthening ICZM capabilities at different levels. An overview of these activities is presented in WCC'93 (1994). In 1993, the IGBP launched its core project LOICZ, which aims to stimulate interdisciplinary scientific coastal research in the context of global change (Pernetta and Milliman, 1995).

Clearly, the wide range of uncertainty in human and natural variables that will affect ICZM emphasizes the need for continued research and monitoring. The results of scientific research and information from monitoring activities need to be integrated into policy development, planning, and decision-making throughout the ICZM process.

9.7. Research and Monitoring Needs

Although much has been achieved since the IPCC First Assessment in 1990, this chapter shows that the understanding of the likely consequences of climate change and sea-level rise is still imperfect. This situation can be improved only through a sustained research and monitoring effort, requiring a major commitment of resources at the national, regional, and global levels. The potential problems of small islands, deltas, coastal wetlands, and developed sandy coasts deserve particular attention as part of these efforts. Coastal zones and small islands illustrate the fundamental need for better coupling of research and models from the natural sciences and the social sciences to provide improved analytical capability and information to decisionmakers. An emphasis on understanding the impacts of climate change at the local and regional scales is essential.

There are a number of critical issues and priorities in ongoing research and monitoring, as initiated by IPCC CZMS (1990, 1992), that should be continued over the next few years to enable better decisionmaking concerning the possible impacts of climate change in coastal zones and small islands:

- Development of improved biogeophysical classifications and frameworks of coastal types for climate-change analysis, including the influence of human activities (IGBP-LOICZ has taken an important step in this direction)
- Investigations of geomorphological and biological responses of coastal types and critical ecosystems to climate change and sea-level rise, with specific attention to the response of seagrass to climate change as well as potential changes in sediment budgets
- Improved methodologies for incorporating existing, high-quality historical and geological coastal-change data into response models for climate change
- Improved coastal-processes data (especially in developing countries), based on instrumentation (tide gauges, current meters, wave recorders, etc.), as well as improved capacity to interpret and analyze the data
- Improved databases for vulnerability assessment and adaptation planning on coastal socioeconomic trends, such as population changes and resource utilization and valuation, taking into consideration differences in sociocultural characteristics of countries and ethnic groups

- Extension of new and existing vulnerability assessment studies to include a range of local scenarios of sea-level rise (rather than a single scenario), other possible impacts of climate change such as changing storminess or precipitation, and an assessment of the range of possible adaptation strategies
- Continued education and training relevant to vulnerability assessment and integrated coastal zone management, employing, as far as practicable, standardized methodologies and frameworks.

Some ongoing initiatives have already been undertaken to address these priorities. For example, the Intergovernmental Oceanographic Commission (IOC) coordinates a Global Sea Level Observing System (GLOSS). However, there still are many gaps, and the system requires increased international support and coordination. IGBP-LOICZ aims to stimulate interdisciplinary scientific coastal research in the context of global change. Focus 2 of LOICZ aims to investigate coastal biogeomorphological interactions under different global-change scenarios. It focuses on the interaction between major ecosystem types with the sedimentary environment and aims to assess the implications of ecosystem perturbations on coastal stability with a rise in sea level. Focus 4 is especially relevant for integrated coastal zone management because it addresses the socioeconomic impacts of global change on coastal zones and aims to investigate how improved strategies for the management of coastal resources can be developed.

New initiatives also are required, as has been recognized by participants of the World Coast Conference (WCC'93, 1994). Increased efforts are needed mainly in the social sciences and adaptation to climate change, including the development of:

- Integrated coastal-response models, which seek to combine the interactions of biogeophysical, socioeconomic, and climate-change factors, incorporating the knowledge and technologies of traditional societies and local peoples
- Methods to quantify the benefits of integrated coastal zone management
- A broad framework for the analysis, planning, and management of coastal zones in the context of climate change, recognizing the co-evolution of natural and social systems.

Such a framework would encourage nations in the formulation and implementation of ICZM strategies and programs that are appropriate to climate change and fully take into account the existing environmental, social, cultural, political, governance, and economic contexts. This would help to fulfill the recommendations made by IPCC CZMS (1990).

To facilitate these goals, an international conference to share experience on coastal impacts and adaptation to climate change might be useful, building on the success of earlier meetings of the IPCC Coastal Zone Management Subgroup and the World

Coast Conference. Particular targets for such a conference could include:

- An updated assessment of coastal vulnerability to climate change
- Examples of biogeophysical/socioeconomic integration in coastal research and coastal management
- Testing of the framework for ICZM via case studies in a range of countries or regions.

These activities could assist coastal nations in meeting their obligations under Agenda 21 of UNCED.

Acknowledgments

CONTENTS

EXECUTIVE SUMMARY

The hydrological system is potentially very sensitive to changes in climate. Changes in precipitation affect the magnitude and timing of runoff and the frequency and intensity of floods and droughts; changes in temperature result in changes in evapotranspiration, soil moisture, and infiltration. The resulting changes in surface wetness, reflectivity, and vegetation affect evapotranspiration and the formation of clouds, as well as surface net radiation and precipitation. Meanwhile, the hydrological system is being affected by other, more direct human activities, such as deforestation, urbanization, and water-resource exploitation.

The effects of climate change on hydrological regimes are generally estimated by combining catchment-scale hydrological models with climate change scenarios derived from general circulation model (GCM) output. In addition to the uncertainties associated with GCM simulations, there are three major problems in estimating the hydrological effects of climate change: (1) expressing scenarios at a scale appropriate for hydrological modeling; (2) the considerable errors inherent in climatic and hydrological data used to validate hydrological models; and (3) converting climatic inputs into hydrological responses. Methods have been developed to address most of these problems, but estimates of the hydrological effects of climate change remain very uncertain. This uncertainty is largely due to difficulties in defining credible scenarios for changes in precipitation and assessing vegetation response to a changed atmosphere at appropriate spatial scales.

There are considerable differences in estimated changes in hydrological behavior both between scenarios and between catchments, but it is possible to draw some general conclusions about sensitivities:

- We have a high level of confidence that an increase in air temperature would increase potential evapotranspiration, but the magnitude of increase depends also on changes in net radiation, humidity, windspeed, precipitation and its temporal distribution, and vegetation characteristics. Actual evapotranspiration may increase or decrease according to the availability of soil moisture.
- The effect of a given change in precipitation and evapotranspiration on river runoff and groundwater recharge varies considerably between catchments, depending on climatic regime and (at shorter time scales) catchment physical characteristics. We have a high level of confidence that, in general, the drier the climate, the greater the sensitivity of hydrological regimes to changes in climate.

- Neither climatic nor hydrological change will be equally distributed throughout the year; in some cases it appears that the variability of river flow through the year would increase if climate were to change, and the frequency of both high and low flows would increase. We have a medium level of confidence in this finding, due to variations between catchments and scenarios.
- We have a medium level of confidence that more intense rainfall would tend to increase the occurrence of floods, although the magnitude of this effect would depend not only on the change in rainfall but also on catchment physical and biologic characteristics. These characteristics also may change due to human activity that may or may not be in response to climate change.
- An increase in the duration of dry spells would not necessarily lead to an increase in the occurrence of low river flows and groundwater levels. River flows may be sustained by increased precipitation earlier in the year. The effect of a change in the duration of dry spells depends significantly on catchment physical and biologic characteristics. We have a medium level of confidence in these findings.
- Hydrological regimes in many continental and mountain areas are determined by winter snowfall and spring snowmelt; if climate were to change and the proportion of precipitation falling as snow decreased, we have a high degree of confidence that in such regions there would be a widespread shift from spring to winter runoff. This effect may be modified by changes in the seasonal distribution and amounts of precipitation.
- Very little is known about possible changes in groundwater recharge, which will depend on the balance between changes in opportunities for recharge and the amount of water available for recharge. Therefore, we have a low level of confidence in any conclusions about or projections of changes in groundwater recharge.

Freshwater ecosystems, including lakes and streams (covered in this chapter) and noncoastal wetlands (see Chapter 6), are scattered across the landscape and tightly linked to regional hydrology. The effects of climate change on freshwater ecology will interact strongly with other anthropogenic changes in land use, waste disposal, and water extraction. Changes in lake and stream ecosystems will occur in the context of existing climates and expected changes; effects will differ greatly from place to place. General conclusions follow:

- We have a high level of confidence that climate change will influence freshwater ecosystems directly

through changes in water availability by altered flood regimes, water levels, and, in the extreme, the absence of water in streambeds and lake basins.

- We have a high level of confidence that changes in water temperature and thermal structure of freshwaters directly affect the survival, reproduction, and growth of organisms; productivity of ecosystems; persistence and diversity of species; and regional distribution of biota.
- We have a high level of confidence that changes in runoff, groundwater inputs, and direct precipitation to lakes and streams will alter the input of nutrients and dissolved organic carbon, which in turn will alter productivity and clarity. Changes in the duration of lake and stream ice and snow on ice will change mixing patterns, oxygen availability, and the survival and reproductive success of certain organisms.
- We have a medium level of confidence that increases in terrestrial productivity will enhance the productivity of streams by increasing the input of organic detritus and likely increasing the export of CO_2 from lakes to the atmosphere.
- We have a medium level of confidence that climate-induced changes in temperature, ice and snow cover, and biological production will be more intense at higher latitudes—where temperature changes are expected to be greatest—and at the lower-latitude edges of the geographic ranges of many taxa—where extinctions and extirpations will be the greatest, especially where isolation prevents the poleward dispersal of organisms in rivers and streams.
- We have a high level of confidence that water-level declines will be most severe in lakes and streams in dry evaporative drainages and in basins with small catchments—where in many years evapotranspiration losses already exceed precipitation and inputs from groundwater plus overland flow.
- We have a high level of confidence that the effects of an increase in severe flood events may be more damaging in drier climates where soils are more erodible and precipitation-runoff relationships are highly nonlinear. Drought events may be more severe in humid areas that have not experienced frequent droughts in the past.
- We have a high level of confidence that climate changes that increase variability are expected to have greater ecological effects than climate changes associated with a change in average conditions; increased variability in hydrologic conditions with associated flash floods and droughts will reduce the biological diversity and productivity of stream ecosystems.
- We have a high level of confidence that assemblages of organisms will tend to move poleward with warming, with range constrictions and local and global species extinctions occurring at the lower latitudes of their distributions and range extensions and invasions occurring poleward. For smaller, more hydrologically isolated basins, dispersal will lag considerably behind the warming in climate—resulting in near-term reductions in diversity.
- We can say with a lower degree of confidence that warming of larger and deeper temperate lakes may increase their productivity, provided that nutrient inputs are not greatly reduced; in some shallow, stratified lakes, this increase in productivity would lead to a greater likelihood of anoxic conditions in deep water, with subsequent loss of cold-water fauna.
- We have a medium level of confidence that changes in vegetation, in rainfall, and in hydrological regimes affect erosion on hillslopes and in river channels, sedimentation, and channel stability.

Water quality will be affected by changes in water temperature, CO_2 concentration, the processes by which water gets into the stream network and aquifers, and the timing and volume of streamflow. The relative importance of these influences varies between catchments and chemical species, and the influences interact to ameliorate or exaggerate the effects of change. Dissolved oxygen concentrations would not change much if higher water temperatures were associated with increased streamflow, but if streamflow were to decline there would be a large decrease in dissolved oxygen concentrations. In many catchments, stream and groundwater quality is determined by human influences—such as the application of agricultural chemicals, urbanization, and the return of treated sewage. The water quality of streams that already are polluted is likely to be affected by changes in temperature and flow regimes, but changes in land use and the input of pollutants may have a far greater effect than changes in climate.

10.1. Introduction

The hydrological cycle and the climate system are intimately linked. Any change in climate is reflected in changes in key hydroclimatic elements of the hydrological cycle and vice versa: Changes in precipitation affect the magnitude and timing of runoff and groundwater recharge, as well as the frequency and intensity of floods and droughts; changes in temperature result in changes in evapotranspiration, soil moisture, and infiltration conditions, with resulting changes in surface wetness, reflectivity, and vegetation that affect evaporation and the formation of clouds, as well as surface net radiation and—completing the cycle—precipitation.

Freshwater ecosystems include lakes, streams, and wetlands scattered across the landscape and are tightly linked to regional hydrology. These surface freshwater systems constitute a set of scarce resources for humans sensitive to climate change; excluding ice, they constitute only 0.009% of the volume of water on Earth (Goldman and Horne, 1983). Of these surface freshwaters, 99% (by volume) are lakes and 1% are streams. Groundwater is 66 times more abundant than surface freshwaters but still represents only 0.6% of the volume of all surface waters. Freshwater systems greatly influence the distribution of populations and economic growth, add greatly to the biological and ecological diversity of the landscape, and provide a variety of goods and services. The effects of climate change on freshwater ecosystems will interact strongly with anthropogenic changes in land use, waste disposal, and water extraction.

This chapter examines the sensitivities of hydrological and freshwater systems to climate change. The chapter covers four main issues: (1) the potential effects of global warming on components of the hydrological cycle; (2) possible changes in the frequency and magnitude of extreme high and low flows; (3) implications for thermal, chemical, and morphological changes; and (4) consequences for stream and lake ecosystems. The consequences of changes in freshwater systems affecting water resources, ecosystem management, agriculture, power production, and navigation are examined in other chapters of this report.

Although some of the principal linkages between climate and the hydrological system are well understood, predicting the effects of global warming is very uncertain. Current general circulation models (GCMs) work at a spatial resolution that is too coarse for hydrological purposes, producing weather averaged over too large a geographic area and producing average conditions rather than changes in ranges, frequencies, seasonal distributions, and so forth. They do not yet include all of the relevant feedbacks between the land surface and the atmosphere. There is considerable uncertainty in the translation of climate changes into hydrological effects through hydrological models and an inability to maintain consistency between GCM and hydrological model water balances, particularly for evaporation. Different models give different sensitivities to change, and a model calibrated under current conditions may not be appropriate under a changed climate. There still are major uncertainties over the effects of increased CO_2 concentrations on plant water use—and hence transpiration rates—in natural settings at the catchment scale.

Because of the spatial complexity of the Earth's climate-water system, there is no ideal method to delineate hydroclimatic regions that could be used in this chapter. The case studies selected cover all the world's main climatic belts as used by L'vovich (1979)—subpolar, temperate, subtropical, tropical, equatorial, and mountain regions—taking into account the degree of climatic aridity and humidity in the regions covered by the study. The literature available does not cover all regions adequately, and major gaps remain in the regional coverage of published studies and the quality of the data.

10.2. The Hydrological Cycle

10.2.1. The Hydrological Cycle in the Climate System

The hydrological cycle is driven by solar energy and involves water changing its form through the oceans, atmosphere, land and vegetation, and ice and glaciers. After precipitation water reaches the Earth's surface, it either remains on the surface as rain or snow; quickly evaporates; infiltrates into the soil, where it is taken up by vegetation (and eventually transpired through photosynthesis and respiration); moves along the surface or through the soil toward rivers and streams; or percolates to aquifers, recharging groundwater and subsequently draining into rivers and oceans, perhaps after delays of years or centuries. Some water is stored over the winter as snow and over longer time scales as ice.

The partitioning of incoming precipitation between storage, evaporation, infiltration, groundwater recharge, and runoff varies widely between catchments, depending on climatic and catchment characteristics. Vegetation cover has a major effect on the water and energy balance, particularly through interception and evaporation. There are many types of hydrological regimes with different combinations of processes, but it helps to distinguish among three major types: snow-dominated, humid, and semi-arid/arid. In the first regime, a significant proportion of precipitation falls as snow and is stored on the surface until it melts during the spring. In a humid regime, rainfall infiltrates into the soil and reaches the stream network by a variety of routes over different time scales. In semi-arid and arid environments, rainfall is short-lived and generally very intense, and soils tend to be thin. A large proportion of rainfall therefore runs directly off the surface, only to infiltrate into deeper soils downslope or along the river bed.

Hydrological responses vary over time scales from seconds, to days or weeks, through years to decades, and have continuous feedbacks with the atmosphere. In the most general terms, the amount of water present at and beneath the surface affects both the proportion of incoming energy reflected back into the atmosphere and the partitioning of the remaining net radiation between sensible and latent heat. A change in the land surface,

and in the hydrological processes operating at the surface, therefore will affect atmospheric processes; the magnitude of the effect depends on the degree and extent of change, as well as local climatic characteristics. It is increasingly clear that hydrological variability can be interpreted in terms of large-scale climatic anomalies—such as those associated with the El Nino/Southern Oscillation (ENSO)—and that there are strong relationships between hydrological anomalies in different parts of the world (e.g., Redmond and Koch, 1991; Aguado *et al.*, 1992; Mechoso and Iribarren, 1992; Simpson *et al.*, 1993; Dracup and Kahya, 1994; Ely *et al.*, 1994).

10.2.2. Anthropogenic Non-Climatic Impacts on the Hydrological Cycle

Human activities are interfering with the hydrological cycle in many regions and catchments. There are many different types of impact; they can be deliberate (perhaps with unanticipated consequences) or inadvertent, and they affect the quantity and quality of water and aquatic biota. Such activities include:

- **River impoundment and regulation**: Dams for flood protection, hydropower purposes, or inland navigation and related control measures generally cause changes in the spatial and temporal distribution of streamflow, which also may have impacts on evaporation and infiltration in areas close to the river bed, as well as on biota. Of particular importance are increases or decreases in river infiltration to groundwater aquifers.
- **Impacts of land use and land-use changes**: Anthropogenic activities that affect the land surface include urbanization; agricultural activities such as irrigation, drainage, land improvement, and the application of agricultural chemicals; deforestation and afforestation; and overgrazing. These activities can cause locally and regionally significant changes in evaporation, water balance, flood and drought frequency, surface and groundwater quantity and quality, and groundwater recharge.
- **Water removal and effluent return**: Water used for municipal, industrial, and agricultural purposes can affect river flows and groundwater levels. This water may subsequently be returned to the hydrological system (although much water used for irrigation is lost by evaporation), but at a lower quality.
- **Large-scale river diversions**: Large-scale diversions of river flow or parts of it, mainly for purposes of irrigation or hydropower generation, can cause serious and manifold changes in the ecosystems of large areas.

10.2.3. Methods for Estimating the Hydrological Effects of Climate Change

There are several possible ways of creating scenarios for climate-change impact studies. Temporal analogs (e.g., Krasovskaia and Gottschalk, 1992) use the past as an analog for the future; spatial analogs substitute one location for another. Many studies have examined the effect of arbitrary changes in climatic inputs on the hydrological system (e.g., Novaki, 1992a, 1992b; Gauzer, 1993; Chiew *et al.*, 1995). Although most studies now use scenarios based on GCM simulations, there is a multitude of uncertainties associated with their use—which are listed here by their relative importance (the first being the most critical):

- Weaknesses of models in coupling the land surface and atmospheric hydrologic cycles and in GCM simulations of regional climate and extremes, particularly with regard to precipitation
- Weaknesses in using GCM simulations to define climate-change scenarios at the spatial and temporal scales required by hydrological models. The spatial resolution of current GCMs is too coarse for their output to be fed directly into hydrological models.
- Weaknesses in simulating changes in hydrological characteristics with given changes in climatic inputs to the hydrological system, which reflect difficulties in developing credible hydrological models with sparse and error-contaminated climatic and hydrological data.

Figure 10-1 attempts to summarize the relative magnitude of the uncertainties. Given that a reasonably realistic hydrological model is used, the greatest uncertainty in hydrological climate-change impact assessment lies in the initial scenarios derived from GCMs—which do not include all of the relevant feedbacks between the land surface and the atmosphere—and the derivation of catchment-scale climate scenarios. Sections 10.2.3.1 through 10.2.3.3 explore further the stages in this cascade of uncertainties.

10.2.3.1. GCMs and Hydrological Requirements

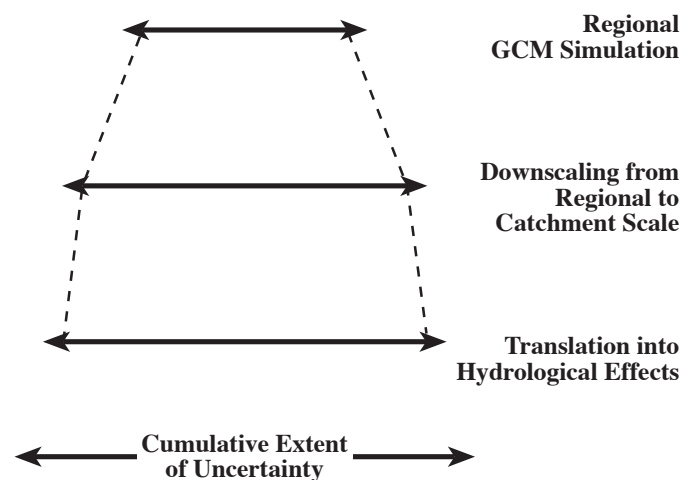
GCMs show progress in simulating the present climate with respect to annual or seasonal averages at large spatial scales ($>10^4$ km^2) but perform poorly at the fine temporal and spatial scales


Figure 10-1: Uncertainties in hydrological impact assessment.

relevant to hydrological studies (Askew, 1991; Grotch and MacCracken, 1991). Although GCMs are unanimous in their projections that a doubling of current atmospheric CO_2 concentrations would lead to an increase in global mean temperature and precipitation, they differ in their projections of changes in temperature and precipitation at regional scales that are the same order of magnitude as projected global changes. The direct use of GCM output to drive hydrological models is considered inappropriate due to the coarse resolution of the spatial grids used by current GCMs (relative to the scale of river basins); the simplified GCM representations of topography, land surface and cloud processes, and energy transfer within the oceans; and the simplified coupling of the atmosphere and the oceans. Until recent GCM transient runs, GCM simulations usually were of short duration (less than 30 years) and may not have captured the extreme events of particular interest in flood and drought analyses.

From a hydrological perspective, there is a need to improve the representation of land-surface processes and their interaction with the atmosphere. There now are intensive field studies into the interaction between land-surface hydrological processes and climate at point and regional scales (e.g., HAPEX-MOBILHY: Andre *et al*., 1986; HAPEX-SAHEL: Goutorbe *et al*., 1993; EFEDA: Bolle *et al*., 1993), as well as work to improve models of land-surface processes (e.g., Wood *et al*., 1992). The World Climate Research Programme (WCRP) sponsored by the World Meteorological Organization (WMO), the Intergovernmental Oceanographic Commission of UNESCO, and the International Council of Scientific Unions has launched a Global Energy and Water Cycle Experiment (GEWEX). The GEWEX Continental-Scale International Project (GCIP) is an initiative to study the water and energy budgets of an extensive geographical area with a large volume of accessible data; the Mississippi River basin has been selected as the primary region of interest. Similar projects have been organized in other areas of the world—such as the Baltic Sea region (BALTEX), the boreal region (BOREAS), and the Himalaya/monsoon region (GAME).

Changes in the temporal distribution of precipitation—even with average precipitation remaining stable—may result in changes in river flow and its extremes, floods and droughts, and water availability for plants and water supply. There is a need to consider changes to the statistical distributions of weather variables rather than just their means because changes in response to climatic warming may be reflected more in extreme events than in average conditions (Katz and Brown, 1992).

10.2.3.2. Creating Scenarios at the Hydrological Scale

GCMs operate at a spatial scale far coarser than hydrological models and do not necessarily simulate regional-scale climate particularly well. It is therefore necessary to downscale GCM results to the catchment scale. Several techniques have been developed to derive scenarios at this spatial scale from GCM output:

- Direct use of GCM-simulated changes in precipitation, temperature, and evaporation, perhaps interpolated to the catchment scale and applied to observed catchment climate data (e.g., Bultot *et al*., 1992; Arnell and Reynard, 1993; Viner and Hulme, 1994; Kirshen and Fennessey, 1995)

- Stochastic generation of point-scale weather, with stochastic model parameters adjusted according to scenarios derived from GCM output (e.g., Nathan *et al*., 1988; Cole *et al*., 1991; Wilks, 1992; Wolock *et al*., 1993; Bates *et al*., 1994, 1995; Valdés *et al*., 1994; Rao and Al-Wagdany, 1995; Tung and Haith, 1995)

- Estimation of catchment-scale weather from large-scale climatic features, such as weather types and mean sea-level pressure fields (e.g., Bardossy and Plate, 1992; Hay *et al*., 1992; Hughes *et al*., 1993; von Storch *et al*., 1993)

- Use of nested regional limited-area models embedded within GCMs to simulate regional climate at a higher spatial resolution (e.g., Leavesley *et al*., 1992; Hostetler and Giorgi, 1993; McGregor and Walsh, 1994).

10.2.3.3. Hydrological Modeling and Impact Assessment

Hydrological models have been used to a large extent to determine the relative sensitivity of hydrological variables to climatic inputs. These simulations have been useful in the search for amplification effects—that is, whether small changes in one (climatic) variable may cause substantial changes in another variable, thus aggravating water problems particularly in areas that are presently vulnerable. Such a sensitivity analysis allows assessment of the impact of the relative increase or change in temperature and precipitation on changes in hydrological variables of interest (e.g., runoff, evapotranspiration, soil moisture, flood potential). Results of sensitivity analyses are useful in practical "what-if" considerations. Sensitivity analyses also underscore uncertainty in the prediction of future water resources. They may include inconsistencies by ignoring other important climatic variables that may be affected by climate change, such as net radiation, wind, and humidity.

Current approaches to hydrological modeling for climate-change impact assessment include empirical models, water-balance models, conceptual rainfall-runoff models, and physically based, distributed models (Leavesley, 1994). Empirical models consider statistical relations between annual runoff and precipitation, temperature, or potential or actual evapotranspiration for present-day conditions (Revelle and Waggoner, 1983; Arnell, 1992; Duell, 1994). Runoff under changed climate conditions is obtained from regression models by perturbing historical climate series. This approach assumes that the functional form as well as the parameters of a regression model remain valid for a changed climate. Leavesley (1994) has questioned the validity of this approach, and Arnell (1992) has shown that it should be used with extreme caution because the estimated sensitivities to change are very dependent on details of the model. Water-balance and conceptual rainfall-runoff models simulate the movement of water from the time it enters a catchment as precipitation to the time it leaves the catchment as runoff, although rainfall-runoff models consider the flow paths and residence times of water in finer detail (Leavesley, 1994). Klemes (1985) and Becker and Serban (1990) state that

calibrated water-balance or conceptual rainfall-runoff models are not directly usable for assessing climate-change impacts because the model parameter estimates are assumed to remain valid for the changed climate. This point was illustrated by Gan and Burges (1990), who found that the calibrated sizes of conceptual moisture storages are not climate-invariant. The size of this problem can be checked, at least approximately, by comparing model prediction errors based on parameters estimated from wet and dry periods within historical records. Physically based models appear to be a superior alternative because their parameters are estimated from field measurements or physically based analyses. These models use physically based process equations to simulate the spatial variability of runoff due to spatial variations in land characteristics such as soil type and topography, as well as rainfall. Although physically based models have the potential to become a universally applicable tool, they come with the price of increased model complexity, data requirements, and computing costs. In practice, there is a paucity of measured field data and a lack of methods for the collection of data at a scale appropriate for such models, limiting their application to studies of small-catchment hydrology (Grayson *et al.*, 1992a, 1992b).

The development of a large-scale model of land-surface hydrology may be started from an even larger-scale continuum of atmospheric processes, which is how GCM researchers were proceeding until recently. In this approach, it is necessary to simplify the spatial distribution of variables of the land surface to an extent that not only distorts their physical significance but provides spatially imprecise inputs to the atmospheric models at the land-atmosphere interface. This problem has been identified by GCM researchers in studies of the regional aspects of changes in climatic variables. Another way to solve the problem is to develop a macroscale model, starting from mesoscale analysis of hydrological processes, as practiced by hydrologists in simulations for water resources management purposes. Although the call for such an approach is being heard more and more frequently, a model of this type is not yet available.

Large-scale hydrological models, which estimate vertical fluxes of the land-surface/atmosphere interface and horizontal fluxes resulting in measurable runoff, using physically based parameters, could be very important in assessing the impacts of climate change and could improve GCM regional simulations through inputs to GCM hydrology. Additional sources of information on these topics include a recent discussion on the type and use of scenarios and hydrological models by Lettenmaier *et al.* (1994), a review of research on climate-change impact on water resources by Chang *et al.* (1992), and the Proceedings of the First National Conference on Climate Change and Water Resources Management (Ballentine and Stakhiv, 1993).

10.3.   Effects of Climate Change on the Hydrological Cycle

10.3.1.   Introduction

The complex and interacting effects of an increasing concentration of greenhouse gases on the hydrological system are shown

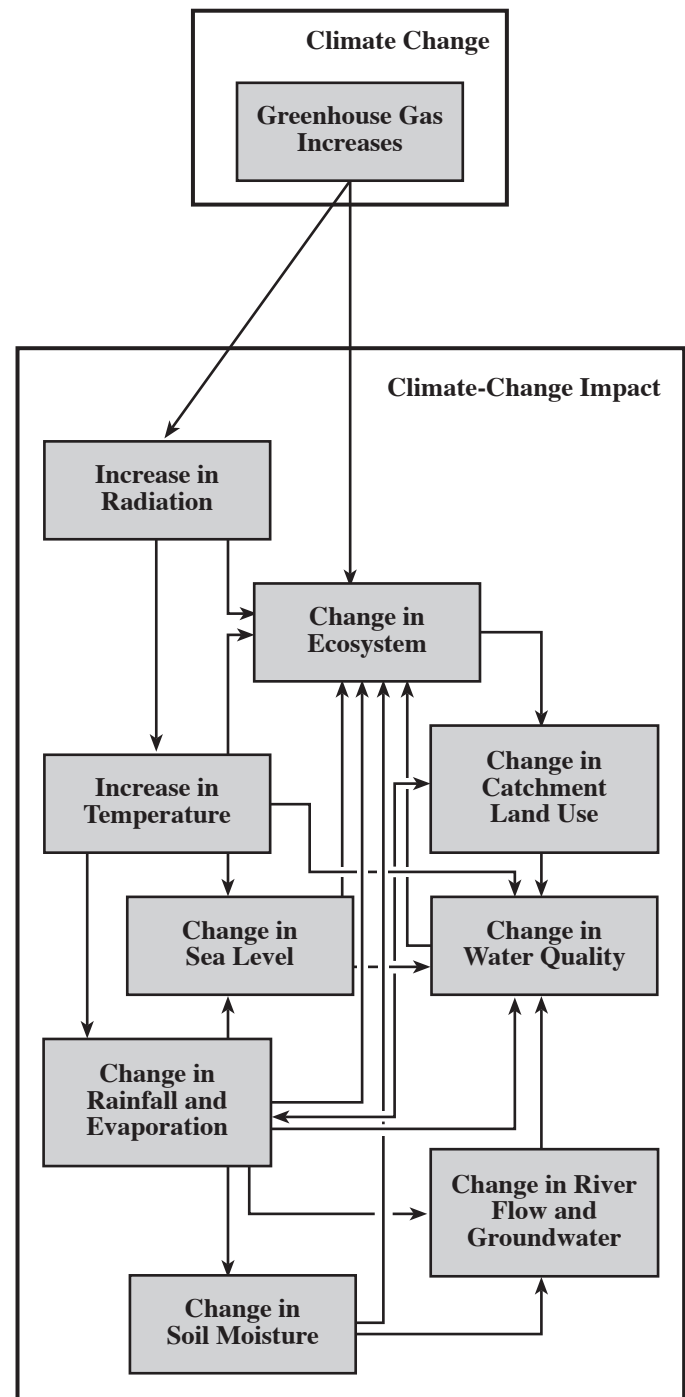
in Figure 10-2 (Arnell, 1994). The increase in greenhouse gas concentrations results in an increase in net radiation at the Earth's surface, which results in changes in temperature, rainfall, and evaporation—and hence soil moisture regimes, groundwater recharge, and runoff. Temperature, rainfall, evaporation, and soil moisture affect vegetation growth, as do changes in incoming solar radiation and the atmospheric CO_2 concentration. Higher CO_2 concentrations also may affect plant water use (see Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, of the Working Group I volume). The


Figure 10-2: Impacts of climate change on the hydrological system (Arnell, 1994).

components of the hydrological system are very clearly linked, and the effects of global warming may be very complex. This complexity is heightened by nonlinear responses and important thresholds in the hydrological system that govern the operation of different types of processes.

The following sections summarize global-warming impacts on various components of the hydrological system. Table 10-1 provides a selection of case studies from the recent literature. Case studies are not available for all regions, but an attempt has been made to list some of the modeling assumptions employed. The results of the studies should be examined in association with the caveats noted in Section 10.2.3 and with the knowledge that hydrological models may not adequately portray the true responses of the modelled processes.

10.3.2. Precipitation

Globally, climate change may result in a wetter world. Present-day climate models project an increase in global mean precipitation of about 3–15% for a temperature increase of 1.5–4.5°C. Although it is likely that precipitation will increase in some areas and decline in others, climate models are not in agreement as to the amount or the regional distribution of precipitation. Projections of regional changes in precipitation are less certain than projections of regional changes in temperature. Higher-latitude regions are expected to experience more precipitation, particularly in the winter. In most cases, this extends to mid-latitudes. Models vary significantly in terms of how the intensity and statistical distribution of rainfall is predicted to shift in the tropics, although little change is expected for the dry subtropics.

10.3.3. Evaporation and Transpiration

Evaporation is a function of the demand for water and the supply of water. It is driven by energy availability, particularly net radiation. An increase in net radiation will increase the demand for evaporation, but this effect will be complicated by changes in the humidity of the air—affecting the ability of the air to accept more water—and by changes in the rate of movement of air across the evaporating surface. In addition, the humidity of air masses is strongly linked to evaporation over land and water bodies, including the oceans. With credible assumptions about increases in radiation and reductions in humidity, a rise of about 2°C could cause an increase in potential evaporation of up to 40% in a humid temperate region (Arnell and Reynard, 1993), but less in a drier environment where changes in humidity are not very important. Higher temperatures will mean that the atmosphere can hold more water—thus enhancing the effects of increased net radiation on evapotranspiration in regions where air humidity currently imposes a constraint on the rate of evaporation (as in humid areas).

The actual evaporation rate often is constrained by moisture availability. A reduction in rainfall or a change in its temporal distribution, and hence in soil moisture, may mean that

Table 10-1: Summary of recent case studies.

Region/Country	Investigators	GCMs/Climate Scenarios[1]	Hydrologic Scenarios
Australia 6 Catchments	Bates *et al.* (1995)	CSIRO 9 (1991)	Increase in magnitude of annual maximum monthly runoff series, with size of increase dependent on hydrological model; increase or decrease in median monthly runoff dependent on location and season.
28 Catchments	Chiew *et al.* (1995)	Hypothetical + BMRC, CCC, CSIRO 9, GFDLH + UKMOH	Annual runoff changes of ±50%; annual soil moisture level changes of -25 to +15%.
China Haihe, Huaihe, and Yellow River Basins	Liu *et al.* (1995)	Output from seven GCMs used as input to hydrological models	Decrease in annual runoff of 2–12%.
Finland 12 Catchments	Vehvilainen and Lohvansuu (1991)	GISS	Increase in mean discharge by 20–50%; considerable increase in mean minumum discharges in winter due to shorter snow-cover period; decrease in mean maximum discharges due to reduced maximum snow water-equivalents; persistent winter snow cover will vanish in southern Finland.
Greece Mesochora Catchment	Panagoulia (1992)	GISS	Decreased spring and summer runoff, soil moisture, and mean snow accumulations; increased winter runoff and soil moisture.

Table 10-1 continued.

Region/Country	Investigators	GCMs/Climate Scenarios[1]	Hydrologic Scenarios
Hungary Danube Basin	Gauzer (1993)	Hypothetical temperature scenarios	Considerable increase in winter streamflow and decrease in summer applied to September 1991–August 1992 flow; no decrease in spring flood peak, but change in timing.
Drainage Systems	Novaki (1990, 1992a, 1992b)	Hypothetical precipitation and temperature scenarios	1–2°C increase in temperature and 5–20% decrease in annual precipitation may cause 15–30% decrease in drainage discharge at start of spring.
India Kolar and Sher Basins	NIH (1994)	Hypothetical scenarios	Sher Basin more sensitive to climate change; impacts large enough in central India to influence storage design and operation.
Japan Various	Harasawa (1993)	Not known	Reduced snowfall, hence snowmelt; changed amount and seasonal pattern of water resources; impacts on water quality.
Nepal Lantang Kola Catchment	Fukushima *et al.* (1991)	Not known	Increase in river flow of 100% with stable glacier area; +30% if glacier area decreases by 30%.
South Asia	Lal (1994)	ECHAM 3–Hamburg	Increase in soil moisture over central India, Bangladesh, and south China in summer; significant decline in soil moisture over central China in winter; increase in runoff over northeastern India, south China, and Indonesia; decline in runoff possible over north China and Thailand.
Switzerland Murg Catchment	Bultot *et al.* (1992)	Various sources	Decreased annual deep percolation; increased winter runoff, but little change to annual flow; reduced soil moisture content in summer; shorter spells with snow cover.
Ukraine Poles'e River Basin	Nazarov (1992)	Scenarios in Houghton (1991)	Increase in annual runoff of 6%; decrease in evapotranspiration of 2%; decrease in soil moisture storage of 17%.
United Kingdom England and Wales Catchments	Arnell (1992)	Hulme and Jones (1989)	Increases in mean annual runoff of 13 to 30% for 10% precipitation increase (15 inches annual rainfall).
United States Boston	Kirshen and Fennessey (1993)	GFDL (1988), GISS (1982), OSU (1984–85), UKMO (1986)	Decrease or increase in reservoir-system safe yield, depending on GCM used.
American River, Washington	Lettenmaier (1993)	2–4°C uniform temperature increase	Snow accumulation substantially reduced; high-flow season shifted from spring to winter; peak actual evaporation shifted to spring or early summer due to reduced soil moisture.
Delaware River Basin	McCabe and Wolock (1992)	GFDL, GISS, OSU	Considerably drier conditions than present; future soil moisture decrease partly masked by interannual variability, and amount of decrease varies according to GCM used.
Trinity, Colorado, and Rio Grande Basins	Schmandt and Ward (1993)	Hypothetical scenarios	Difficulty in meeting demand in 2030 under record drought conditions; severe shortages under 2°C increase and 5% decrease in precipitation.
Texas (6 Sites)	Valdés *et al.* (1994)	Various sources	Decrease in mean soil moisture concentration.

[1] Acronyms used in Table 10-1 follow: Bureau of Meteorology Research Center (BMRC), Canadian Climate Center (CCC), Commonwealth Scientific and Industrial Research Organization (CSIRO), Geophysical Fluid Dynamics Laboratory (GFDL), Goddard Institute for Space Studies (GISS), Oregon State University (OSU), and United Kingdom Meteorological Office (UKMO). GFDLH + UKMOH refers to high-resolution GFDL and UKMO models.

actual evaporation would decline even if evaporative demand were to increase.

The evaporative loss of water from vegetation, or transpiration, is influenced by vegetative properties such as albedo, surface roughness, root depth, and stomatal characteristics—and all of these may change with climate. The timing of plant growth and the species of vegetation in a catchment also might change. Plant water use also is related to atmospheric CO_2 concentrations. There are two main effects. First, there is experimental evidence that some groups of plants use water more efficiently when CO_2 concentrations are higher, leading to reduced transpiration (Dooge, 1992; Drake, 1992). Kimball *et al*. (1993) found that spring wheat grown at a CO_2 concentration of 550 ppm had an evaporation rate 11% lower than wheat grown at 370 ppm. The modeling studies of Kuchment and Startseva (1991) show that CO_2 enrichment can lead to a decrease in evapotranspiration despite climate warming and that evapotranspiration responses to changes in climate variables and plant factors can differ greatly from those that consider temperature changes alone. Second, many plants grow more when CO_2 concentrations are higher, and the increased leaf area may compensate for the increased leaf water-use efficiency. These experimental effects may not be reproduced in the field—where plant growth is subject to limitations in nutrients and moisture, as well as competitive interactions—and there is some evidence that plants acclimatize to increased CO_2 concentrations (Wolock and Hornberger, 1991; Dooge, 1992; Hatton *et al*., 1992; Koerner, 1995; Chapter A; Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, of the Working Group I volume).

10.3.4. Soil Moisture

Depending on rainfall or snowmelt intensities, as well as soil capillary and aquifer hydraulic conductivities, water will infiltrate and percolate into the soil. Soil water storage plays a decisive role in evaporation and evapotranspiration of plants. For a given soil depth and soil type, any change in the seasonal distribution of precipitation or its intensities will change soil water storage, runoff processes, and groundwater recharge. Land use, river flow, and groundwater resources are affected. Improved modeling of the hydrological cycle and of these land-surface processes in GCMs is a critical research issue (Chahine, 1992; Dooge, 1992; Rind *et al*., 1992; Milly and Dunne, 1994).

All climate models show increased soil moisture in high northern latitudes in winter, with some areas of reduction. Most models produce a drier surface in summer in northern mid-latitudes and a reduction in summer precipitation over southern Europe. Reductions over North America are less consistent, and there is greater variation between models over northern Europe and northern Asia. When aerosols are included, the patterns of soil-moisture change in the northern winter are similar but weaker, and summer drying over North America and southern Europe is reduced (see Chapter 6, *Climate Models—Projections of Future Climate*, of the Working Group I volume).

10.3.5. Snow-Cover Accumulation and Melt

Mountainous regions are particularly important in a hydrological context. They are source areas of a significant part of the water resources for many continental areas outside the tropics because of orographically induced high precipitation. Water stored as snow during the winter becomes runoff in the spring. Higher global temperatures in winter would result in more precipitation falling as rain rather than as snow, reducing snow-cover duration and causing the ascent of the snow line. These changes would lead to increased winter runoff and decreased spring and summer runoff, resulting in seasonal changes and possible disruptions in supply in regions without reservoir-based water management.

The melting of snow and glaciers is sensitive to changes in air temperature during the melt season, although temperature is only a rough index of melt energy fluxes—which consist of net radiation, sensible heat, and latent heat. Brun *et al*. (1992) used a physically based snow model to investigate the sensitivity of snow cover in the French Alps to increased incoming energy. They found that at an elevation of 1,500 m above sea level, snow cover can be considered "sensitive" during about half of the days of its existence. This means that even a slight increase in air temperature throughout the winter or a few individual warm spells have important consequences in reducing the snow cover. At 3,000 m above sea level, there is about a 6-month period during which the sensitivity to increased energy input is very weak; the sensitive days constitute about 30% of the total snow-covered period, which essentially represents the melting period. It also was shown that the entire area of the French Alps can be considered to react homogeneously to increases in incoming energy at elevations above 2,400 m above sea level, but that below this elevation the southern part of the Alps reacts more sensitively. This effect is related to latitude effects of air temperature and solar radiation.

Not much is known about evaporation in high mountain areas. Although evaporation seems to be of secondary importance in the water balances for these areas, it may play a considerable role in controlling daily variations in melt rates (Lang, 1981). With increasing altitude, vegetation activity decreases, soil (with its capacity to store water) decreases, and the duration of snow cover increases—together contributing to the general decrease of evaporation with altitude. In a warmer climate, evaporation potential is generally expected to increase, which also is expected for high mountainous terrain.

Mountain orography exerts a great influence on the atmospheric circulation at all spatial scales, which affects the horizontal and vertical distribution of precipitation. This is a point of utmost importance. If the directions of atmospheric moisture advection change (as a consequence of a change in the general route and activity of cyclones), the spatial distribution of precipitation in mountain regions could be strongly modified, compared with the general and large-scale results of present GCM simulations. High mountain areas exposed to strong windward and leeward effects will be affected significantly by such changes.

10.3.6. *Groundwater Recharge and Storage*

Despite the critical importance of groundwater resources in many parts of the world, there have been very few direct studies of the effect of global warming on groundwater recharge. A change in recharge will depend on the balance between an alteration in the recharge season (or the number of recharge events) and the amount of water available for recharge during the season. In northern Europe, it is uncertain whether increased winter rainfall (as simulated by most GCMs) would make up for a shorter recharge season caused by increased temperatures and evaporation in spring and autumn. In semi-arid and arid areas, where groundwater recharge occurs after flood events, a change in the frequency of rainfall occurrence and the magnitude of those events will alter the number of recharge events.

Using a model of water drainage beyond the rooting zone of plants and assuming rainfall changes of ±20% and unchanged vegetation, Peck and Allison (1988) found that recharge may change by -70% to +230% and -60% to +35% for sites near Khorat in northeastern Thailand (summer-rainfall environment) and near Collie in southwestern Australia (winter-rainfall environment), respectively. A 20% decrease in potential evaporation was found to increase recharge by the same amount or more under low-drainage conditions.

Vaccaro (1992) used a coupled stochastic weather generator and a deep-percolation compartment model to study the sensitivity of groundwater recharge in the Ellensburg basin in Washington state to climatic variability in the historical record and projected climate change. He found that the variability in estimated annual recharge under a climate scenario based on average monthly changes in precipitation and temperature for three different GCMs was less than that estimated from the historical record. The median annual recharge for the scenario was 25% lower than that for the historical simulation.

Wilkinson and Cooper (1993) studied the impact of climate change on aquifer storage and river recharge using a simple model of an idealized aquifer-river system. They found that changes in the seasonal distribution of recharge may have a critical effect on rivers supported by baseflow. The delay in the response of slowly responding aquifers to climate change may be large enough to allow adjustments to water-resources planning over an extended period.

Zhang *et al*. (1994) used a groundwater balance model to study the influence of climatic scenarios on groundwater recharge in the area of Jing-Jin-Tang, China. The results show that a temperature increase of 0.6 to 1.3°C and a precipitation change of -2% to +6% will change groundwater recharge within the range of ±5%.

10.3.7. *Streamflow*

Even in areas where precipitation increases, higher evaporation rates may lead to reduced streamflow. High-latitude regions may experience increased annual runoff due to increased precipitation, but lower latitudes may experience decreased runoff due to the combined effects of increased evaporation and decreased precipitation. Areas where runoff increases may experience more frequent floods and higher lake and river levels.

Regional changes in streamflow are illustrated by a study examining the impact of global warming on the flow of 33 of the world's major rivers. Miller and Russell (1992) found that all rivers in high northern latitudes showed increased flow of an average of 25% in response to increased precipitation. The largest decreases occurred at low latitudes, with a maximum of -43% for the Indus, -31% for the Niger, and -11% for the Nile due to the combined effects of increased evapotranspiration and decreased precipitation. This study used the NASA/GISS GCM and a 3-year model simulation. It found that the computed runoff for a doubled CO_2 climate depends on the model's treatment of precipitation, evaporation, and soil moisture storage (Miller and Russell, 1992). The authors also discuss the great discrepancies between observed and simulated river flow in some cases, due to oversimplified and unrealistic representations of the hydrological cycle in current GCM models.

Streamflow is highly sensitive to climate change. Shiklomanov (1989) presents a contour map of changes in mean annual runoff of rivers in the former Soviet Union (FSU) with a rise in global air temperature at an early stage of warming (0.5°C). The map shows a 10–20% decrease in the central regions of the European FSU but a 7–10% increase in the northern European FSU and western and middle Siberia. Georgiadi (1991) reports the work of N.A. Speranskaya, which for the same air-temperature rise suggests decreases in mean annual runoff of 6–20% for the Volga and 15% for the Don river systems, an increase of 7–10% for the upper reaches of the Yenisei and Ob river system, and an increase of 5–20% for the Amur river system.

The case studies in this chapter provide a clear indication that dry areas are more sensitive than wet areas to climate variations. Low-flow and dry climates will be more affected than high-flow and humid regions. Warming of the atmosphere alone will decrease streamflow far less than warming accompanied by changes in precipitation. In the case studies presented in this chapter, some areas show increasing annual and monthly flow due to increased precipitation, while other regions show decreased flow due to increased evaporation or decreased precipitation or both. High-latitude regions belong to the former category, lower latitudes more to the latter. Depending on specific scenarios, model simulations may produce an increase or a decrease in annual river flow for the same region, as well as changes in the variability of river flow through the year.

All regions with snowmelt flow regimes point out a shift of seasonal high flow from early summer and spring to the winter season. These regions will very probably have more low-flow problems in the summer. Plain regions with snowmelt floods in the melt season will have fewer meltwater floods in the future scenario—because of decreased snow precipitation—and

therefore less snow water-equivalent storage.

Conceptual snow and runoff models have been used to simulate discharge from mountain regions under changed climate conditions (e.g., Kuchment *et al.*, 1987, 1990; Lettenmaier and Gan, 1990; Bultot *et al.*, 1992, 1994; Rango, 1992; Braun *et al.*, 1994). The necessary model parameter values have been evaluated under present-day conditions, usually with the assumption that these parameter values do not change under changed climatic conditions. Most studies show a shift of snowmelt runoff to early spring months at the expense of summer months. In heavily glaciated basins, there is a negative feedback between snow cover and discharge: The smaller the seasonal snow cover, the larger the runoff from glaciers due to increased icemelt caused by reduced albedo as soon as the snow cover disappears (see Roethlisberger and Lang, 1987; Chen and Ohmura, 1990). This aspect generally has not been dealt with in sensitivity studies. Another aspect is the increased loss of glacial areas with increasing summer temperatures. The additional contribution of meltwater to streamflow experienced through decades of strong glacial shrinkage would gradually turn into decreasing streamflow rates. All scenario studies presently available are limited in predictive value because they have distributed the positive temperature change more or less evenly over the year, without taking account of the importance of short-time scale (weather) processes. Detailed discussions of the limitations of GCMs to provide scenarios in alpine regions, and the impact of climate change on these regions, are presented in Beniston (1994) and Chapter 5.

10.3.8. Lakes and Surface Storage

Surface storage waters are important parts of freshwater systems. They often are intensively used for multiple purposes—such as navigation, river flood and low-flow control, recreation, water supply, irrigation, and fishing. To allow an optimal adjustment of water levels, most artificial lakes are regulated, as are natural lakes to some degree. Climate-change impacts on the hydrology of upstream river basins will affect regulated lakes mostly in seasonal and annual regimes and average turnover. Flow and temperature changes also may change the internal stratification of lakes, with consequences to aquatic ecosystems. An increase in air temperature and/or windspeed will cause an increase in lake evaporation.

10.4. Extreme Hydrological Events

10.4.1. Floods

Although the potential impact of climate change on the occurrence of flood disasters has been alluded to frequently in popular accounts of global warming, there have been very few studies addressing the issue explicitly. This is largely because it is very difficult to define credible scenarios for changes in flood-producing climatic events (Weijers and Vellinga, 1995; Beran and Arnell, 1995). Some assessments of the potential effects of global warming on flood occurrence can be made, and it is useful to distinguish among rain-generated floods,

snowmelt-generated floods, and hybrids.

Global warming can be expected to produce changes in the frequency of intense rainfall in a catchment for two reasons: (1) There may be a change in the paths and intensities of depressions and storms, and (2) there probably will be an increase in convective activity (Gordon *et al.*, 1992; Whetton *et al.*, 1993). Higher sea-surface temperatures can be expected to increase the intensity of tropical cyclones and to expand the area over which they may develop. The IPCC Working Group I Second Assessment concludes from the analysis of several climate-model experiments that rainfall intensity is likely to increase with increasing greenhouse gas concentrations and that there may be an increasing concentration of rainfall on fewer rain days.

The effects of a change in the frequency of high rainfall will depend not only on the change in rainfall characteristics but also on the characteristics of the catchment. Small catchments with impermeable soils will be very responsive to short-duration intense rainfall; larger catchments, and those with more permeable soils, will be sensitive to longer-duration storm rainfall totals and general catchment wetness.

Changes in the magnitudes of snowmelt and rain-on-snow floods will deserve particular attention in some regions. The magnitudes of snowmelt floods are determined by the volume of snow stored, the rate at which the snow melts, and the amount of rain that falls during the melt period. Many studies have simulated a reduction in snow cover after global warming, but higher precipitation totals still may lead to a greater volume of snow being stored on the catchment. Floods caused by snowmelt may therefore either increase or decrease. A reduction in snow cover also may mean that more rain-generated floods occur during winter, leading to a shift in the seasonal distribution of floods.

A few studies have attempted to quantify changes in flood occurrence. Gellens (1991) used a daily rainfall-runoff model to simulate river flows in three Belgian catchments, assuming an increase in rainfall during winter. He found more frequent floods, with flows remaining above high thresholds for longer periods. The mean annual flood peak increased between 2 and 10% under the scenario used, with the greatest increase in the most-responsive catchment. Bultot *et al.* (1992) used the same model and scenario to estimate possible changes in flood frequency in a small Swiss catchment and found the same results; the mean annual flood increased by 10%.

For the Sacramento-San Joaquin basin in California, Lettenmaier and Gan (1990) found a reduction in snowmelt floods but an increase in the frequency of rain-generated floods, with a consequent increase in the occurrence of a particular discharge being exceeded. Knox (1993) examined a 7,000-year geological record of overbank floods for upper-Mississippi River tributaries in North America. He found that changes in mean annual temperature of about 1–2°C and changes in mean annual precipitation of less than 10–20% can cause large and abrupt adjustments in the magnitudes and fre-

quencies of floods.

Kwadijk and Middelkoop (1994) investigated potential changes in flood risk in the Rhine basin, using both hypothetical change scenarios and scenarios based on GCM simulations, and found large changes in the frequency of given threshold events; an increase in precipitation and a rise in temperature would lead to major increases both in flood frequencies and in the risk of inundation. However, the hydrological simulations were limited to a monthly time-step. At this temporal resolution, the simulation of snow cover is not reliable—especially at low elevations, where the snow cover is built up and disappears again several times, in time scales of days, during one winter.

Liu (1995) simulated increases in the variability of floods over time and in flood frequencies in both northern and southern China. Bates *et al.* (1995) used a stochastic weather generator coupled with two daily rainfall-runoff models to investigate changes in the behavior of annual maximum monthly runoff series for six Australian catchments within a variety of climatic settings. In five cases, the series were noticeably higher for a changed climate than for the present day. The sizes of projected changes were found to depend on the rainfall-runoff model chosen.

There is evidence from climate models and hydrological impact studies that flood frequencies are likely to increase with global warming. The amount of increase is very uncertain and, for a given change in climate, will vary considerably between catchments. In some catchments, floods may become less frequent. There are four main reasons for the large uncertainty: (1) It is very difficult to define credible scenarios, at the catchment scale, for changes in flood-producing precipitation; (2) it is often difficult to model the transformation from rainfall (or snowmelt) to flood in a catchment; (3) available climatic and hydrological records often provide limited information about flood events; and (4) at present, in many cases, it is difficult to differentiate the effects of climatic change from those associated with anthropogenic changes to land use.

10.4.2. Droughts

Drought is a relative term that may refer to a period in which actual moisture supply at a given location cumulatively falls short of climatically average moisture supply; soil moisture is insufficient to meet evapotranspirative demands for the initiation and sustainment of plant growth; below-normal streamflow or above-normal reservoir depletion occurs; or a local or regional economy is adversely affected by dry weather patterns (Rasmusson *et al.*, 1993).

A decrease in average total rainfall, an increase in the frequency of dry spells due to a decline in rain-days, and an increase in potential evapotranspiration due to higher temperatures have the potential to increase drought frequency and severity and to extend their effects into less-vulnerable areas. Increases in the frequency and magnitude of large rainfall events may result in reduced drought potential if they result in higher soil moisture

levels and groundwater recharge (Whetton *et al.*, 1993).

The frequency and severity of droughts has received little attention. Four features of most hydrological impact studies make it difficult to assess the effect of climate change on low-flow frequency: (1) Most climate scenarios do not assume any change in interannual climate variability; (2) the rate of occurrence of extreme events in perturbed climate series is influenced strongly by the relative severity of events in the original series; (3) the length of concurrent climatic and hydrological records can be relatively short; and (4) feedback between catchment vegetal cover and atmospheric moisture has been neglected (Savenije and Hall, 1994). Many studies focus on simple descriptive statistics of daily, monthly, seasonal, or annual soil moisture and flow over the simulation period, including minimum annual discharge (Mimikou and Kouvopoulos, 1991); mean minimum discharge (Vehviläinen and Lohvansuu, 1991); annual minimum daily streamflow (Bultot *et al.*, 1992); and flow equalled or exceeded 95% of the time (Arnell and Reynard, 1993; Bultot *et al.*, 1992).

A few studies have attempted to quantify changes in low-flow or drought occurrence and their impacts. Gellens (1991) examined the behavior of low-flow episodes in three Belgian catchments, each with more than 80 years of records. The low-flow behaviors of the catchments were found to respond differently to climate change. Whetton *et al.* (1993) examined changes in drought occurrence in terms of seasonal soil water deficits for nine Australian sites. Results indicate that significant drying may be limited to the south of Australia. These researchers qualify their results by noting that possible changes in ENSO events due to global warming were not considered because no current GCM simulates ENSO effects. The observed interannual variability of rainfall in north and east Australia is strongly influenced by ENSO. Several researchers have investigated the impact of climate change on reservoir reliability using stochastic weather generators or resampling methods to generate long-term sequences of synthetic weather data (e.g., Nathan *et al.*, 1988; Cole *et al.*, 1991; Lettenmaier and Sheer, 1991; Wolock *et al.*, 1993). Descriptions of these and other similar studies appear in Chapter 14.

10.5. Physical and Chemical Changes in Freshwater Ecosystems

This section integrates freshwater ecosystems via hydrology and presents potential effects of climate change on their physical/chemical properties and processes.

10.5.1. Integrated Landscapes of Lakes and Streams via Hydrology

Inland aquatic ecosystems such as freshwater wetlands (Chapter 6) and lakes and streams (covered in this chapter) represent distinct elements of the hydrologic continuum from the atmosphere to the sea. Water flows first downwind as weather systems and then downhill toward the sea. Patterns of atmospheric deposition

are closely related to regional- or continental-scale atmospheric "flow paths" (Galloway and Likens, 1979). Freshwater ecosystems occupy landscape depressions where subsurface flows emerge or surface flows and direct precipitation are channeled or retained. Ecological conditions along the freshwater continuum are determined by local factors (soils, vegetation, lake basin shape, stream gradient, temperature) and the legacy provided by spatially and temporally antecedent patches on this flow path. The interplay of climate and catchment controls biogeochemical processes that add particulates and solutes to water during transport in the catchment and within the stream or lake. These materials and physical features regulate biota in streams and lakes, and feedbacks from ecological processes modify water quality and physical features of freshwater ecosystems. Water quality, fisheries, and recreational values of lakes and streams are determined by interactions between the chemical and physical characteristics and the biota of freshwater ecosystems.

Stream ecology has acknowledged the close link between terrestrial catchments and aquatic systems since Hynes (1963, 1975). Progressive longitudinal changes in channel morphology and in dominant sources of water and organic matter, together with downgradient flow, produce predictable ecological patterns along the continuum from small streams to large rivers (Vannote *et al.*, 1980; Minshall *et al.*, 1983). Nutrient and organic-matter input to streams is closely related to terrestrial and wetland processes (Bormann *et al.*, 1969; Likens, 1984; McDowell and Likens, 1988; Wetzel, 1990) and to the flow path of water controlling its dissolved load. The chemistry of water entering streams in Alaska, for example, is dependent not only on the types of terrestrial vegetation through which water flows but also their sequential order (Giblin *et al.*, 1991). Physical and chemical properties of lakes are linked strongly to terrestrial processes via effects on stream discharge and chemistry. Recent studies of lake districts show the importance of landscape influences on internal lake properties (Swanson *et al.*, 1988). In headwater lake districts, biotic diversity and ecological functioning depend upon landscape position; higher drainages receive proportionately more input from direct precipitation and differ markedly from those lower in the landscape that receive larger inputs of water and materials from terrestrial sources (Kratz *et al.*, 1991, 1996).

Changes in climate influence water supply and quality directly through altered precipitation and atmospheric deposition and indirectly by the altered nature of landscape elements through which water and transported substances pass. Many of the most profound effects of climate change on lakes and streams will involve changes in terrestrial ecosystems that alter water and material inputs to freshwaters.

10.5.2. Changes in Streamflow and Lake Water Levels

Streamflow, groundwater flow, and lake levels respond to changes in precipitation and evapotranspiration. Under hotter and drier scenarios, lower runoff and greater evaporation would reduce stream baseflows and could result in periodic drying of some perennial headwater streams. Even in regions that experience increased annual precipitation, reduced summer rains or still-larger increases in evapotranspiration would produce lower baseflows and increased intermittency in summer. Warmer and wetter scenarios—particularly at higher latitudes— would increase runoff, with some intermittent streams becoming perennial and with higher flows altering channel geomorphology. Some lakes could become smaller or dry up entirely as evaporation exceeds water inputs; others could increase in size where precipitation increases more than evaporation.

Long-term, irregular water-level fluctuations occur mainly in semi-arid and dry tropical regions with distinct wet and dry seasons and high interannual variability (John, 1986). Water-level changes are most pronounced in lakes with relatively short retention times, in association with seasonal precipitation patterns. Paleohydrology and paleolimnology are particularly important approaches for obtaining information on paleo lake levels related to climate change. Analyses point out that lake levels and lake hydrology are sensitive to changes in climate (Almquist-Jacobson, 1995; Digerfeldt *et al.*, 1992; Almendinger, 1993; Webb *et al.*, 1944). Lake level response to climatic fluctuations, reconstructed using diatoms for the northern prairie region of the United States, shows such sensitivity (Fritz *et al.*, 1993, 1994; Laird *et al.*, 1996). Moon Lake
Figure 10-3: Changes in salinity of Moon Lake over the last 11,000 years, inferred from diatom assemblages in sediments (Laird *et al.*, 1996).

underwent three major changes in climate: a mid-Holocene period of high salinity indicative of low effective moisture; a transitional period from 4700–2200 before present (BP) with poor diatom preservation; and a late-Holocene period of lower salinity and greater variability, indicating fluctuations in effective moisture (Figure 10-3). Large lakes in the Great Basin of the United States underwent considerable variations in lake levels during the Pleistocene (Benson *et al.*, 1990), and similar variations have been inferred for Mono Lake, California (Stine, 1990).

Lakes have individualistic and often rapid responses to climate changes (Figure 10-4). Lake Titicaca experienced a 6.3-m rise in water level from 1943 to 1986. This increase equals 140 mm per year and exceeds by a factor of 40 the change in mean sea level estimated from global warming. Even Lake Michigan, at temperate latitudes, has oscillated over a 1.7-m range from 1960 to 1993. Fluctuations in lakes with large temporal changes in water level are expected to be exacerbated by climate change.

Larger changes in lake water levels are likely at high latitudes where climate warming scenarios are greatest. In the largest
Figure 10-4: Water levels as deviation from the mean for Lakes Kinneret (Middle East), Michigan (North America), and Titicaca (South America) from 1912 to 1993. For Lake Michigan, changes in lake level were calculated as the deviation of the mean annual lake level from the long-term mean lake level (1860–1993) from National Ocean Service, National Oceanic and Atmospheric Administration, USA. For Kinneret and Titicaca, deviation was calculated as the difference between mean annual minimum and maximum water levels and long-term mean [1926–1994 for Kinneret (Serruya, 1978; Gophen and Gal, 1991) and 1912–1993 for Titicaca (Aquize, pers. com.)].

Antarctic desert, the McMurdo Dry Valleys, closed-basin lakes fed by glacier meltwater streams, rose as much as 10 m from 1970 to 1990, or almost 480 mm per year (Chinn, 1993). Marsh and Lesack (1996) project with a hydrologic model and a 2 x CO_2 climate that many lakes in the Mackenzie Delta in the Canadian arctic could disappear in several decades owing to decreased precipitation and flood frequency. Some drainage lakes (no inlets but with an outlet) and seepage lakes (no surface inlet or outlet) in the north central United States (Eilers *et al.*, 1988a) are responsive to changes in precipitation; during recent droughts in the late 1980s, lake levels declined substantially. Some of these lakes operate as drainage lakes during high water and as seepage lakes during dryer periods.

Despite relatively small climatic changes predicted for the tropics, tropical lakes also may be quite sensitive to climate change (see Box 10-1). The level of Lake Victoria (East Africa) rose rapidly in the early 1960s following only a few seasons with above-average rainfall and has remained high since (Sene and Pinston, 1994).

Patterns of water-level change are sensitive to global warming scenarios. For Lake Michigan, 2 x CO_2 scenarios produce a reduced net basin water supply and a lowering of water level of 1 to 2.5 m, depending on the GCM used (Croley, 1990). Assuming that atmospheric CO_2 will double in 33–40 years (see Chapter 6, *Climate Models—Projections of Future Climate*, of the Working Group I volume), this constitutes a decline in water level of 25 to 62 mm/year and exceeds by a factor of about 10 (in the opposite direction) increases in mean sea level estimated from global warming.

10.5.3. Changes in Biogeochemical Fluxes

Physical and biological characteristics of catchments—such as geology, soils and microbes, vegetation, and dominant flow paths of water—control the chemistry of surface water and groundwater. If the water table is close to the surface, flow is routed primarily through organically rich and biologically active upper soil horizons; concentrations of most major ions are lower and concentrations of dissolved organic material higher than if water tables are deep and water moves through lower mineral soil horizons and bedrock before entering lakes or streams. Vegetation and soils, in conjunction with hydrologic flow paths, control the effects of nutrient inputs from atmospheric deposition or fertilizer applications. In agricultural catchments, the effects of fertilizer application on surface-water nutrient concentrations are reduced substantially if water moves through riparian areas where natural vegetation has been preserved (Peterjohn and Correll, 1984). Climate changes that alter hydrologic flow paths or vegetation and soil characteristics will result in changes in groundwater and surface-water chemistry. For streams, these chemical shifts may be episodic or seasonal; for lakes with long residence times, the shifts may be in average chemical characteristics.

Dynamic, process-based water-quality models are needed to

Box 10-1. African Lakes and Climate Change

African Great Lakes are sensitive to climate variation on time scales of decades to millennia (Kendall, 1969; Livingstone, 1975; Haberyan and Hecky, 1987). Lake Victoria (the world's second-largest freshwater lake by area), Lake Tanganyika (the world's second-deepest lake), and Lake Malawi were closed basins for extended periods in the Pleistocene and Holocene (Owen *et al*., 1990). Lakes Malawi and Tanganyika were hundreds of meters below their current levels; Victoria dried out completely. Today these lakes are in delicate hydrologic balance and are nearly closed. Only 6% of water input to Tanganyika leaves at its riverine outflow—which was blocked totally when the lake was explored by Europeans (Bootsma and Hecky, 1993).

Higher temperatures would increase evaporative losses, especially if rainfall also declined. Minor declines in mean annual rainfall (10–20%) for extended periods would lead to the closure of these basins even if temperatures were unchanged (Bootsma and Hecky, 1993). Tropical temperatures are increasing; temperatures in the 1980s were 0.5°C warmer than a century earlier and 0.3°C warmer than from 1951–1980. Concurrently, Lake Victoria's epilimnion was warmer by 0.5°C in the early 1990s than in the 1960s (Hecky *et al*., 1994). Although current climate scenarios project small increases in tropical temperatures, small changes in temperature and water balance can dramatically alter water levels, as well as mixing regimes and productivity.

Recent temperature and rainfall data and GCM simulations indicate increasing aridity in the tropics (Rind, 1995). Increases of 1–2°C in air temperatures could substantially increase the stability of stratification in permanently stratified Tanganyika and Malawi. Their deep waters are continuously warm, but the less than 1°C difference between surface and deep water in warm seasons maintains a density difference that prevents full circulation. Lake Tanganyika's deep water has been characterized as a "relict" hypolimnion that formed under a cooler climate within the past 1,000 years (Hecky *et al*., 1994). Since then, warming has created a barrier to vertical circulation. Additional warming could strengthen this barrier and reduce the mixing of deep, nutrient-rich hypolimnetic water and nutrient-depleted surface layers; that mixing sustains one of the most productive freshwater fisheries in the world (Hecky *et al*., 1981).

---

estimate effects of climate change because biogeochemical processes controlling water quality are complex. Such models must accurately represent the hydrologic regime—especially the timing and intensity of infiltration (rainfall and snowmelt), as well as the various flow paths through the catchment and changes in vegetation. Examples of coupled hydrologic-water quality models being developed include the Regional HydroEcological Simulation System (Band *et al*., 1996), modifications of Topmodel for transport of dissolved organic material (Hornberger *et al*., 1994), and the Alpine Hydrochemical Model (Wolford and Bales, 1996).

Streams in catchments with low acid-neutralizing capacity periodically may become more acidic. Higher-elevation streams and lakes may receive larger pulses of acidity in the spring if winter snowfall increases or snowmelt occurs over a shorter period—for example, the modeled response with the Alpine Hydrochemical Model for the Emerald Lake catchment in the southern Sierra Nevada region of the United States (Wolford and Bales, 1996). In mountain streams of the southeastern United States, Mulholland *et al*. (1996) project an increase in the frequency or duration of acidic episodes with an expected increase in storm intensity. However, in the northeastern United States, reductions in winter snowpack with climate warming might reduce the intensity and duration of stream acidification in the spring (Moore *et al*., 1995, 1996). At boreal latitudes, soil drying associated with climate warming can lead to oxidation of reduced forms of sulfur in soils and concurrent acidification of streams (Bayley *et al*., 1992b;

LaZerte, 1993; Schindler *et al*., 1996; see Box 10-2). Warmer climates could affect nitrate fluxes through changes in microbial processing rates. Higher temperatures may lead to increased mineralization of organic nitrogen in soil, with increasing amounts available for flushing into lakes and streams. Peak nitrate concentrations in United Kingdom catchments tend to occur following flushing by heavy rainfall after prolonged dry spells; an increase in the duration of dry spells would increase the leachable nitrogen accumulating in soils (Jenkins *et al*., 1993).

For lakes, position in the local groundwater flow system affects their chemical response to shifting hydrologic conditions. Two mechanisms control drought response in northern Wisconsin (Webster *et al*., 1996): Longer residence times and evapoconcentration in lower lakes cause conservative solutes to increase in concentration, whereas lesser inflow of solute-rich groundwater in higher lakes decreases solute concentrations. In prairie lakes and wetlands of north-central United States and Canada, differences in local geomorphology, groundwater flow paths, and vegetation produce somewhat different responses in water chemistry to droughts, with salinity increasing in some and decreasing in others (Evans and Prepas, 1996; LaBaugh *et al*., 1996).

Export of organic matter from terrestrial systems to streams and lakes is expected to change with climate. The amount of wetland drainage strongly influences the concentration of dissolved organic carbon in streams and rivers (Mulholland and Kuenzler, 1979; Eckhardt and Moore, 1990), and changes in

Box 10-2. Climatic Warming Effects: Boreal Lakes and Streams

Boreal soft-water lakes and streams at the Experimental Lakes Area (ELA) in Ontario, Canada, represent numerous ecosystems throughout North America and Eurasia. At ELA, natural variability has been studied for the past 25 years through measurements of climatic, hydrological, physical, chemical, and biological parameters. Analyses of this warmer and drier interval have provided a holistic picture of the potential interactive responses of lakes and streams to climate warming (Schindler *et al*., 1996, and references therein). The almost 2°C of warming and more than 50% decline in runoff are comparable to GCM predictions for a 2 x CO_2 climate. Biological responses in the lakes were linked to changes in biogeochemical processes in the catchments and physical properties of the lakes. Major changes were in:

*   *Hydrochemical fluxes*: Export of many constituents decreased in response to decreased streamflow, weathering rates, and decomposition of organic material; drier soils resulted in shorter periods of elevated water tables and saturated soils. Export of dissolved silica and dissolved organic carbon (DOC) decreased more than 50%. Base cations decreased less, suggesting that dry or burned vegetation was less efficient at retaining base cations than vegetation with adequate moisture. Export of acid anions generally decreased, but acid anions increased relative to base cations—causing lower alkalinity and pH in streams. Soil drying apparently enhanced oxidation and the release of sulfate. Nitrogen and phosphorus flux increased somewhat after drought-enhanced fires and major windstorms, but overall export of these nutrients declined.

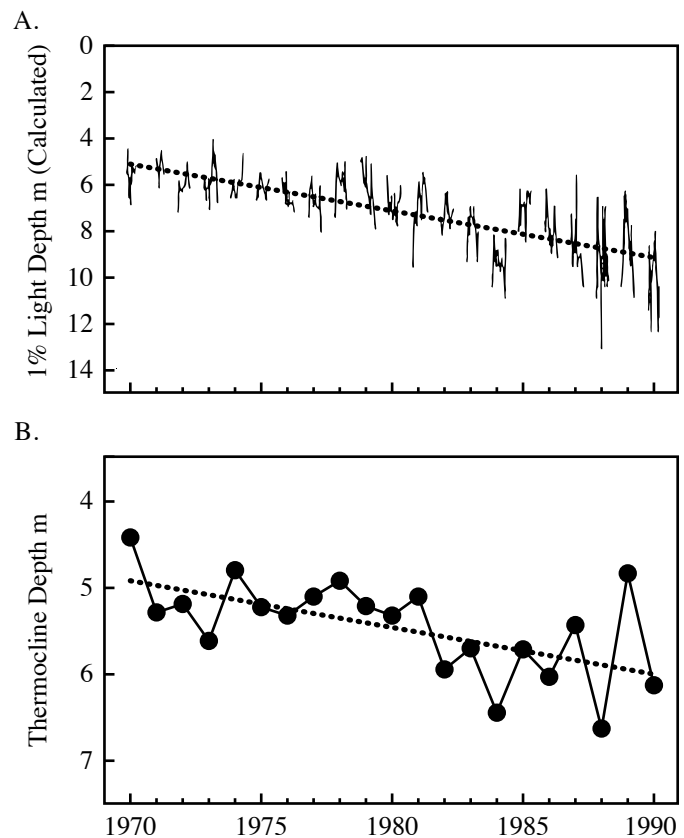
*   *Lake physics, chemistry, and biology*: The lakes generally became warmer and more transparent, and the increased transparency facilitated the deepening of thermoclines (Figure 10-5). The average ice-free period increased by about two weeks. Even though exports from catchments decreased, concentrations of many inorganic constituents increased because residence time in the lakes and evaporative concentration increased. Unlike streams, lakes became more alkaline because lake processes dominated—with longer residence times specifically from the removal of sulfate by microbial reduction and the dissolution of base cations in lake sediments. Slight increases occurred in phytoplankton biomass and species diversity; primary productivity and chlorophyll concentrations did not change. In one lake, suitable habitat for lake trout was reduced and lake trout disappeared.


Figure 10-5: (A) Changes in penetration of photosynthetically active radiation (PAR) as the depth of isopleth representing 1% of surface light (equivalent to photic zone depth), from Schindler *et al*. (1996); (B) changes in depth of thermocline.

wetland distribution and connectivity with streams and lakes would alter DOC concentrations. Drought can reduce DOC inputs to streams and lakes on the Canadian Shield (Schindler *et al*., 1996). Changes in the amount and chemical form of organic-matter inputs can occur because vegetation is altered in the catchment overall or in the riparian zone (Band *et al*., 1996). Increasing atmospheric CO_2 or climatic warming may increase the rate of organic-matter inputs to streams because riparian plants produce more foliage, and species composition may change (Bazzaz, 1990)—which in turn would increase produc-

tion of heterotrophic organisms. This might be countered by drier conditions that would reduce organic-matter inputs from riparian zones. Complexities become most apparent when considering interactions between organic matter and nutrient inputs. Higher atmospheric CO_2 concentrations may increase plant foliage but reduce its nitrogen content (Koerner and Miglietta, 1994); rates of organic-matter decomposition and production in detritus-based food webs actually might decline (Meyer and Pulliam, 1992). Under drier climates, reduced runoff from streams that drain wetlands could reduce inputs of

dissolved organic carbon but increase inputs of nitrogen from increased organic-matter oxidation. In a simulation of such changes in a Welsh peatland stream, primary production increased (Freeman *et al*., 1994).

In warmer, drier climates, an increase in wildfires can increase runoff, sediment, and nutrient load (Schindler *et al*., 1980). Wildfires also cause longer-term (5–50 years) reductions in woody debris and material retention in streams (Minshall *et al*., 1989).

Observations over a 20-year period of warmer and dryer conditions at the Experimental Lakes Area (see Schindler *et al*., 1996) illustrate the complex interactions and responses that can be anticipated from climate warming and the value of careful long-term study of aquatic ecosystems to identify critical processes and interactions (Box 10-2).

10.5.4. Changes in Temperature, Dissolved Oxygen and Carbon Dioxide, and Light

Stream water temperature is determined by air temperature, the origin of streamflow (groundwater is often cooler than quick flow in temperate-zone warm seasons), local shading of the stream, and, to a lesser extent, flow volume. Changes in stream temperatures are about 0.9 times as great as changes in air temperature in the UK (Webb, 1992) and the north-central United States (Stefan and Preud'homme, 1993). Simulations from air temperature increases of 1.5° to 4.5°C, using a heat-balance model, produce increases in summer stream temperatures of 2.4° to 4.7°C for Minnesota (Stefan and Sinokrot, 1993). Projected increases in stream temperatures are substantially greater if riparian vegetation is removed, as are stream temperatures where riparian vegetation is experimentally removed (Burton and Likens, 1973). Higher water temperature, along with lower streamflows, could lead to reduced oxygen concentrations in streams receiving organic loading from effluents or in eutrophic streams, where warmer temperatures could stimulate algal blooms.

Thermal regimes in lakes are responsive to climate change because they are controlled by solar radiation, wind velocity, air temperature, humidity, and evaporation, as well as by lake area, depth, and transparency. In north temperate regions, 2 x CO_2 climate scenarios increase summer epilimnion (surface mixed waters) temperatures by 1–7°C, and hypolimnetic (deep cooler waters) temperatures change by -6 to +8°C depending on the size and morphology of the lake (Stefan *et al*., 1993; DeStasio *et al*., 1996; Magnuson *et al*., 1995). Warming increases the duration of warm-season stratification and the sharpness of the metalimnion (the zone of sharp temperature change, >1°C/m, between the epilimnion and hypolimnion). Warming decreases the duration of ice cover or the frequency of winters with winter ice cover. To the south, loss of lake ice cover at some latitudes indicates that lakes that mix twice per year in spring and fall would become monomictic—that is, they would mix through the fall, winter, and spring and stratify longer in the summer. To the north, some lakes that presently are monomictic and mix during

summer would stratify in summer and mix twice a year in spring and fall. Some deep lakes that mix twice a year would be less likely to mix completely (McCormick, 1990). Changes in the water level of shallow lakes could change the heat budget or the mixing properties of lakes.

Changes in catchment DOC fluxes would change the mixing regimes of lakes because water clarity and light absorbance are partially functions of DOC concentrations (see Box 10-2). The strong effect of DOC inputs on lake mixing properties appears to be limited primarily to lakes smaller than 500 ha, based on Canadian Shield lakes (Fee *et al*., 1996).

Climate change could cause changes in the amount of oxygen entering lakes and streams through direct atmospheric exchange or through changes in lake and stream metabolism. With a warmer climate, concentrations of dissolved oxygen are expected to be lower because concentrations at saturation are lower and respiration rates are higher at higher water temperatures. Upland streams in the UK tend to be fast flowing and oligotrophic, with high dissolved oxygen owing to rapid reaeration rates (Jenkins *et al*., 1993); lowland river systems tend to be slow flowing, with low turbulence and with dissolved oxygen below saturation. Simulations with the QUASAR dynamic water-quality model suggest that higher temperatures and lower streamflow would result in lower oxygen concentrations in UK rivers. Conditions are exacerbated in lowland rivers, which also tend to have agricultural catchments and often are used as disposal routes for sewage and industrial effluents.

Dissolved oxygen levels in lakes, especially in the deep hypolimnetic waters, are responsive to climate warming scenarios. Simulations with 2 x CO_2 climates for Lake Erie in North America (Blumberg and DiToro, 1990) suggest that losses of 1 mg/L in upper layers and 1–2 mg/L in lower layers can be expected, as can an increase in the area of the lake that is anoxic. This is because at warmer lake temperatures, bacterial activity increases in deep waters and surficial sediment, not from a relocation of the thermocline and smaller hypolimnetic volume. Smaller lakes (Figure 10-6) have similar responses to simulations with a 2 x CO_2 climate (Stefan *et al*., 1993; Stefan and Fang, 1994). In surface waters, dissolved oxygen remains above 7 mg/L and declines by not more than 2 mg/L. In deep hypolimnetic waters, simulated concentrations are as much as 8 mg/L lower in midsummer and never less than 2 mg/L lower. Depletion would occur up to 2 months longer than under baseline conditions owing to longer periods of stratification. Declines in dissolved oxygen are projected to occur in productive (eutrophic) and nonproductive (oligotrophic) lakes but to be more rapid and of longer duration in productive lakes. Simulated declines in dissolved oxygen are more apparent in spring and fall because stratification would be extended into these seasons. Changes in water levels would interact with the mixing properties of shallow lakes and thus their oxygen dynamics.

Dissolved CO_2 concentrations are supersaturated with respect to atmospheric concentrations in most lakes and streams (Kling
Figure 10-6: Simulated deep-water (hypolimnetic) dissolved oxygen levels in 18 Minnesota lakes (Stefan *et al.*, 1993). Past conditions are on the left, projected 2 x CO$_2$ climate scenario in the middle, and the difference between future and past climate conditions on the right. Small lakes are on top, medium lakes in the middle, and large lakes on the bottom.

et al., 1991; Cole *et al.*, 1994)—a result of high CO$_2$ concentrations in groundwaters and high rates of respiration in many freshwaters. Direct effects of increasing atmospheric CO$_2$ will be significant only in streams and lakes with low alkalinity and relatively high primary productivity; dissolved CO$_2$ and HCO$_3$ concentrations are depleted during daylight, causing increases in pH. In such systems, an increase in atmospheric CO$_2$ will increase carbon flux from the atmosphere to the water body.

Changes in cloud cover and shading could change light profiles in lakes and streams and affect primary productivity. Light is a major control on photosynthesis in freshwater ecosystems. Reduction in riparian vegetation under drier climates would decrease shading, thus increasing light availability and primary productivity in headwater streams. DOC in freshwaters responds to climate change and alters light availability (see Section 10.5.3 and Box 10-2). High light intensity also can inhibit photosynthesis at the surface, and UV radiation inhibits both algae and invertebrates. Interaction between DOC and UV attenuation is particularly important, given that increased UV radiation is associated with the depletion of ozone. In North American lakes, even small decreases in DOC could significantly enhance the penetration of biologically harmful UV-B radiation into the water column (Scully and Lean, 1994; Williamson *et al.*, 1995).

10.5.5. *Erosion, Sedimentation, and River Channel Stability*

Changes in vegetation, rainfall, and hydrological regimes affect erosion on hillslopes and in river channels, sediment transport and sedimentation, and river channel stability (Schumm, 1977). Separating the effects of climate fluctuations from changes in land use is difficult because land use also affects hillslope erosion and sediment loads in streams and hence the river channel. Three other general points are apparent from published studies: (1) Much geomorphological activity is episodic, occurring during extreme events; (2) there may be critical thresholds in the geomorphological system, beyond which change is more dramatic; and (3) the effects of climate change work through the geomorphological system over many decades.

Soil and hillslope erosion are sensitive to land-use practices and changes in catchment vegetation. In simulations with no change in land use, increased winter rainfall results in greater erosion from arable lowlands in the UK but lower losses from arable fields in uplands because the warmer climate includes

longer growing seasons and hence greater ground cover (Boardman *et al*., 1990). Hillslope erosion only occurs once rainfall exceeds a critical threshold in an upland UK catchment (Harvey, 1991). If rainfall frequency and/or intensity were to increase significantly and more erosion were to follow, increased river flows would influence channel erosion, with erosion potential increasing for higher flows. Not all sediment generated on hillslopes reaches the river channel, but increased hillslope and channel erosion should increase sediment loads. Sediment loads in the Yellow River (China) increase in simulations of a conceptual hydrologic and sediment model because high intensity rainfalls were more frequent, even though total runoff decreased in the scenarios (Bao, 1994).

Historical analogs provide useful information about possible changes in sediment loads. Sediment loads on the River Garonne (France) during a wet period in the 1840s were four to five times higher than in drier periods (Probst, 1989). River sediment loads in northern regions will be affected not only by flow regime changes but also by temperature rise. If warming raises temperatures above freezing for longer periods, snow and icemelt and permafrost degradation would increase, releasing more sediment into rivers (Woo and McCaan, 1994). Changes in flow regime and sediment loads would change river channel stability; specifics depend not only on changes in inputs but also on the channel's proximity to a change in threshold. A channel at the boundary between braided and meandering would be more sensitive to change than one with a clearly defined, meandering channel. An upland channel might be most sensitive to changes in the supply of sediments from adjacent hillslopes, whereas a lowland channel would be more sensitive to changes in sediment loads from upstream.

Extreme events are most important in triggering channel change (Newson and Lewin, 1991). Given an increase in the frequency of extreme events (Section 10.4), the location of channel instability and sites of erosion and sedimentation should change, although this will depend greatly on local channel characteristics. Changes in channel geomorphology should be greater in unconstrained alluvial channels, owing to their more dynamic geomorphology, than in constrained channels on or near bedrock. However, as noted by Newsom and Lewin (1991), "The interactions between river channel change, sediment transport, climatic and hydrological fluctuations, and human activities are so complex that a simplistic response model relating morphological response to alternative climate-change scenarios is just not practical at present."

10.6. Lake and Stream Biology

This section considers the potential effects of thermal and hydrologic changes on biological rates, life histories, and reproduction, and resulting changes in geographic distribution and biodiversity, as well as possible adaptations to climate change.

Inland waters are perhaps most sensitive to landscape-level effects of climate change and as such serve somewhat as "canaries" for effects on landscapes. Effects are difficult to dissect into their components because lakes and streams aggregate many other influences of human activity. Lakes and streams, as well as wetlands (see Chapter 6), integrate many human and natural events occurring on the landscape. Streams, in a sense, are the arteries of the continents; lakes and wetlands are the integrative sensors of changes in climate, pollution, and land use (Degens *et al*., 1991). The effects of climate change on terrestrial systems, such as vegetation (see Chapter 1) and land use, are transmitted to and accumulate in freshwater ecosystems. Ecological responses of freshwater to climate change will be exacerbated by other anthropogenic changes.

Climate scenarios used in many of the references cited in this section (and in Section 10.5) differ from the most recent IPCC scenarios. Analyses of climatic warming effects from earlier scenarios may overestimate effects, compared with new analyses with more recent scenarios. Previous IPCC 2 x CO_2 scenarios suggested globally averaged mean annual temperature increases of 1.5° to 4.5°C (IPCC, 1992)—about twice the values from current IPCC scenarios with ramped models and the effect of atmospheric aerosols. Nonetheless, the climate warming effects described in this section are reasonable in direction, if not in magnitude. Current scenarios also suggest that warming will be greater in fall/winter and at night during summer than at other times. Regional differences in future climatic change will be important, and GCM-based global scenarios still do not provide adequate regional scenarios. Regional warming may be considerably less than or greater than globally averaged warming.

10.6.1. Thermal Effects on Biota

Extreme water temperatures can kill organisms. More moderate water temperature variations control physiological rates and behavioral performances, and influence habitat preference (e.g., for fish: Fry, 1947, 1971). Given that species have varying tolerance ranges for temperature, shifts in temperature can produce changes in species composition that can affect the overall productivity of individual freshwater ecosystems and their utility to humans.

Direct effects of climatic warming on the productivity, life history, and reproduction of organisms in streams and lakes will result primarily from increases in average water temperatures and growing season, increases in winter water temperatures and a shorter winter period of cold water or freezing, and increases in maximum summer water temperatures. Indirect effects of warming on productivity and life history include changes in hydrology, especially of extreme events (Section 10.6.2), and in vertical mixing (Section 10.5.4). In streams, ecological effects should be strongest in humid regions where streamflows are less variable and biological interactions control organism abundance (Poff and Ward, 1990). Warming effects should be strong in small, mid-latitude streams where large groundwater discharges currently maintain relatively low maximum water temperatures in summer, as well as in mid-latitude and high latitude streams that experience large increases in annual degree days. Direct thermal effects on lake organisms

should be greatest at higher latitudes where the largest changes in temperature are expected.

10.6.1.1. Freshwater Invertebrates

Production rates of plankton and benthic invertebrates increase logorithmically with temperature, with rates increasing generally by a factor of 2–4 with each 10°C increase in water temperature, up to about 30°C or more for many organisms (Regier *et al*., 1990, and citations therein). Macroinvertebrate production rates increased by 3 to 30% per 1°C rise in mean annual water temperature in a comparison of 1,000 stream studies at mid- to high latitudes (Benke, 1993); annual macroinvertebrate production increased and production-to-biomass ratio increased by 3 to 25%.

Regier *et al*. (1990) posit that increases in primary production, zooplankton biomass, and fish yields with temperature indicate that the thermal effects of warming will superficially resemble eutrophication (increasing production from increased nutrients). The effects of these temperature-dependent changes would be least in the tropics, moderate at mid-latitudes, and pronounced in high latitudes. Such increases assume that as temperatures warm, warmer-water assemblages replace the cooler-water ones because in most cases individual species do not continue to increase over the entire temperature range.

Ecosystem production-to-respiration (P:R) ratios decline with warming because respiration increases more rapidly with temperature than photosynthesis does. Even though the photosynthetic rates of many algae increase with temperature—at least up to about 25° to 30°C (Davison, 1991)—ecosystem primary production may increase little because nutrient concentrations and light availability often limit algal production, and these factors also change with climate change. Respiration rates increase with temperature at both the organism and ecosystem levels. At average levels of light and biomass, ecosystem P:R ratio in Arizona declines from 3.0 at 19°C to 1.6 at 30°C (Busch and Fisher, 1981). In Ontario, Canada, the P:R ratio of stream communities on stone surfaces declines from 4 at 4°C to 0.5 at 28°C (Rempel and Carter, 1986). A drop in P:R ratio tends to reduce the average mass of benthic organic matter and/or the export of organic matter downstream (Carpenter *et al*., 1992). Higher rates of microbial respiration with higher temperatures suggest that food resources for invertebrates feeding on seasonally available detritus from terrestrial vegetation might increase in the short term following its input to streams. However, higher microbial respiration rates will increase organic-matter decomposition rates and may shorten the period over which detritus is available to invertebrates (Rempel and Carter, 1986).

Temperature has strong influences on virtually all physiological and life-history parameters (Table 10-2). That is the reason for increases in secondary production rates with temperature. These direct effects can be used with zooplankton as indicators of biotic vitality in systems undergoing changes in climate. At stressful temperatures, survival and reproduction decline while mortality and development times increase (Roff, 1970; Herzig,

Table 10-2: *Response of physiological characteristics and processes of zooplankton and benthic invertebrates to increasing water temperature, based on studies for which temperature remains well below tolerance limits.*

Process	Effect of Increasing Temperature
Life-Stage Development	Faster
Reproduction Rate	Greater
Ingestion Rate	Greater
Growth Rate	Greater
Respiration Rate	Greater
Mortality Rate	Lower
Generation Times	Shorter
Generations per Year	More
Average Body Size	Smaller
Production:Biomass Ratios	Greater

Sources: Lei and Armitage, 1980; Vidal, 1980; Ward and Stanford, 1983; Woodward and White, 1983; Sweeney, 1984; Sweeny *et al*., 1986; Rempel and Carter, 1987; Short *et al*., 1987; Jamieson and Burns, 1988; Maier, 1989; McLaren *et al*., 1989; Abdullahi, 1990; Moore and Folt, 1993; Moore *et al*., 1995a; Hogg *et al*., 1995.

1983; Orcutt and Porter, 1983; Cowgill *et al*., 1985; Jamieson and Burns, 1988).

Communities in mid-latitude streams dominated by groundwater springs and seepages are particularly susceptible to climatic warming because summer water temperatures are low in these streams and because increases in groundwater temperatures will be approximately equal to increases in average annual air temperature for the region. Thermal optima for many cold-water taxa from the mid- and high latitudes is less than 20°C; summer temperatures may exceed thermal tolerances and reduce production. The growth rate of the stonefly (*Leuctra nigra*) in the UK increases with temperature in experiments up to about 20°C, but survival is reduced by 67% and egg production by 90% at temperatures between 12 and 16°C (Elliott, 1987). In Pennsylvania, experimental increases in stream temperature during autumn—from ambient, near 10°C, to about 16°C—are lethal to 99% of stonefly (*Soyedina carolinensis*) larvae (Sweeney and Vannote, 1986).

Changes in the temporal pattern of warming may have significant and surprising effects because temperature is a cue that stimulates both the production and the release from dormancy of zooplankton over-wintering stages (Korpelainen, 1986; Stirling and McQueen, 1986; Sullivan and McManus, 1986; Marcus, 1987; Hairston *et al*., 1990; Hairston, 1996; Chen and Folt, 1996). Warming events in autumn could alter the timing or occurrence of resting stages, thus potentially causing the loss of an entire cohort or population and the reduction of eggs in the "seed bank." Resting eggs of the copepod (*Epischura lacustris*) are stimulated to hatch prematurely in autumn by raising temperatures above 15°C (Chen and Folt, 1996).

Invertebrates that can reproduce asexually may be buffered from local extinction at high temperature because they have populations comprising clones with different thermal tolerances. Electrophoretically distinguishable winter and summer clones of *Daphnia magna* from a single pond exhibit large differences in responses to temperatures of 25 and 30°C (Carvalhoe, 1987; LaBerge and Hann, 1990). Winter clones die, whereas summer clones survive and reproduce. This seasonal phenotypic variation in thermal response may increase the ability of these species to adapt. Other species are more likely to go extinct. Glacial relicts (some cold-water species) often lack resting stages and have poor dispersal capabilities. If excessive warming eliminated an entire cohort one year, resting stages would not be available in the sediments to reestablish the population the next year—and local extinction would result. Local extinctions are more likely when warm summer temperatures and anoxia erode the hypolimnetic refuge required by particular species (Dadswell, 1974; Stemberger, 1996).

More-persistent thermal stratification of lakes with warming (Schindler, 1990; DeStasio *et al.*, 1996) could reduce secondary productivity. Greater anoxia in the hypolimnion (Section 10.5.4) may eliminate a refuge from predation or from thermal stress. Warmer epilimnetic temperatures could decrease the nutritional quality of edible phytoplankton (Soeder and Stengel, 1974; Ahlgren *et al.*, 1990; Moore *et al.*, 1995, 1996) or shift the species composition of the phytoplankton community toward less-preferable cyanobacteria and green algae (George and Harris, 1985; Tilman *et al.*, 1986; Moore *et al.*, 1995a).

Temperature increases can reduce the availability of more-nutritious foods for stream invertebrates as well. Water temperatures exceeding 20–25°C reduce diatom taxa (more nutritious) and increase green algae and cyanobacteria (less nutritious) (Patrick, 1969; Lamberti and Resh, 1983).

10.6.1.2. Fish

Body growth and behavioral performances such as swimming ability and foraging success (Bergman, 1987) are controlled by temperature, as are the hatching success of eggs and survival of larvae (Edsall, 1970; Colby and Nepsy, 1981); all are maximum at some intermediate optimum temperature. In North America, freshwater fish have been grouped into three broad thermal groups—called cold-water, cool-water, and warm-water guilds—based on temperature differences in these optima (Hokanson, 1977; Magnuson *et al.*, 1979). As temperatures warm, the performance of each species increases or decreases depending on which side of the optima the temperature began; if dispersal is possible in a heterothermal habitat, each species will have a greater tendency to move into or out of the habitat.

Fish in all three thermal guilds grow faster in $2 \times CO_2$ climate/lake thermal structure/fish growth simulations for the Laurentian Great Lakes in North America (Hill and Magnuson, 1990), given the assumptions that increased food is available to meet higher metabolic rates and that cooler

water refuges are available. For Lake Erie, cold water with sufficient oxygen would not likely be available in the hypolimnion after a warming of this extent (Section 10.5.4), so the assumption of refuges is not always reasonable; for Lakes Michigan and Superior, the assumption is reasonable. (Shallow, unstratified lakes and larger rivers would not be expected to have thermal refuges.) Increased prey appears likely with warming of this extent based on correlation models with inter-lake comparisons of primary production, zooplankton biomass, and fishery yields (Regier *et al.*, 1990).

Population simulations for smallmouth bass (*Micropterus dolomieui*) under a $2 \times CO_2$ climate in the Laurentian Great Lakes (Shuter in Magnuson, 1989a) included thermal effects on reproduction, hatching success, and growth at all life stages. Simulations were made for warmer (Erie), intermediate (Huron), and colder (Superior) lakes. Warming in the models produced greater young-of-year survival in the intermediate and cold lakes but no change in the warm lake; in all lakes, warming produced an earlier age of maturation, greater young-of-year growth, a longer growing season for adults, greater year-class strengths, and larger fishable populations. Similar results would be expected for sea lamprey (*Petromyzon marinus*) in the Laurentian Great Lakes based on the effects of temperature on hatching success and growth (Holmes, 1990)—except that sea lamprey are a problem there, and considerable funds are spent for lamprey control.

Warmer winter temperatures would increase the winter survival of warmer-water fish and decrease the reproduction of fish that require a cold period for normal gonadal development. Because climate scenarios suggest that warming will be greater in winter than in summer, such influences may be significant for populations at the high- or low-latitudinal edges of their ranges. Winter survival would be enhanced for young-of-year white perch (*Morone americana*) at the northern edge of their range in the Laurentian Great Lakes (Johnson and Evans, 1990). Increases in mean annual temperature from logging activities in a British Columbia (Canada) stream also result in earlier emergence of salmon fry, and a lengthened growing season—and, as a result, increased over-winter survival rates (Holtby, 1988). Warmer winter temperatures are not beneficial for all fish because low winter temperatures for sufficient periods are required for normal gonadal maturation in some species (Jones *et al.*, 1972). For yellow perch—a cool-water fish—the highest percentages of viable eggs produced were 93% after over-wintering at 4°C, 65% at 6°C, and 31% at 8°C.

10.6.1.3. Contaminant Accumulation

Warming of lakes could increase the occurrence of methyl mercury in lakes and the accumulation of mercury in fish. In lake ecosystems, methylation is positively and demethylation negatively related to water temperature; the ratio of methylation to demethylation increases with temperature (Bodaly *et al.*, 1993). In six lakes, 70–80% of the variation in size-adjusted mercury concentrations in fish are associated with temperature:

in cisco (*Coregonus artedi*), northern pike (*Esox lucius*), walleye (*Stizostedion vitreum*), and yellow perch, but not for two bottom-feeding fishes, the white sucker (*Catostomus commersoni*), and lake whitefish (*Coregonus clupeaformis*). Mercury concentrations are not associated with other physical or chemical properties of the lakes.

Heavy metals and pesticide accumulation are greater at higher water temperatures (Reinert *et al*., 1974). In-depth treatment of these processes may be found in Wood and McDonald (1996).

Indirect effects of climatic warming on contaminant accumulation in freshwater plankton are likely to occur as well. Predicted water-chemistry changes, such as a decrease in DOC concentrations, may result in a decrease in chemical binding capacity, as hypothesized by Schindler (1996)—thus causing biotic effects of toxins to increase (Connell and Miller, 1984; Moore *et al*., 1995, 1996).

10.6.1.4. Ice and Snowmelt Effects

Ice cover in lakes and streams is expected to decrease with climatic warming (see Chapter 7). Reduced durations of ice cover are expected under scenarios with 2 x CO_2 climates; at the lowest latitudes where ice now occurs seasonally, ice is not expected to form at all in many winters (DeStasio *et al*., 1996). Observed ice durations decreased markedly during a 20-year period of warming in central North America (Schindler *et al*., 1990). In the Antarctic Dry Valley, ice cover has thinned for some of these permanently ice-covered lakes. Lake Hoare thinned by 20 cm/yr over a 10-year period beginning in 1977; ice cover is now 3.5 m thick (Wharton *et al*., 1992). Because light attenuation by the ice is a major limiting factor, these climate-related changes are expected to cause shifts in the biota of lakes with substantial periods of ice cover (Doran *et al*., 1994).

In the Laurentian Great Lakes, loss of winter ice cover results in year-class failure of lake whitefish, because the eggs incubate over the winter and increased turbulence and winter mixing reduce their survival (Brown and Taylor, 1993). On Grand Traverse Bay, Lake Michigan, the number of winters without ice cover has increased in recent years (Assel and Robertson, 1995). If this trend continues—as is expected with greenhouse warming—the lake whitefish are expected to decline in abundance.

In shallow lakes and the backwaters of large rivers, a decrease in ice-cover duration and especially the absence of ice cover would reduce the winter anoxia common at mid- to high latitudes. This could be countered somewhat by lower water levels, which reduce water volumes under the ice and increase the likelihood of winter kill. Winter kill of fish, owing to loss of oxygen under the ice, is a common occurrence in North America and northern Europe; this severe event greatly influences the fish assemblage structure (Tonn, 1990). Small, shallow lakes in midwestern North America that are anoxic in winter and presently have assemblages dominated by the central mud minnow (*Umbra limi*) would be expected to change to

ones dominated by northern pike and largemouth bass (Tonn *et al*., 1990) without ice cover and winter anoxia. In northern Europe, assemblages presently dominated by crucian carp (*Carassius carassius*) would be expected to change to ones dominated by European perch (*Perca fluviatilis*), roach (*Rutilus rutilus*), and other species.

10.6.2. Hydrological Effects on Biota

10.6.2.1. Streams

The largest effects of climate-induced changes in hydrology on productivity in streams and rivers will result from reduction in streamflows predicted for mid-latitudes, changes in the amount and form of winter precipitation and the timing of snowmelt at high elevations, and increases in the magnitude or frequency of extreme events (e.g., floods, droughts).

Reduced streamflows produced by lower precipitation and/or increased evapotranspiration would increase the probability of intermittent flow in smaller streams. Drying of streambeds for extended periods reduces ecosystem productivity because the aquatic habitat is restricted, water quality is reduced (e.g., expanded hypoxia), and intense competition and predation reduce total biomass (Fisher and Grimm, 1991; Stanley and Fisher, 1992). Intermittent streams in Australia and the southwestern United States have invertebrate communities dominated by organisms with resistant life stages and short life cycles (Boulton and Lake, 1992; Gray, 1981). Recovery of benthic invertebrates with the resumption of flow can be slow. More than 4 months were required for recovery of macroinvertebrate biomass following two 12-hour periods of streambed drying in the Colorado River caused by dam operations upstream (Blinn *et al*., 1995). Effects of drought also can be delayed. Effects of reduced recruitment during a drought in an Australian stream were not observed until the following year (Boulton and Lake, 1992).

For perennial runoff streams (Poff and Ward, 1989), the potential for intermittent flow may be particularly great in relatively humid climates that have low baseflows owing to low groundwater discharges; nearly one-half of such streams in the eastern and southeastern United States may become intermittent with only a 10% decline in annual runoff (Poff, 1992). A 14% decline in average annual precipitation for Alabama is projected to result in declines of 50–60% in minimum 7-day stream flows (Ward *et al*., 1992)—greatly increasing the possibility that perennial streams will become intermittent, even in this relatively humid region, because groundwater storage is limited.

Reduction in streamflow is likely to reduce the productivity of large flood-plain rivers and low-gradient streams dependent on periodic flooding. Inundation of flood plains provides expanded food-rich habitat and sources of organisms and organic matter for river ecosystems (Welcomme, 1979; Junk *et al*., 1989; Meyer, 1990). Fish yields are 1.5 to 4 times greater in river-flood plain systems than in equivalent systems without flood-plain inundation (Bayley, 1995). Inputs of

organic carbon from flood-plain wetlands account for about 80% of the metabolism in the main channel of a low-gradient stream in Georgia (Meyer and Edwards, 1990). Because organisms in flood-plain rivers and streams are adapted to reg-ular flooding cycles, reduction in flood frequency should have greater effects than increases in flooding. A record flood had little effect on Mississippi River biota, but the absence of a flood during a drought year caused substantial short- and

---

Box 10-3. Flood and Drought in Aridland Streams

In aridland streams, biomass and productivity are limited severely by both flood scouring and stream drying (Grimm and Fisher, 1992; Grimm, 1993). Small changes in precipitation may produce large increases in flow variability because runoff response to precipitation is nonlinear (Dahm and Molles, 1992). Longer periods of drought and more-intense storms may produce severe streambank and channel erosion because aridland riparian vegetation is sensitive to the avail-ability of water, and unvegetated soils are highly erodible (Grimm and Fisher, 1992).

Changes in the timing of flood and drought may be more important than changes in the annual averages. In the Sonoran Desert of Arizona, stream communities may be shaped by flash floods and subsequent colonization dynamics; biotic inter-actions, such as competition for a limiting resource; or morphometric and state changes associated with drought—shrinking ecosystem boundaries and eventual loss of surface water (Figure 10-7). These controlling processes are important because they shape community structure, instantaneous and annual primary and secondary production, and nutrient retention.
Figure 10-7: Changes in relative importance of major controlling factors in hypothetical years in which annual runoff and storm number are constant but the distribution of floods in time varies.

The contribution of each controlling process to the system's state depends on the temporal pattern of flooding rather than on the total annual discharge. In years with floods evenly distributed in time, drought effects are rare and biotic interac-tions are moderate. When between-flood periods are long, biotic interactions become more important and drought condi-tions characterize a substantial proportion of the year (Fisher and Grimm, 1991). In Sycamore Creek, annual runoff in 1970 was equivalent to 1988 but occurred as two flash floods compared to eight in 1988. Consequently, drought dynam-ics influenced the ecosystem during 76% of 1970 but only 29% of 1988; benthos colonization, succession, and rapid growth and reproduction were prevalent during 55% of 1988 but only 16% of 1970 (Grimm, 1993).

Changes in long-term processes also are important. Catchment-derived fluxes of nitrogen to desert streams are higher in floods that occur after several years of low precipitation (Grimm, 1992), presumably owing to accumulation of nitrate in soils during droughts. Century-scale arroyo-cutting episodes alter drainage patterns, drain wetlands, and shape stream chan-nels (Hastings and Turner, 1965). Small changes in atmospheric circulation patterns exert large effects on the occurrence, timing, and magnitude of convective storms on the Sonoran Desert and thus the flow variability of its streams and rivers.

long-term changes in plant and invertebrate communities (Sparks *et al.*, 1990).

Increases in flow variability should produce larger effects than changes in mean flow. Large floods scour the beds of small streams and rivers, flushing organisms and detritus downstream and depressing biomass and productivity for some time. New Zealand streams with more-frequent high flows had lower algal biomass and presumably lower primary production than those with more stable hydrographs (Biggs and Close, 1989).

Streams in arid regions such as the Sonoran Desert of Arizona are particularly susceptible to climate-induced changes in flow variability (see Box 10-3).

10.6.2.2. *Lakes*

Changes in lake water levels (Section 10.5.2; Figure 10-4) have large effects on nearshore biotic assemblages. In Lake Titicaca, South America, submerged macrophytes experience significant mortality when water levels change more rapidly than they can adapt (see Dejoux and Iltis, 1992). In Lake Kinneret in the Middle East, changes in inshore ecosystems occur with rapid water-level fluctuations, even though upper and lower water levels are regulated; the lake is a major reservoir of Israel's freshwater supply. A 4-m water-level decline in Kinneret reduces the stony belt around the lake by 30–94% (Gafny *et al.*, 1992), and the littoral slope changes from steep to slight (Gasith and Gafny, 1990). During low lake levels, wave action affects more areas of soft sediment than at high lake levels, resulting in short-term effects on water quality (Gafny and Gasith, 1989, 1993). Emergent vegetation develops in areas with gentle slope (Gasith and Gafny, 1990). The community of fish breeding in the littoral zone switches from dominance by fish that spawn on stones to those that spawn on sand (Gafny *et al.*, 1992). This may affect year-class strength of the primary planktivorous fish and eventually the entire food web. A warmer and drier climate in the Middle East would exacerbate such changes in inshore aquatic communities.

With declining water levels, lakes might in the short term become more separated from their bordering wetlands. A number of lake fish use these wetlands for spawning and nursery areas (Brazner and Magnuson, 1994). Northern pike, which spawn in flooded sedge meadows in early spring and whose young remain for about 20 days after hatching (Becker, 1983), would be especially damaged by low spring water levels.

Connectivity among lakes would be decreased by the cessation of flow in connecting streams in some lake districts, which could influence community structure and rates of extinction and invasion. For shallow, ice-covered, winter-kill lakes, loss of stream connections can eliminate access of seasonal migrants such as northern pike to adjacent deeper lakes during the winter. Loss of access would eliminate pike from shallow-lake assemblages, and the assemblage would shift toward species more tolerant of low oxygen and intolerant to northern pike predation (Lodge, 1993).

Large water-level changes characteristic of inland waters (Section 10.5.2; Figure 10-4), especially when exacerbated by climate change, have costly effects on urban and agricultural coastlines.

In 1986, agricultural and residential lands surrounding Lake Titicaca became inundated. At the highest water levels, people living in river valleys adjacent to the lake had to move upslope and switch their transport from connecting roads to boats. When the waters receded, the lower elevations began to be used only for agricultural purposes. The costs to adapt to future changes in water levels are $120 million for the first 5 years, based on a plan developed with the help of the European Community (Autoridad Binacional Autonoma de la Cuenca del Sistema TDPS, 1994). For Lake Michigan, bluff erosion during storms at high water results in property loss that includes destruction of residential and other shoreline developments. An extensive study concludes that the cost of controlling water level on all five Laurentian Great Lakes would be prohibitively expensive. Costs associated with adaptation to 2 x CO_2 water-level scenarios also are high. Changnon *et al.* (1989) estimate that increased dredging of harbors for a rather small length of Lake Michigan shoreline, including Chicago, would cost $138 to $312 million if water levels dropped by 1.25 to 2.5 m. Measures such as lowering docks, extending water supply sources and stormwater outfalls added another $132 to $228 million.

These examples demonstrate that water-level fluctuations at present and from climate-change scenarios can be large for lakes. Adaptation to, rather than control of, such large changes appears to be a common historical result in widely different settings and cultures. Such changes challenge the ability of human and natural communities to adapt and, in some cases, may be prohibitively expensive (see Chapter 12).

10.6.3. *Species Distributions and Biodiversity*

With climate warming, the poleward movement of freshwater communities will be at least as dramatic as the poleward movements of terrestrial vegetation (see Chapter 1). Extinctions and extirpations (local extinctions of species found elsewhere) will occur at the lower latitude boundaries of species distributions; where possible, poleward migrations will occur at the higher latitude boundaries of species distributions. Within geographic ranges, cool- and cold-water assemblages will be reduced in many rivers and shallow, unstratified lakes and ponds; suitable thermal habitat in many deep, stratified lakes will increase for warm-, cool-, and even cold-water organisms (see also Chapter 16).

Biodiversity increases from high to low latitudes (for fish, see Nelson, 1984; for streams, see Allan and Flecker, 1993). One might think that climatic warming, with adequate time, would increase the species diversity of many groups of organisms in mid- and high latitudes. In North America, species densities of fish in quadrates 1° latitude by 1° longitude are better correlated with the climatic factors of the quadrates than with the

latitude or longitude of the quadrates (Hocutt and Wiley, 1985). Species density increased with temperature and decreased with aridity, but temperature and aridity together accounted for only 38% of the variation in species density. These general associations for large regions provide little information about the decade to century influences of climate warming on the biodiversity of individual waters. Interaction with more local conditions and local species distributions will be more informative.

10.6.3.1. Edges of Geographic Ranges

Species extinctions and extirpations will occur at the lower latitude boundaries of distributions if summer temperatures increase in streams and shallow, unstratified lakes and ponds and cooler-water refuges are not available. In the southern Great Plains of the United States, summer water temperatures of 38–40°C already approach the lethal limits (less than 40°C) for many native stream fish, most of which are minnows (Matthews and Zimmerman, 1990). Fish aggregate in slightly cooler shaded waters of pools and tributary streams (32–35°C); this crowding induces various stresses, including overexploitation of prey resources. These wide, slow-moving streams have no high-altitude refuges; they flow to the south or east, making escape poleward unlikely. If a 3–4°C warming occurs, many endemic species could become extinct.

Biogeographic distributions of aquatic insects are centered around species' thermal optima (Vannote and Sweeney, 1980). Climatic warming would shift the optimum temperatures poleward and eliminate species near their lower latitude limits. In North America, a 4°C warming is projected to shift stream thermal regimes—and potentially the center of species distributions—about 640 km northward (Sweeney *et al.*, 1992).

At the higher latitude boundaries of species' distributions, organisms should be able to migrate poleward with climate warming, provided the new habitats are accessible through connecting waters. In North America, a 4°C increase in air temperatures is sufficient to move the simulated ranges of smallmouth bass and yellow perch northward across Canada by about 5° latitude, or about 500 km (Shuter and Post, 1990). These simulations include the entire life cycles and seasonality in both thermal and biological models.

10.6.3.2. Within Geographic Ranges

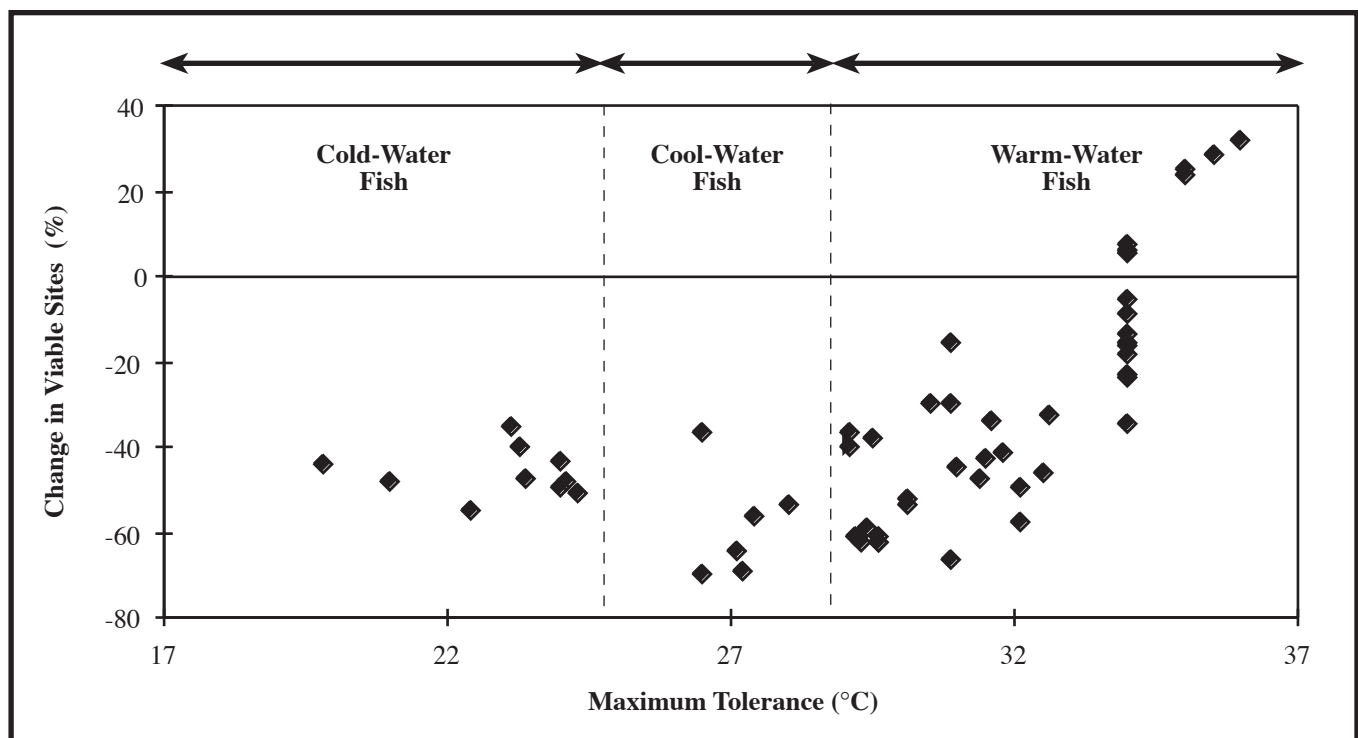
With projected climatic warming, stream fish habitats are predicted to decline across the entire United States by 47% for cold-water, 50% for cool-water, and 14% for warm-water species, independent of influences from other climate-related changes such as reduced stream flow (Eaton and Scheller, 1996). Only a few warm-water fish—bluegill, largemouth bass, channel catfish (*Ictalurus punctatus*), and common carp (*Cyprinus carpio*)—increase markedly in these simulations (Figure 10-8). These simulations assume that waters mix from


Figure 10-8: Changes in percentage of sites suitable for cold-, cool-, and warm-water fish at 1,700 U.S. Geological Survey stream sites across the United States, under a CCC GCM 2 x CO$_2$ scenario. Each point is a species plotted against its maximum thermal tolerance. Analysis and definitions are from Eaton and Scheller (1996).

surface to bottom and local thermal refuges do not exist. Scenarios are derived from air-temperature simulations across the United States with a 2 x CO_2 climate and a 0.9 factor to convert air to stream temperatures.

Heterogeneous thermal habitats can provide thermal refuges. In laboratory gradients, most freshwater fish spend two-thirds of their time within a 4°C range and all of their time within a 10°C range around their preferred optima (Magnuson *et al.*, 1979; Magnuson and DeStasio, 1996). This ability allows them to seek out survivable or optimum temperatures in lakes and streams that are thermally heterogeneous. In summer, stream fish can move to higher elevations (Rahel *et al.*, 1996), to reaches closer to groundwater sources (Meisner, 1990), or to shaded cooler areas (Matthews and Zimmerman, 1990); in thermally stratified lakes, fish can move downward to deeper, cooler waters (Magnuson and DeStasio, 1996).

In mountain streams of Wyoming, habitat loss is predicted for cold-water fish even with small increases in temperature (Rahel *et al.*, 1996). An increase of 1°C reduces stream habitat for cold-water fishes by 7–16%, 2°C by 15–26%, 3°C by 24–39%, 4°C by 42–54% and 5°C by 64–79%. Remaining enclaves of cold-water fish would exist as smaller fragmented populations, with an increased probability of extinction from ecological disturbances such as fire or drought (Allendorf and Waples, 1987; Mills and Smouse, 1994).

Biotic interactions for stream invertebrates also intensify as flows decline or streams dry; mobile organisms are concentrated into smaller areas, resulting in intense predation and competition and potentially a loss of some taxa and diversity (Carpenter *et al.*, 1992; Grimm, 1993).

In deep, thermally stratified temperate lakes, thermal habitat generally increases with 2 x CO_2 scenarios of global warming, not only for warm- and cool-water fish, but also for cold-water fish (Magnuson *et al.*, 1990; DeStasio *et al.*, 1996; Magnuson and DeStasio, 1996) (Figure 10-9). Similar increases are projected in smaller and larger lakes in Wisconsin for warm- and cool-water fish, but results were equivocal among GCM scenarios for cold-water fish in the smaller lakes. Increases occurred because the length of the growing season increased and because fish could move to deeper, cooler waters when surface waters exceeded preferred temperatures. Deep-water thermal refuges for cold-water fish are maintained in model projections over large latitudinal ranges (McLain *et al.*, 1994), assuming that deep-water oxygen is sufficient.

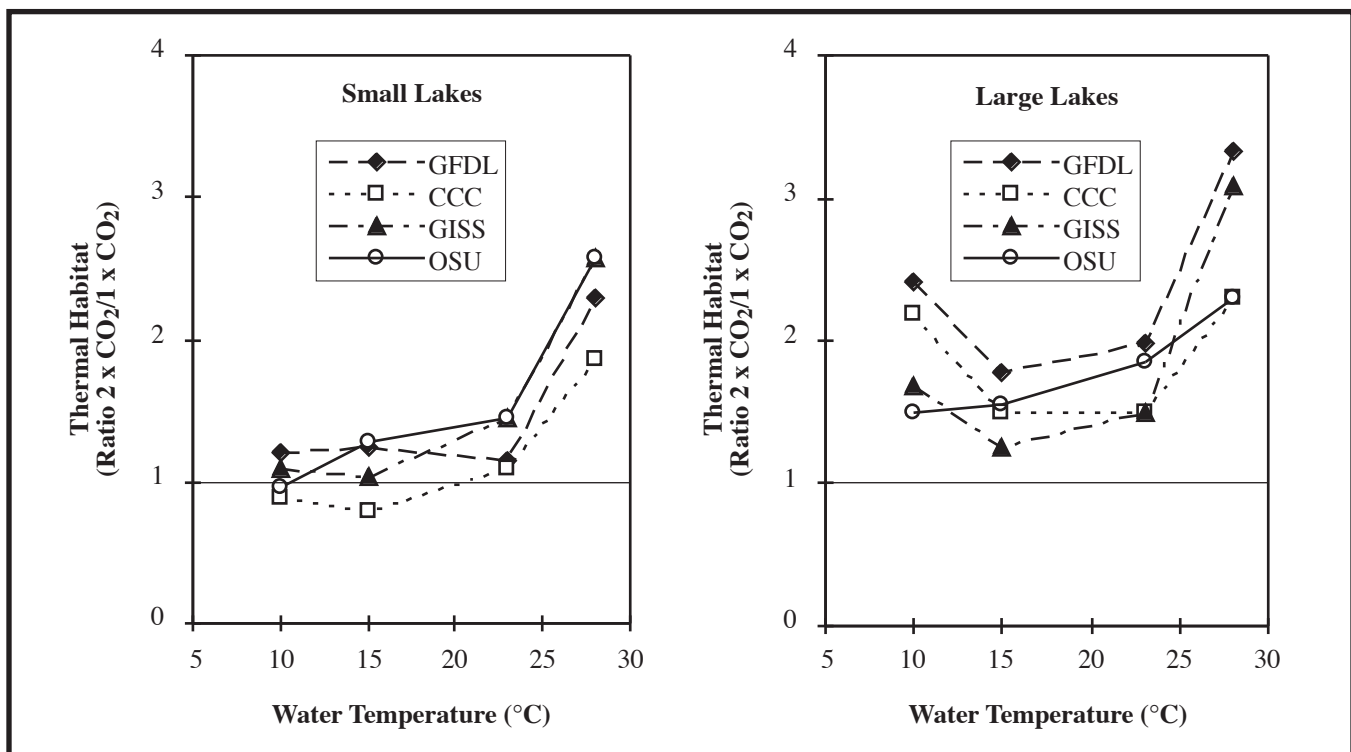
Changes in deep-water oxygen and other habitat variables may prevent cold-water fish from occupying their thermal niches in a warmer and drier climate (Magnuson and DeStasio, 1996). Increases in water clarity can deepen the thermocline of small lakes, so that deep cold waters are significantly reduced in size (see Sections 10.5.3 and 10.5.4 and Box 10-2), and dissolved oxygen may be reduced in deep waters (see Section 10.5.4 and


Figure 10-9: Simulated changes in thermal habitat in small (Crystal and Sparkling) and large (Michigan, Mendota, and Trout) stratified temperate lakes for cold- (10 and 15°C), cool- (23°C), and warm-water (28°C) fish under a 2 x CO_2 climate with four GCMs (GFDL, CCC, GISS, and OSU), as modified from Magnuson and DeStasio (1996).

Figure 10-7). Other relevant analyses exist for northern pike in impoundments (Headrick and Carline, 1993), striped bass in reservoirs (Coutant, 1985, 1987), and anadromous salmon (Crawshaw and O'Connor, 1996).

10.6.3.3. Genetic Adaptation, Dispersal, and Invasions of Exotic Organisms

Rates of climate warming are likely to exceed rates of genetic adaptation for some local populations of aquatic invertebrates, as well as the rate of natural dispersal of warm-tolerant populations that might be expected to replace them (see Box 10-4). Similar projections can be made for fish. Genetic variation in critical and chronic thermal maxima has occurred in separated populations of largemouth bass (Fields *et al.*, 1987), but thermal preference has not changed among populations (Koppelman *et al.*, 1988). Crawshaw and O'Connor (1996) speculate—from mammalian studies and similarities between fish and mammal thermoregulatory anatomy and processes—that genetic shifts in thermal preferences of fish might be fast under certain conditions.

The lack of suitable north–south migration routes (drainages) may limit dispersal, as well as replacement of cold-water fauna with warmer-water fauna. If dispersal rates of arriving warm-water species are low in freshwaters with declining cold-water taxa, the biomass and productivity of the community would be reduced with climate warming, at least initially, because range shifts may lag behind changes in thermal regimes (for stream invertebrates, see Sweeney *et al.*, 1992). This problem would be most restrictive for taxa that are less vagil (e.g., aquatic insects with fragile or short-lived adult stages) and for isolated freshwater ecosystems such as closed-basin lakes and streams. Isolation would be less severe for organisms that can be carried by the wind, such as very small organisms (e.g., algae and microbes) and those with small resting stages (e.g., cladocerans and rotifers), or for organisms with flying adults such as many aquatic insects. Fish dispersal (Magnuson *et al.*, 1989b; Tonn *et al.*, 1990) would be more restricted to water courses, transport by humans, or even rare extreme events (Dennis and Wolff, 1992) such as tornadoes.

Dispersing organisms arriving for the first time in a new ecosystem are exotic (new) to that system. Such invading species often interact with existing species in unexpected ways. Invasions of exotics can disturb the existing community structure and the productivity of species of value to humans. Rates of species invasion would increase poleward as conditions warm (Mandrak, 1989). These invasions can hasten changes associated with climate warming by increasing the rate of decline of existing species (Lodge, 1993) and add to the uncertainty (Magnuson, 1976) of predicting the effects of climate warming.

10.6.3.4. Observed Changes in Biodiversity

Box 10-4. Genetic Response to Warming

Genetic variability in mayflies of eastern North America decreases to the north; thus, populations for which global warming may be most pronounced are least-equipped genetically to adapt (Sweeney *et al.*, 1992). Many species of mayflies are weak dispersers and may be unable to move rapidly enough to keep up with poleward migration of isotherms (Sweeney *et al.*, 1992). Increasing temperatures and associated ecological changes may tax their ability to adapt.

Some aquatic invertebrates show high genotypic variability with little differentiation among sites; others vary greatly among sites but exhibit little genetic variability within a site. Hogg *et al.* (1995) tested the hypothesis that populations with little genetic variability would fare less well in a changing environment than those with more genetic variability. The amphipod *Hyalella azteca* disperses poorly but has high genetic variation; a stonefly, *Nemoura trispinosa*, has flying adults but low genetic variation. On one side of a split southern Ontario stream, temperature was raised year-round by 2.0–3.5°C for 3 years. Total invertebrate fauna was reduced by this treatment, but neither *H. azteca* nor *N. trispinosa* declined, although they did show life-history changes. Under warm conditions, the amphipod bred two months earlier and the stonefly emerged two weeks earlier at slightly smaller sizes. The authors postulate that endemic populations with poor dispersal abilities would suffer the long-term consequences of environmental warming.

Long-term observations as well as observed paleolimnological changes in organisms and in chemical conditions recorded in lake sediments can suggest the kinds of responses of freshwater biodiversity to future changes in climate.

Lake sediments accumulate over time and can contain an interpretable record of the history of the lake's biota from the remains of diatoms, chrysophytes, zooplankton and other aquatic invertebrates, and, rarely, even fish. A variety of organisms have been examined for use in inferring changes in climate; they explicitly indicate changes in lake biota in response to climate change. Diatoms appear to be the most sensitive indicators of past lake conditions; they are being used to examine the history of lakes in closed basins (Juggins *et al.*, 1994) and water levels (Gont *et al.*, 1988). They have been used to examine changes in the duration of ice cover (Smol, 1988). As a consequence of habitat specificity related to temperature (Douglas and Smol, 1995), they may be sensitive indicators of increases in temperature, especially in the high Arctic. Diatom communities respond to changes in salinity (Fritz *et al.*, 1993) that result from changes in precipitation or runoff. Diatoms respond to a number of environmental conditions, and they are sensitive to light and nutrient availability (Kilham *et al.*, 1996).

Diatoms and chrysophytes have been especially responsive to past changes in climate and climate-induced changes in water chemistry (Battarbee *et al*., 1990; Bradbury and Dean, 1993; Cumming *et al*., 1993; Davis *et al*., 1994; Smol and Dixit, 1990).

In natural thermal gradients of streams and in experimental streamside channels, the total number of algal species increases with temperature up to 25–30°C, then declines above 30°C as many diatom species are replaced by fewer species of green algae and cyanobacteria (Patrick, 1971; Squires *et al*., 1979; Lamberti and Resh, 1983). Phytoplankton biodiversity increased slightly over a 20-year period of warmer and drier weather in a Canadian Shield lake (Schindler *et al*., 1990).

The greatest biodiversity is expected at intermediate disturbance regimes; thus, large increases or reductions in flood frequency or size in streams (Ward and Stanford, 1983; Reice, 1994) or severity of winter kill in lakes (Tonn and Magnuson, 1982) can alter diversity. Analyses of streams in Wisconsin and Minnesota and in New Zealand indicate that fish communities are simpler and comprise more generalist species in streams with more-variable hydrologic regimes (Poff and Allan, 1995; Jowett and Duncan, 1990).

Increases in the frequency or severity of droughts may affect biodiversity in streams more than increases in the size of flood events because droughts result in longer-term habitat loss. Sharp reductions in the diversity of stream invertebrates followed dry years in arid streams of Arizona (Stanley and Fisher, 1992) and Australia (Boulton *et al*., 1992). Even if streams do not become intermittent, extended periods of low flow would reduce the diversity of organisms intolerant of reduced water quality (Chessman and Robinson, 1987; Boulton and Lake, 1990). Despite short-term reductions in densities and biomass, floods do reduce predation pressure and lessen competition and thus can increase species diversity (Dudgeon, 1993; Grimm, 1993).

10.6.4. Adaptations to Changes in Climate

10.6.4.1. Land Use: Catchment, Riparian/Flood Plain

In smaller streams and rivers, augmentation and protection of riparian vegetation will provide shade and reduce the negative effects of warming. For the north-central United States, Stefan and Sinokrot (1993) estimate that the predicted summer rise in stream temperature will be 6°C higher if streamside vegetation is lost. In the southern United States, the rise in summer stream temperatures is primarily from increased radiation; predicted summer increases in water temperature can be reduced by at least 50% in the more humid regions with more riparian vegetation (Cooter and Cooter, 1990).

10.6.4.2. Hydrological Regime and Water Level

Maintenance of existing flood plains and flood plain-river

exchanges or restoration by removing barriers such as levees may help in some cases to detain water during flood events, reducing flood peaks in downstream areas. Flood plains are vital to reducing flow variability and flood peaks in river basins.

Restoration of river and stream channels to more-natural morphologies would mitigate some negative effects of climatic drying and reduced flows. Natural morphologic features such as meanders and variable channel topography with deeper pools provide temporary refuges for organisms intolerant of reduced water depths or streambed drying. Permanent pools are critical refuges for many species when flow ceases in intermittent streams (Williams and Hynes, 1977; Boulton and Lake, 1992).

The already large water-level changes of lakes will be exacerbated and in most regions will be in the direction of lower levels. Shoreline structures and facilities, water intakes, and waste discharge will need to be extended or rebuilt. Human populations in most cases will begin to use the newly exposed lands for agriculture, habitation, and recreation and will have to retreat when water levels rise—with loss of property uses and values (see Chapter 12).

10.6.4.3. Heat-Loading Interactions with Nutrient and Toxic Wastes

Climate changes that produce higher water temperatures and lower flows and water levels will increase the negative effects of wastewater and thermal effluents on freshwater ecosystems. Because warmer temperatures make lakes and streams more productive—in a sense, more eutrophic in their behavior—it may be necessary to reduce alternate causes related to unwanted or nuisance production. Among the options would be to further decrease the loading of nutrients such as phosphorus and nitrogen from sewage treatment plants or to reduce leakage from diffuse agricultural and urban sources. Human adaptations that reduce these effluents—such as recycling or land application of wastewater effluents where appropriate—and increased use of recirculating cooling systems with cooling towers could help. Because the accumulation of many toxic substances in the freshwater food web is greater at higher temperatures, it also may be necessary to further reduce the release of these contaminants or further constrain the ingestion of contaminated fish by humans.

10.6.4.4. Biological Management: Harvest, Removals, Introductions

Zoogeographic responses to the loss of livable habitat at lower latitudes and gains in livable habitat poleward could be assisted by moving organisms poleward where warranted. Although this might save species that are about to be extirpated or go extinct at lower latitudes and expand the ranges at higher latitudes into suitable habitat, the introduction of these species into new habitats will not necessarily be successful. Two problems can be anticipated. First, these species may not establish viable

populations in many cases, and the species may be lost before the consequences of introductions become predictable. Second, if they do establish a population they may negatively impact existing species already under stress from climate warming or emigrate into other connected freshwaters and exert unwanted effects there. A common effect of introductions in freshwaters is the extinction of existing species. This also may have negative influences on existing uses of the freshwater ecosystem for fishing and other purposes that rely on water quality.

10.7. Research Needs

Further research is needed to reduce the level of uncertainty in hydrological and freshwater ecosystem impact assessments, focusing mainly on developing credible change scenarios. Specific areas requiring improvements follow:

- The accuracy of and reductions in the discrepancies between GCM simulations at the regional scale
- The understanding and modeling of land–atmosphere exchange processes at a range of spatial and temporal scales
- The understanding of the effects of CO_2 enrichment on plant water use in natural settings at the catchment scale
- Methods for defining credible scenarios for changes in weather patterns leading to flood and drought, including stochastic weather generators and nested regional climate modeling
- The understanding and modeling of hydrological systems under nonstationary climatic conditions, which involve the maintenance and enhancement of monitoring networks; the development of methods for the acquisition of spatially distributed estimates of state variables such as soil moisture, evapotranspiration, and infiltration by remote or inexpensive direct measurements; and the development of credible hydrological models with climate-invariant parameters
- The understanding of the effects of the El Nino/Southern Oscillation (ENSO) and other large-scale atmospheric features on hydrological characteristics, and the changes caused by global warming.

There is a need to reverse the decline in climatic, hydrological, and ecological monitoring networks and services in many countries, particularly coupled precipitation and streamflow monitoring in small catchments that provide whole-system indices of changes in evapotranspiration. Continuing decline will make the detection of climate change impossible in many parts of the world and prevent the production of credible hydrological scenarios.

Research needs in freshwater ecology related to climate change include approaches to a predictive understanding of long-term, slow changes and processes with time lags greater than one year that determine the regional and local behavior of land/water ecosystems. The most important general needs follow:

- Long-term research and monitoring of key physical, chemical, and ecological properties (particularly water temperature and mixing properties; concentrations of nutrients, carbon, and major ions; acid/base status; and populations of key organisms) and processes (e.g., primary production, organic matter decomposition)
- Comparative studies of populations or ecological processes across latitudinal and hydrologic gradients and system types
- Paleo studies using sedimentary records of climate-sensitive parameters aimed at a more complete integration of paleohydrology and paleoecology trends, patterns, and future expectations
- Whole-system experiments altering the thermal, hydrological, or mixing regimes in small lakes and streams, including whole catchments, or in large-scale mesocosms (e.g., lake enclosures, artificial stream channels) to determine the responses of organisms and processes to projected climate changes
- Testing whole-catchment and regional approaches to improve predictive understanding of integrated land/water systems.

CONTENTS

EXECUTIVE SUMMARY

Introduction

Climate change will have *direct* impacts on economic activity in the industry, energy, and transportation sectors; impacts on *markets for goods and services;* and impacts on the *natural resources* on which economic activity depends. Activities directly sensitive to climate include construction, transportation, offshore oil and gas production, manufacturing dependent on water, tourism and recreation, and industry that is located in coastal zones and permafrost regions. Activities with markets sensitive to climate include electricity and fossil fuel production for space heating and air conditioning, construction activity associated with coastal defenses, and transportation. Activities dependent on climate-sensitive resources include agroindustries (food/drink, forestry-related activity, and textiles), biomass production, and other renewable energy production.

The overall effect of climate change in the industry, energy, and transportation sectors will be the aggregation of a large number of varied individual impacts. The interconnectedness of economic activity means that many of the impacts are indirect and will be transmitted by transactions within and between economic sectors. Energy, water, and agricultural products in particular will transmit climate sensitivity through the economic system.

Findings

There is generally a high level of confidence concerning the sensitivities of specific activities to given changes in given climate variables. Reliable climate scenarios describing climate variables, apart from temperature, do not exist at the regional level, however. There is, therefore, a low level of confidence about the direction as well as the magnitude of some climate impacts when uncertainties about climate change at the regional level are taken into account.

Certain components of the industry/energy/transportation sectors display a greater degree of sensitivity to climate than does the sector as a whole.

- There is a high level of confidence that agroindustries that depend on products such as grain, sugar, and rubber are vulnerable to changes in precipitation patterns and the frequency and intensity of extreme weather events. Agroindustry is of relatively greater significance in many developing countries where, together with agriculture, it constitutes the bulk of economic activity. In areas with low agricultural productivity and

high population densities, climate change could have a significant effect on the production of biomass (i.e., living matter that can be burned to meet energy needs).
- There is a high level of confidence that hydroelectric production will be influenced by changes in precipitation and water availability. There is low confidence concerning whether these changes will be beneficial or otherwise because much depends on the relationship between seasonal patterns of precipitation and electricity demand in specific regions.
- It is certain that higher temperatures resulting from climate change will reduce energy needs for space heating and increase those for air conditioning. There is a low level of confidence concerning the balance between these changes. For example, one study of the United States concluded that energy needs could fall by 11% with a 1°C rise in temperature. Another concluded that electricity demand would increase by 4–6% with a rise of 3.7°C.
- There is a high level of confidence that sea-level rise will increase the cost of protecting transportation infrastructure and industrial plants located in coastal regions. Coastal protection will provide a market opportunity for the construction industry.
- There is a high level of confidence that climate change will increase the vulnerability of infrastructures located in permafrost regions.
- There is a high level of confidence that skiing seasons will shorten with consequent impacts on some local economies. There is also a high level of confidence that sea-level rise will affect tourism in beach resort areas.

Although the energy, industry, and transportation sectors are of great economic importance, the climate sensitivity of most activities is low relative to that of agriculture and natural ecosystems, while the capacity for autonomous adaptation is high, as long as climate change takes place gradually. The lifetimes of most assets are short compared to projected time scales for climate change. Consumer goods, motor vehicles, and heating and cooling systems will be replaced several times over the next half century. Even medium-life assets such as industrial plants, oil and gas pipelines, and conventional power stations are likely to be completely replaced, though there will be less opportunity for adaptation. Additional difficulties and costs could arise with long-lived assets, including some renewable energy projects and residential buildings.

The technological capacity to adapt to climate change will be realized only if the necessary information is available and the

institutional and financial capacity to manage change exists. Autonomous adaptation cannot be relied upon, and governments may have to set a suitable policy framework, disseminate information about climate change, and act directly in relation to vulnerable infrastructures. Many developing countries are dependent on single crops or on fishing and therefore are economically vulnerable to climate change through impacts on agroindustry. Diversifying economic activity could be an important precautionary response that would facilitate successful adaptation.

Context

In comparison with natural ecosystems and agriculture, little work has been carried out on impacts and adaptation in the industry, energy, and transportation sectors. The literature on adaptation and adaptation policies is particularly sparse. This partly reflects the perception that climate sensitivity is low and that adaptation could take place autonomously. Much of the attention of the policy and research communities has been focused on mitigation actions in the energy and transportation sectors.

Research on climate impacts has focused largely on developed rather than developing countries, even though the latter have less diversified economies that may be more vulnerable to climate change. Within the developed countries, work has focused on a small number of impacts, notably the possible effects of climate change on energy demand. This may reflect the availability of research tools as much as priority-setting.

Further research would be assisted by the generation of climate scenarios covering a fuller range of variables at the regional level. There is a need to broaden the scope of work to cover a wider range of activities (for example, agroindustry) and a wider range of countries, especially developing countries. Studies that begin to draw out the interdependence of economic activities in relation to climate would be particularly helpful.

11.1. Introduction

This chapter reviews literature addressing the potential impacts of climate change on the energy, industry, and transportation sectors and the associated capacity for adaptation. The chapter begins by considering broad issues relating to impacts and adaptation in the three sectors. It moves on to a more precise definition of the sectors, identifying their economic importance and the more important climate sensitivities. There follows a general overview of the different types of studies that have been conducted and the range of methodologies that have been used. The largest part of the chapter is devoted to a detailed review of this literature. For this purpose, activity is classified according to three types of climate sensitivity: activities with markets that are sensitive to climate, activities and processes that may be directly affected by climate change, and activities that are dependent on climate-sensitive resources.

A wide range of individuals and organizations will be affected directly or indirectly by climate change in the energy, industry, and transportation sectors. These include:

- Individuals in their role as consumers or citizens
- Businesses, operating over a wide range of scale and technological sophistication, which may be privately owned or run as state enterprises
- Policymakers concerned with land-use planning and the development of transportation, energy, or industrial infrastructures that may be affected by climate change
- Policymakers making high-level decisions about the adequacy of policies to deal with climate change and the appropriate balance between adaptation and mitigation strategies.

Because global warming and other climatic changes will result from the impact of past economic activity, the first three groups will be affected by climate change independently of current and future mitigation actions. This chapter is aimed at the needs of these groups. The needs of policymakers who are responsible for balancing mitigation and adaptation strategies are addressed, especially in Chapter 6, *The Social Costs of Climate Change: Greenhouse Damage and the Benefits of Control*, and Chapter 7, *A Generic Assessment of Response Options*, in the IPCC Working Group III volume; Nordhaus (1993) also addresses these issues.

11.1.1. Adapting to Climate Change

Adaptation to a changed climate may occur through the actions of individuals and enterprises, or it may be stimulated by policies promoted by those concerned with planning and infrastructure development. "Autonomous adaptation," i.e., action taken by individuals and enterprises on their own initiative, may reduce the need for explicit adaptation policies.

The technological capacity to adapt to climate change depends partly on the rapidity of climate change and the rate of replacement of equipment and infrastructure. On the whole, the lifetimes of assets in the energy, industry, and transportation sectors are short compared to the timescales for change projected using climate models. Table 11-1, based on Skea (1995), shows that, over the 60–70 years during which CO_2 concentrations in the atmosphere might double, many short-lived assets such as consumer goods, motor vehicles, and space heating/cooling systems will be replaced several times, offering considerable opportunities for adaptation. Even medium-life assets such as industrial plants, oil and gas pipelines, and conventional power stations are likely to be completely replaced over such a timescale, though there will be less opportunity for adaptation.

More difficulties could arise with long-lived assets such as certain residential buildings and infrastructure. Some assets (for example, a dam or a tidal barrage) have a design life of more than a century. Long-lived assets may need to function in a climate for which they were not designed. Infrastructure may be modified during its lifetime, however. For example, roads, port facilities, or coastal protection construction may be rebuilt periodically while retaining the same location and basic function. Rebuilding or upgrading offers substantial opportunities to adapt to changing climate conditions. Even medium-life assets such as power stations may be modified substantially during their lifetime—for example, by changing the fuel inputs, improving efficiency, or adding pollution control equipment.

The technological capacity to adapt to climate change will be realized only if the necessary information is available; enterprises and organizations have the institutional and financial capacity to manage change, and there is an appropriate framework within which to operate. In this respect, autonomous adaptation cannot necessarily be relied upon. Governments

Table 11-1. *Examples of asset lifetimes in the energy, industry, and transportation sectors (based on Skea, 1995).*

Short Life (up to 15 years)	
Conventional light bulb	up to 3 years
Cooking stoves in developing countries	2–3 years
Consumer goods	5–10 years
Motor vehicles	10–15 years
Space heating boilers/air conditioning systems	up to 15 years
Fuel supply contracts	up to 15 years
Medium Life (15–50 years)	
Industrial plant	10–30 years
Renewable energy projects (e.g., solar energy)	10–30 years
Commercial/residential buildings	20–30 years
Conventional power plant	30–50 years
Long Life (>50 years)	
Older residential buildings	50 years plus
Infrastructure	50–100 years
(roads, railways, port facilities)	or longer
Tidal barrage	120 years

may have a role in terms of disseminating information about climate change, setting policy and regulatory frameworks for individual actions, and acting directly to protect vulnerable infrastructure.

Rapid sea-level rise or changes in climate (Horgan, 1993) would limit the scope for autonomous adaptation, put considerable strain on social and economic systems, and increase the need for explicit adaptation policies.

A good indicator of the capacity for climate adaptation is the importance of the climate signal in relation to other pressures for change in the sector concerned. How do the pressures of climate change compare with those of changing demographics, market conditions, technological innovation, or resource depletion? Over periods of half a century or more, many sectors will change beyond recognition, while others may disappear completely. New products, markets, and technologies will also emerge. An industry coping with other, more significant changes may be able to adapt easily to climate change.

Different regions of the world vary greatly in their capacity to adapt. More vulnerable regions include those with less access to new technology, those that rely heavily on single sources of energy, and those dependent on single crops or on fishing. It has been argued (National Academy of Sciences, 1992) that poverty makes people more vulnerable to change and reduces their flexibility to respond. Both individuals and institutions in developing countries are likely to have less capacity to adapt to a changed climate. If climate change takes place gradually and if the potential impacts of climate change are allowed for in the development process, then the prospects for successful adaptation will be enhanced. Diversifying economic activity could be an important precautionary response that would facilitate successful adaptation to climate change.

Individuals and activities can adapt to climate change by migrating towards other climate zones, even if this involves crossing national frontiers. The migration of economic activity could be regarded as a successful adaptation to climate change. Policymakers at the national level, however, will be concerned about the balance of economic activity and autonomous adaptation actions that affect this activity.

11.1.2. Adaptation and Mitigation

Although the balance between adaptation and mitigation strategies is not the focus of this chapter, mitigation is a key concern in the energy sector. Energy plays a pivotal role in the assessment of climate change since fossil fuel combustion is one of the most important sources of greenhouse gas emissions. The energy sector is therefore likely to be one of the main targets for policies and measures aimed at mitigating climate change. Climate change, however, will also modify patterns of energy demand and industrial activity and, hence, greenhouse gas (GHG) emissions. As a result, the amount of mitigation action required to reach any given target for either emissions or concentrations of GHGs will be altered. At the same time, mitigation actions will themselves modify the impacts of climate on the energy sector—for example, by stimulating switches to more or less climate-sensitive energy resources.

A fully consistent treatment of the industry, energy, and transportation sectors would require an "integrated" approach to the assessment of impacts/adaptation and mitigation. Such approaches are now beginning to be developed (for example, Dowlatabadi and Morgan, 1993; Cohan *et al.*, 1994), but few studies take account of feedbacks *within* the energy sector. For the most part this chapter, of necessity, ignores interactions between impacts/adaptation and mitigation actions.

11.2. Characteristics and Sensitivities of the Sectors

Energy, industry, and transportation together cover a wide range of economic activity. Using the international standard industrial classification (ISIC) of all economic activities (United Nations, 1990) as the basis for definition, the sectors cover: manufacturing; mining and quarrying; electricity and gas; construction; transport, storage, and communications; and tourism and recreation.

Among the activities covered in this chapter is agroindustry—the processing of agricultural products into forms that make them suitable for meeting final consumer demands. Food, textiles, and paper are examples of agroindustry. Agriculture, forestry, and fishing, however, are not included. Most of the service sector is not sensitive to climate change, and there are few references in the literature. Notable exceptions are tourism and recreation, which are covered in this chapter, and insurance, which is covered in Chapter 17.

The "energy sector" is spread across a range of ISIC activities and includes: coal, oil, and natural gas production; coke manufacture, refined petroleum products, and nuclear fuel; and electricity generation, electricity and gas transmission, and distribution. Biomass fuels and renewable energy are also covered. Transportation is a major component of the world economy, accounting for 10–20% of gross domestic product (GDP) in most countries. Transportation is growing rapidly; it now accounts for approximately one-fifth of CO_2 emissions from fossil fuel use (Lashof and Tirpak, 1990).

The sensitivity of industry and energy to climate change is widely believed to be low in relation to that of natural ecosystems and agriculture, while adaptability is high (National Academy of Sciences, 1992; Nordhaus, 1993). Different branches of industry, however, vary considerably in their climate sensitivity. Broadly speaking, sectors that are high up the manufacturing chain or are directly dependent on primary resources (agroindustries, renewable energy) display greater sensitivity than do sectors further down the manufacturing chain—for example, engineering. The interactions and interdependence of various activities and systems have been emphasized by some (National Academy of Sciences, 1992; footnote), particularly in relation to adaptive

Table 11-2: Weight of different sectors in industrial production in 1991 (%), based on UNIDO (1993) and FAO (1993).

actions. Little work has been carried out that explores these interactions and interdependencies, though some preliminary studies have been carried out (Scheraga *et al.*, 1993).

The magnitude of climate impacts is a function of both the severity of the impact and the importance of the affected sector (National Academy of Sciences, 1992). Table 11-2 shows both the contribution of industry to total economic output in different regions of the world and the contribution of different sectors to industrial output (UNIDO, 1993). Broadly speaking, developing countries are less reliant on industry than are developed countries, but climate-sensitive industrial sectors such as energy and food make a relatively greater contribution to economic output in developing countries. The greater importance is reflected even more strongly in terms of employment (UNIDO, 1993). The number of people working in the food industry in developing market economies rose from approximately 10.5 million in 1970 to 17 million in 1990. Between 1977 and 1989, the rate of growth in developing countries was 5.3% per year as opposed to 2.0% per year in industrialized countries (Table 11-3).

The diverse range of activities covered in this chapter is affected by a correspondingly wide range of climate variables (Table 11-4). Temperature changes over daily and seasonal cycles are of key importance, but other relevant variables include precipitation, humidity, ground moisture, insolation, wind speed, storminess, and sea-level rise. Ideally, impacts and adaptation should be reviewed in the context of climate scenarios covering a wide range of variables at the regional level. The uncertainties in present computer simulations of regional climate change, however, are too large to yield a high level of confidence. This, coupled with the sparse use of climate scenario frameworks in most impacts and adaptation work in the industry, energy, and transportation sectors, means that much of this chapter must be restricted to reviewing climate sensitivities. Recent climate scenarios can be used as benchmarks against which to judge reported sensitivities or the results of impact studies based on different climate assumptions. Many existing impact studies are based on assumptions about benchmark CO_2 doubling that have a range of implications for specific climate

Table 11-3: *Economic importance of production and employment in the food industry, in % (UN Statistical Office, 1993).*

Type of Economy	Weight in Industrial Employment (1990)	Annual Growth Rate of Employment (1977–89)	Annual Growth Rate of Production (1977–89)
World	15.5	1.5	2.6
Developed	9.5	-0.4	2.0
Developing	27.1	2.9	5.3

variables, including temperature and precipitation. The following key points highlight differences between current best estimates of climate change and assumptions that have often been made in the climate impacts literature:

- Globally averaged temperatures, which would, for example, influence energy demand, are projected to rise by 0.15–0.25°C per decade. Many impact studies, however, typically assume a 4.5°C increase by the middle of next century and need to be reviewed with more modest temperature increases in mind. Regional temperature changes may be greater or less than the mean.
- Water availability and agroindustry could be affected by precipitation patterns. Precipitation is likely to increase throughout the year at high northern latitudes. In mid-latitudes, winters could be wetter, while summers could be drier. Precipitation during the Asian monsoon season is likely to increase.
- The frequency of extreme weather events has implications for vulnerable infrastructure in the energy, industry, and transportation sectors. There is little agreement on how storminess might change in a warmer world. There is growing evidence, however, that heavy rain events will become more frequent.
- Sea-level rise could affect coastally located infrastructure. The current estimate of average global sea-level rise is 25–70 cm for the year 2100, which is lower than the range presented by IPCC in 1990 and lower than the range assumed in many impact studies. Sea-level rise at the regional level could be as much as twice or as little as half the global average.

11.3. Overview of the Literature

The sensitivity of the industry, energy, and transportation sectors to climate change has received less attention than has the sensitivity of natural ecosystems or agriculture. This reflects the perception that climate sensitivity is relatively low in the industry and energy sectors (National Academy of Sciences, 1992) and the attention focused on the mitigation of climate change through the reduction of GHG emissions (see Chapters 19–22).

11.3.1. Methods

The studies reviewed in this chapter address:

- The sensitivity of specific activities to weather conditions or sea level
- The potential impacts of climate change on a given sector or activity
- The impacts of climate change on a particular country or region
- The broader economic impacts of climate change, typically by integrating the results of work on several sectors into a single macroeconomic model.

While considerable progress has been made in developing protocols for research on climate impacts (Carter *et al.*, 1994), most studies do not conform to these standards. The methods used in the studies vary considerably in scope and sophistication. The studies do not yet provide a coherent picture of climate impacts in the industry, energy, or transportation sectors.

The studies vary greatly in their use of climate and socioeconomic scenarios. Sensitivity studies make no use of scenarios but simply identify the effect, or the degree of autonomous adaptation, that a given climate stimulus would induce. Some studies have used an historic "analog" of anticipated climate change (Rosenberg and Crosson, 1991), while others (Smith and Tirpak, 1989) have used the results of scenarios generated by climate models. Many studies that use consistent climate scenarios estimate the effects of climate change on *existing* technology and patterns of economic activity. Such exercises have a heuristic value but cannot be taken as a prediction of the actual impacts of climate change because they do not take adequate account of the impacts of technological and economic changes unrelated to climate and the possibility of autonomous adaptation over timescales of decades.

Only the most sophisticated studies use internally consistent scenarios for socioeconomic change as well as climate scenarios. The industry and energy sectors, however, will change significantly over the next half century. The process of economic development will result in changes in the scale, composition, and location of industrial activity. Technological change, changes in resource availability, and environmental constraints likewise will affect activity patterns. The great uncertainties attached to future patterns of activity are reflected in the range of socioeconomic scenarios that have been developed to describe, for example, future energy demand and supply (IPCC, 1992; World Energy Council, 1993a). The failure to take account of socioeconomic change is one of the greatest weaknesses of the impacts/adaptation literature relating to energy, industry, and transportation.

11.3.2. Biases in the Literature

Research is biased toward specific world regions and sectors. Much of the literature is concerned with impacts in developed

Table 11-4: Summary of climate sensitivities in the industry, energy, and transportation sectors.

	Temperature	Precipitation	Windiness	Frequency of Extreme Events	Water Availability	Sea-Level Rise	Other
Agroindustry and Biomass	Impact on inputs from agriculture	Impact on inputs from agriculture		Damage to crops, trees, industrial infrastructure	Impact on inputs (e.g., irrigation)	Impacts on coastally sited fish processing	Main impacts via inputs from agriculture
Renewables	More evaporation from reservoirs	Hydroelectric potential	Wave potential, reservoir evaporation, wind potential	Many renewable systems vulnerable, especially wind turbines, solar systems	Hydroelectric potential	Design of tidal, wave systems	Cloudiness affects solar potential
Energy Extraction	Impact of reduced ice on offshore Arctic operations			Offshore oil and gas		Offshore oil and gas	
Energy Demand	More space heating, less air conditioning		Space heating				More humidity, more air conditioning
Energy Conversion	Slightly less efficient thermal generation				Cooling water availability	Coastal power stations, refineries	
Energy Transport/ Transmission	Pipelines over permafrost vulnerable; lower capacity of power lines	Icing of power lines		Effects on power lines			
Transportation Infrastructure	Vulnerability if permafrost melts; changed freeze-thaw cycles on roads			Effects on roads, railways, bridges		Effects on coastal infrastructure; migration of coastal activity	Changes in movements of agricultural products; settlement patterns
Transportation Operations	Ice and coastal shipping in high latitudes; road maintenance costs; air conditioning in cars	Impact of snow and ice on road and air transport		Safety and reliability of operations (e.g., airports)	Inland navigation		Effects of fog, snow, rain, and ice on operations and safety

Table 11-4 continued

	Temperature	Precipitation	Windiness	Frequency of Extreme Events	Water Availability	Sea-Level Rise	Other
Tourism and Recreation	Shorter skiing seasons	Skiing season		Impact on attraction of mountainous and coastal regions		Impact on beach resorts and marinas	Many climate variables will affect demand for and location of facilities
Construction	Building design	Changed productivity of construction activity (snow, rain)		Impact on construction activity and building design		Larger markets through coastal zone management	
Manufacturing	More demand for air-conditioning equipment; markets for clothing, beverages				Availability of process water for heavy users; industries heavily dependent on hydropower		
Pollution Control	More ozone formation and control needs		Pollution dispersion		Water quality and discharges		

Note: This table identifies impacts and their degree of significance; the direction of impacts and uncertainties are discussed in the text.
Key: Dark grey boxes indicate a significant impact requiring adaptive response at a strategic level; light grey indicates modest impacts requiring adaptive response; and no shading indicates minor impacts.

countries, especially the United States, which was the first country to produce a comprehensive climate effects report (Smith and Tirpak, 1989). Other developed countries have since published comprehensive reviews (UK Climate Change Impacts Review Group, 1991; Nishioka *et al.*, 1993), and some work has been carried out in developing countries (Nguyen *et al.*, 1993). Recent impact studies covering transportation refer only to developed countries such as Canada, New Zealand, and the United States (Nishioka *et al.*, 1992). Such studies generally analyze only the direct impacts of climate on infrastructure and operations. Climate-induced changes in flows of freight and passengers that would affect infrastructure demands have been acknowledged but not quantified.

There are also biases in terms of the topics covered in the literature. The potential impact of climate change on demand for electric power and the consequent impact on investment in new power capacity accounts for a significant proportion of the energy-related literature (e.g., IPCC, 1990b, 1993). The ready availability of information relating electricity demand to weather conditions enables work of some sophistication to be carried out. The topic, however, may not be as important as the volume of literature would suggest.

11.3.3. Framework for the Review

This review classifies economic activity in three ways:

- Economic activity with markets sensitive to climate change
- Economic activity that is directly sensitive to climate
- Economic activity that is dependent on climate-sensitive resources.

Given the wide range of activity covered in this chapter, impacts and adaptation have been covered jointly under each topic.

This framework, which is simpler than that used in the first IPCC Assessment Report (IPCC, 1990b), highlights interactions among different branches of industry and linkages among industry,

energy, transportation, and other sectors, such as agriculture and human settlements. These interactions may transmit climate sensitivities through the economic system and are critical to an understanding of the broader impacts of climate change. Table 11-5 splits economic activity into four broad sectors—energy, agroindustry, transport, and other sectors—which are subdivided further into narrower bands of activity. It identifies those classes of climate sensitivity to which each sector is subject and gives a broad indication of the degree of sensitivity. The energy sector and agro-based industries show, in a qualitative sense, the greatest sensitivity. Since energy is an input to most other industrial activity, the impacts of climate change as reflected in energy costs will cascade through the industrial sector. Water (Chapter 14) is another important vector for transmitting climate sensitivity through an economy.

Markets for consumption goods, intermediate goods, capital goods, and transportation services all may be affected by climate change. The task of reinforcing coastal defenses in response to climate change, for example, will fall on the construction industry. Changing flows of freight and passengers will affect investment in new transportation infrastructure. Climate change will influence patterns of energy demand and, consequently, the need for investment in power plant and other supply facilities. Consumer demand for clothing and beverages and, in some parts of the world, air conditioning equipment, will also be altered by climate change.

Economic activity directly sensitive to climate is found in the construction, electricity, oil, gas, transportation, and water sectors. For oil and gas, offshore production is more sensitive than onshore production. In addition, some industrial activity is located in zones that are sensitive to climate change. Oil refining and some types of power generation, for example, tend to be located in coastal zones in order to facilitate the transport of raw materials and products. Transportation is vulnerable through the effects of sea-level rise on coastal infrastructure and the more direct effect of weather on operations. Constructions in the permafrost regions are especially vulnerable to climate change.

Climate-sensitive resources on which industry is dependent include agricultural, forestry, or marine products; water; energy; and various raw materials. Among the sectors and activities that are affected are food, beverages, and tobacco; textiles, leather, and clothing; timber products; pulp and paper; renewable energy; and sectors such as aluminum that are heavily dependent on hydroelectricity.

Table 11-5: *Sectors sensitive to climate.*

	ISIC No.	Markets	Production	Resources

N/A= Activity not easily classified within ISIC.

11.4. Economic Activity with Climate-Sensitive Markets

11.4.1. Energy Demand

The two uses of energy most sensitive to climate change are space heating and air conditioning in residential and commercial buildings and agricultural applications such as irrigation pumping and crop drying. Supply companies will adapt by changing the amount of new investment required to meet peak demand on electricity and gas networks and the composition of investment that would most cost-effectively meet changed temporal patterns of demand. Many studies that assess the impact of climate change on building energy demand have been conducted. The majority focus specifically on electricity markets. A smaller number of studies address energy demand in the agricultural sector and impacts on energy supply investments. The impact of climate change on energy demand will be perceptible but modest in relation to the impact of factors such as changes in technology and patterns of economic activity.

This chapter is primarily concerned with the consequences of climate change for the energy supply sector. Chapter 12 focuses on the impacts of changed energy demand in buildings and their occupants. Climate change also could lead to the increased use of air conditioning in motor vehicles; the resulting reduction in fuel efficiency is discussed in Section 11.5.2.

11.4.1.1. Energy Demand for Space Heating and Air Conditioning

11.4.1.1.1. Space heating and air conditioning markets

The mix of energy sources used for space heating varies widely from one region of the world to another but may include electricity, fossil fuels (coal, oil, or gas), or wood. Patterns of energy use in residential and commercial buildings are discussed in Chapter 22 on mitigation options in human settlements. Among the key points are (Hall *et al.*, 1993; Schipper and Meyers, 1992; World Energy Council, 1993a):

- The significant use of biomass fuels in developing countries
- The heavy use of coal in China, Poland, and other countries
- The increase in natural gas use in Europe and North America over the last 2 decades
- An increasing market share for electricity in new homes.

In the commercial sector, air conditioning accounts for a greater proportion of final energy demand than in the residential sector, due partly to internal heat gains from lighting, office equipment, and occupants. The use of air conditioning is still quite low in temperate regions of the world, though its use is growing because the use of electronic equipment is adding to internal heat gains and sealed buildings help to isolate occupants from a noisy or polluted environment (Herring *et al.*, 1988). The use of air conditioning is growing rapidly in a number of developing countries (Schipper and Meyers, 1992). As described in Chapter 22, energy demand in buildings is growing rapidly in developing countries and in countries with economies in transition but is virtually level in the industrialized world.

11.4.1.1.2. Climate sensitivity

The factors determining the use of energy for space heating and air conditioning are discussed in Chapter 12 in relation to human settlements. Energy suppliers, particularly in the electricity and gas sectors, are highly conscious of the link between energy demand and climate because peak capacity needs are determined for extreme weather conditions. In the UK, for example, where natural gas is the dominant heating fuel, annual send-out can vary by as much as ±10% because of variations in annual average temperature. In the UK, the climate-related variability of gas demand since the mid-1980s has been much larger than it was over the period 1950–85 (British Gas plc, 1992).

11.4.1.1.3. The impacts of climate on energy demand

Many national studies assessing the impact of climate change on energy demand have been carried out. The studies cover the United States as a whole (Linder *et al.*, 1989; Niemeyer *et al.*, 1991; Rosenthal, Gruenspecht, and Moran, 1995); Finland (Aittoniemi, 1991); the UK (Parry and Read, 1988; UK Climate Change Impacts Review Group, 1991; Skea, 1992); Japan (Nishinomiya and Kato, 1990; Kuroasaka, 1991; Matsui *et al.*, 1993; Nishioka *et al.*, 1993); and New Zealand (Mundy, 1990). Unpublished work on the former Soviet Union also has been carried out. Within the United States, there also have been a number of regional studies covering: Missouri, Iowa, Nebraska, and Kansas—"MINK" (Darmstadter, 1991); the Pacific Northwest (Wade *et al.*, 1989; Scott *et al.*, 1993); the Southeast and New York State (Linder *et al.*, 1989); and the Tennessee Valley (Miller and Brock, 1988). Some work has addressed specific categories of energy demand such as air conditioning (Milbank, 1989; Scott *et al.*, 1994). Chapter 12 also considers some of these studies.

Table 11-6 summarizes the results of regional and national studies that have sought to quantify the relationship between climate change and energy demand. Table 11-6 illustrates the great diversity in climate scenarios, time-frames, the focus in terms of fuels or specific energy end-uses, and the methodologies used. Climate sensitivities have been deduced either from established statistical relationships between weather and energy demand or from projected climate-induced changes in physical parameters such as degree days. The merits of the two approaches are discussed in Chapter 12. Table 11-6 demonstrates the strong emphasis that has been placed on the study of impacts on electricity demand, probably because this issue is "directly analyzable" (National Academy of Sciences,

1992). Although the results of the various studies are very location-dependent, several broad themes emerge:

- **Fossil Fuel Demand**—Climate change will cause the use of fossil fuels for space heating to decline. For example, a temperature increase of 1.3–2.9°C in the UK could reduce the demand for natural gas by 7–20% in 2050 compared with demand without the effects of climate change (UK Climate Change Impacts Review Group, 1991). In the MINK (Missouri, Iowa, Nebraska, Kansas) region of the United States it has been suggested that fossil fuel demand for space heating would decrease by 7–16% as a result of a temperature increase of 0.8°C (Darmstadter, 1991).

- **Electricity Demand**—Whether electricity demand is likely to rise or fall as a result of climate change depends on the relative importance of space heating or air conditioning (Linder *et al*., 1989). In areas with a high summer load associated with cooling, climate change will result in increased electricity demand. Conversely, where there is a high winter load associated with space heating, demand is likely to fall. In some temperate zones, where air conditioning is growing in importance, it is not clear whether in the long-term the increase in demand for cooling will exceed the reduction in demand for heating (UK Climate Change Impacts Review Group, 1991).

- **Total Energy Demand**—According to a study referring to representative residential buildings conducted by the Japan Architecture Society (1992), temperature rise will lead to a reduction in energy consumption in Sapporo (43°N), whereas in Tokyo (36°N) the reduction

of energy for heating in winter is balanced by an increase due to cooling in summer. At Naha (26°N), the overall energy load will be increased by 50 MJ/m^2 due to a 1°C temperature rise. Rosenthal, Gruenspecht, and Moran (1995) concluded that a 1°C global warming would reduce total U.S. energy use associated with space heating and air conditioning by 1 petajoule (PJ), 11% of demand, in the year 2010. Costs would be reduced by $5.5 billion (1991$). A 2.5°C global warming would reduce total costs by $12.2 billion (1993$). This estimate accounts for the latitudinal and seasonal variations in warming but not for daily variations.

- **Peak Demand**—In the UK, peak demand for heating fuels will decline less than total annual demand, leading to a reduced demand load factor. This would be due partly to a shorter heating season (UK Climate Change Impacts Review Group, 1991). The seasonal occurrence of the peak demand for electricity is an important factor. If peak demand occurs in winter, maximum demand is likely to fall, whereas if there is a summer peak, maximum demand will rise. The precise effects are highly dependent on the climate zone (Linder and Inglis, 1989). Climate change may cause some areas to switch from a winter peaking to a summer peaking regime.

11.4.1.1.4. Impacts on investment in electricity supply

Fewer studies have estimated the possible impact of climate change on investment requirements in electricity supply. An exception is the "infrastructure" component (Linder and Inglis, 1989) of the U.S. national climate effects study (Smith and

Table 11-6: *Summary of results of studies relating climate change to energy demand (based on Ball and Breed, 1992).*

Study	Country/ Region	Temperature Change (°C)	Date	Method	Coverage	Change in Annual Demand	Change in Peak Demand
Aittoniemi, 1991	Finland	1.2–4.6			electricity	7–23% down	
Darmstadter, 1991	U.S. MINK	0.81	2030	degree days	agriculture cooling heating	3% up <2% up 7–16% down	
Matsui, 1993	Japan		2050		electricity	5% up	10% up
Rosenthal, Gruenspecht, and Moran, 1995	USA	1	2010	degree days	space heating and cooling	11% down	
Smith and Tirpak, 1989	USA	3.7	2055	weather analog	electricity	4–6% up	13–20% up
UK Climate Change Impacts Review Group, 1991	UK	2.2	2050	degree days	all energy electricity	5–10% down 1–3% down	

Tirpak, 1989). The principal *quantitative* conclusions arising from that study, under one scenario based on large regional temperature rises in the range 3.4–5.0°C by 2055, were that:

- By 2010, peak demand would increase by 29 gigawatts (GW), or 4% of the baseline level for that year. For 2055, peak demand could be increased by 181 GW, or 13% of the baseline level.
- By 2010, additional investment in new capacity attributable to climate change would be 36 GW, or 13% of the new capacity requirements in the baseline scenario. By 2055, the extra capacity needed could be 185 GW, or 16% of new capacity requirements.
- Cumulative generation costs could be 5% higher by 2010 and 7% higher by 2050.

Among the more qualitative conclusions regarding adaptation to climate change were that:

- There could be a need for relatively more peaking, as opposed to baseload, capacity.
- The generation fuel mix would be altered.
- Different regional impacts could lead to more transfers of power from one area to another.
- Construction requirements and greater levels of fuel use may cause further environmental damage.

11.4.1.2. Energy Demand in Agriculture

Changes in energy demand in agriculture will largely be driven by changes in the level of food production on existing land, especially in developing countries. Changes in energy inputs to fertilizers would be an important indirect impact. Climate change, however, would have some direct impacts on energy needs. The MINK study (Darmstadter, 1991) included some approximate estimates of the impacts of a 0.6–0.9°C temperature rise on energy needs for irrigation pumping and crop drying. Energy demand for pumping would rise by around 25%, while demand for crop drying would decline by around 10%. Irrigation pumping demand is likely to be more sensitive to changes in temperature than to changes in precipitation (Wolock *et al.*, 1992). Taking into account the proportion of agricultural energy demand associated with pumping and drying, Darmstadter concluded that energy demand in agriculture in the MINK region would rise by less than 3% as a result of climate change. This conclusion appears not to have been based on any specific assumptions about climate-induced changes in cropping patterns.

11.4.2. Space Heating/Air Conditioning Equipment

Markets for air conditioning equipment are growing independently of climate change. A broader discussion will be found in Kempton (1992) and Andrews (1989). A small number of studies concerning the weather dependency of demand for air conditioners has been conducted. According to new work on

patterns of electricity consumption carried out by the Tokyo Electric Company (1994), for example, electricity consumption in the company's supply area rose exponentially during 1990 when air temperatures exceeded 17°C, with most of the increase due to air conditioning. In Japan, sales of air conditioners tend to rise by 40,000 units per day of maximum temperature of over 30°C (Sakai, 1988).

11.4.3. Construction

The construction industry, which is very weather sensitive, embraces architecture, building, and civil engineering. The direct impact of climate change on construction *activity* is addressed in Section 11.5. This section focuses on the impact of climate change on various types of construction and on the level of demand for construction work.

The construction industry carries out work both above and below ground in a wide range of terrains, some sheltered, others exposed. A variety of specific types of construction, including port facilities, are needed in coastal zones. The construction industry also plays an important role in the development of river and other hydrological works. These include dams, water supply systems, and works that safeguard against risks such as flood and urban drainage failure. Other works are required to secure water quality. The industry is also responsible for the civil engineering component, above and below ground, for land-based transportation systems such as roads, railways, oil/gas pipelines, and electric power lines, as well as airports. All of these works are climate sensitive.

11.4.3.1. Climate Sensitivities

The problem of assessing the impacts of likely climate change on construction falls into two distinct parts (UK Climate Change Impacts Review Group, 1991):

- The assessment of the likely impacts of climate change on existing constructions. Modifications needed to counter any unacceptably adverse effects of climate change must be identified. The appropriate timing for modifications must also be decided.
- The assessment of how current design practices might require modification. This assessment should also address design changes that could reduce future emissions of GHGs and other pollutants.

The key climatic risks in relation to constructions are high wind, snow load, driving rain, thermal expansion, excessive rates of weathering, thawing of permafrost, and sea-level rise. In general, risks are created by extreme values and events (for example, very high winds) rather than average conditions. Therefore, the use of climate models to predict changes in the magnitude and frequency of extreme events is a prerequisite for assessment work in this area. There are great uncertainties attached to the future frequency of extreme events at the regional level. Other

risks are associated with the increased vulnerability of timber and timber products to insect and fungus attack, the interaction of short wave radiation with cloudiness, and the impact of ambient temperatures on indoor climate (Page, 1990).

11.4.3.2. Adaptation to Sea-Level Rise

The construction industry will be called on to implement adaptation options associated with sea-level rise. The degree to which coastal infrastructure is at risk is described in Chapters 9 and 12. Existing protective constructions, such as breakwaters and sea walls, will also be affected by sea-level rise. A number of examples serve to illustrate the likely consequences.

Titus *et al*. (1991) estimate that about 2,600 km² of low-lying land in the United States may need to be protected from sea-level rise. The cost would be $5–13 billion for a 50 cm rise—approximately the current best estimate for the year 2100—and $11–33 billion for a 100 cm rise. Dikes would not be used on barrier islands because of their narrowness and aesthetic considerations. As a result, 420 km² of land on Atlantic Coast islands would need to be gradually raised. The cost of elevating buildings would be $15 billion under the 50 cm sea-level rise scenario and $30 billion under the 100 cm scenario. Gradually elevating roads and other infrastructure may be cheaper than building dikes. This has very different implications for the construction industry.

Hata *et al*. (1993) have assessed the impact of sea-level rise on Japanese fishing ports and adjacent coastlines. Quantitative analyses were performed for three different types of fishing ports assuming sea-level rises of 65 cm and 110 cm. It would be necessary to increase the height of the design wave and, consequently, the weight of breakwater structures. Breakwater weight would need to be increased by more than a factor of two assuming a very high sea-level rise scenario of 110 cm. An increase in the structural buoyancy of loading wharves and sea walls would result in a loss of stability. In addition, loading activities and vessel mooring functions would be impaired. In some cases, the surrounding communities themselves would be subject to severe flooding. Kitajima *et al*. (1993) have estimated a cost of $92 billion for protecting Japanese ports, harbors, and adjacent coastal areas against sea-level rise.

An even greater amount of construction activity might be required in Africa, where industry tends to be concentrated in capital cities, many of which are seaports (Tebicke, 1989).

11.4.3.3. Building Design and Climate Change

The technology of building design and construction will continue to evolve over the next half century, permitting adaptation to changed climate conditions. In temperate zones, the use of air conditioning systems has grown (UK Climate Change Impacts Review Group, 1991). In principle, climate change would stimulate the wider introduction of air conditioning

systems. In practice, however, this will be influenced by other changes in building design. The use of suitable design techniques could obviate the need for air conditioning systems in many buildings.

A survey by the Japan Architecture Society (1992) identified the following impacts of climate change on urban planning and architecture:

*   The effect of wind, solar radiation, and air pollution in urban areas
*   The effect of temperature rise and wind upon architecture, indoor climate, and human adaptation
*   Effects on the thermal capacity of concrete, asphalt, and other building materials
*   Effect on the use of water in buildings.

The greatest negative impacts on constructions are likely to arise from the interaction between sea-level rise and inland water hydrology. The impacts will be in vulnerable areas. The stability of foundations built on shrinkable soils would be affected by increased winter rainfall combined with drier summer soil conditions. Southeastern England, for example, has many properties at risk (Boden and Driscoll, 1987). Building design codes, currently based on historical climate records, may need to be changed in order to anticipate risks assessed in climate impact studies.

11.4.4. Demand for Transportation Infrastructure and Services

Transportation activity and associated energy consumption are growing very rapidly. Recent trends and future projections are discussed in Chapter 21 on mitigation options in the transportation sector. The essential points are:

*   Air and highway transport are the fastest growing modes.
*   The fastest rates of growth will take place in developing countries.
*   Transport-related CO_2 emissions could rise by between 40 and 100% by 2025.

With the exception of electrified rail and pipelines, transportation relies entirely on fossil energy, principally petroleum. Alternative fuels remain a very minor energy source for transportation, although the ethanol-from-biomass experiment in Brazil is notable (Sperling, 1987). Fossil fuels account for a significant share of tons moved in freight transport. In the United States, coal and petroleum constitute 30% of rail carloads, while petroleum, coal, and coke comprise 60% of waterborne ton-miles. Agricultural and food products are second to energy in terms of freight ton-miles. Changes in the location and nature of agricultural activities could have a large impact on the freight transport system.

Climate-induced changes in the distribution of population and economic activity and the consequent effects on the performance

of transportation infrastructure and infrastructure needs are of great potential importance. Transportation requirements are closely linked to patterns of human settlement and have been addressed in this context in several infrastructure-based assessments (e.g., Walker *et al.*, 1989). Changes in the nature and location of agricultural production, in the rates of population growth in different regions, in the volumes and types of fossil fuels used, and in tourism and recreational travel can have profound effects on the performance of existing transportation facilities and on requirements to construct new ones. Although it is widely acknowledged that climate change could produce significant redistributions of population and economic activities, particularly agriculture, detailed geographic predictions of these phenomena are lacking (Johnson, 1991; Jansen *et al.*, 1991). Such regional predictions are a prerequisite for quantitative assessment of the impacts of regional redistribution on transportation.

Existing assessments of transportation impacts have recognized the potential significance of changes in geographical patterns of economic activity on the transportation network. Black (1990) notes that even gradual, long-term global warming could cause a major disruption of the movement of goods and people in North America. Irwin and Johnson (1988) suggest that there would probably be a northward spreading of agricultural, forestry, and mining activities, resulting in increased population and intensified settlement patterns in Canada's mid-north and even in Arctic areas. Marine, road, rail, and air links would have to be expanded accordingly. While this would entail substantial extra capital and operating costs, it would also be an economic opportunity.

While increasing temperatures may open up regions to increased development in northern climates, sea-level rise may also force massive migrations from settlements on river deltas and other low-lying areas. Jansen, Kuik, and Spiegel (1991) point out that a possible 26% land loss in Bangladesh would displace 27% of the population and that a 21% land loss in Egypt would displace 19% of the population. The implications of such a population movement for transportation infrastructure requirements have not been addressed.

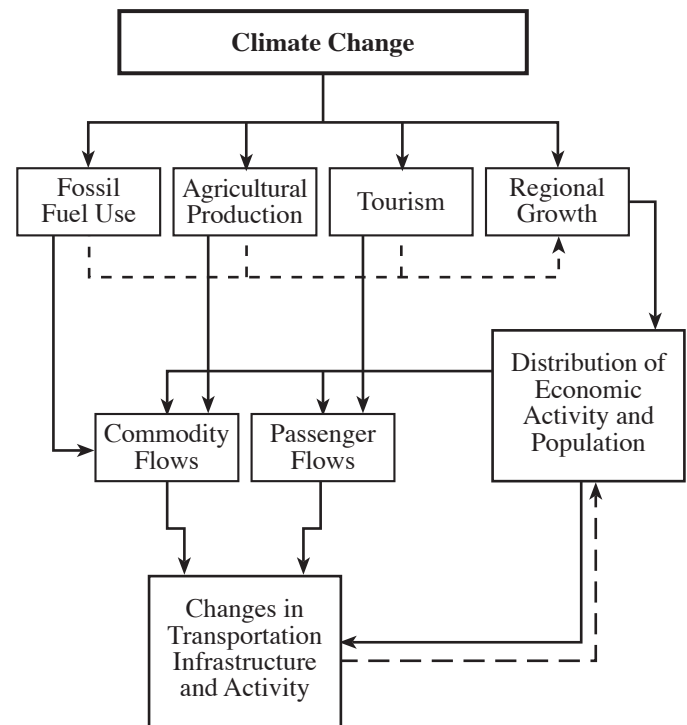
To date, no quantitative assessments of the impacts of climate on demand for transportation in areas such as tourism and recreation have been made, partly because the necessary regional economic scenarios do not exist (see Section 11.5.9). The current state-of-the-art in intercity passenger and freight transportation modeling is adequate for quantifying major changes in flows and predicting the magnitude of changes in transport networks that would be required to accommodate them (Friesz *et al.*, 1983; Bertuglia *et al.*, 1987). The interactions that would have to be modelled are represented in Figure 11-1. Climate change affects the geography of specific climate-sensitive sectors such as agriculture and tourism, but it also affects population distribution and regional economic growth more generally. Actions taken to mitigate climate change affect other activities, notably the extraction, processing, and distribution of fossil fuels. Changes in the location of these activities


Figure 11-1: Indirect effects of climate change on transportation.

affect the demand for flows of passengers and freight on a regional and global level. These demands then influence the development of transportation infrastructure and transportation movements. In addition, there are feedback effects by which the transportation infrastructure and activity influence patterns of regional growth. The anticipation of climate change would be appropriate in planning investments of a long-lasting infrastructural nature.

11.4.5. Other Market Impacts

The first IPCC assessment report (IPCC, 1990b, Chapter 5, Section 5.2.1.1) reported that climate change could be expected to influence patterns of demand for food, beverages, and clothing. The report suggested that:

- There could be an increased demand for cold drinks such as carbonated beverages, fruit juices, lemonade, and iced tea, and a reduced demand for hot beverages such as hot coffee or tea.
- There could be an increased demand for cotton clothing and certain synthetics and a potential reduction in demand for wools.

At the time, no studies that investigated these possible patterns of change could be cited. This remains the case. While some change in demand for beverages and textile products may be likely as a result of global warming, changes will take place over the long term, and the impacts may be small compared with those induced over a shorter timescale by product innovations and changes in consumer preference.

11.5. Economic Activity Sensitive to Climate

A wide range of economic activity displays some degree of direct sensitivity to climate change. On the whole, the direct impacts of climate change will be minor compared to impacts on resources or markets. The direct effects on activity located on coasts or in permafrost regions could be greater, however. Affected sectors include construction, transportation, energy, and tourism.

11.5.1. Construction

Rain, snow, high winds, and frost all hinder construction. Increased rainfall in winter, which may occur in mid-latitudes, would reduce productivity directly through impacts on working conditions and indirectly through impacts on ground conditions. A warmer winter climate could reduce the negative impacts of frost on construction activity. In areas such as Siberia, however, warming could cause permafrost shrinkage and lead to structural damage. If wind speeds were to increase, there would be a need to pay greater attention to wind protection during construction. Existing work on the variability of the impacts of present climate on the construction process could provide a basis for examining future climate impacts on site production (UK Building Research Establishment, 1990). A study in Japan reported that warm winters and springs have a favorable impact on the ceramic and quarrying industries, while the following have a negative impact: extended periods of rain in early summer, heavy snow, cool and rainy summers, and typhoons (Tokyo District Meteorological Observatory, 1986). Typhoons and other heavy rain, which may increase, can reduce the production of cement tiles and concrete blocks because of their impact on drying processes (Fukuoka District Meteorological Observatory, 1987).

11.5.2. Transportation Operations and Infrastructure

Climate change will have some direct effects on transportation infrastructure and the operation of transportation systems. These may be divided into three categories: the effects of climate on operations, the effects of sea-level rise on coastal facilities, and the effects of climate on infrastructure. These subjects have been included in existing impact studies in which transportation has been treated as one component of human settlements (e.g., Daniels *et al.*, 1992; Walker *et al.*, 1989).

11.5.2.1. Transportation Operations

Global warming will have both negative and positive impacts on the operation and maintenance costs of transportation systems. Studies in temperate and northern climates have generally indicated that higher temperatures will result in lower maintenance costs, especially with fewer freeze-thaw cycles and less snow (Parry and Read, 1988). Black (1990) points out, however, that increased pavement buckling due to longer periods of intense heat also is a possibility. Engineering standards for facility design and maintenance represent a sound, if not completely precise, means of quantifying the relationship between climate and factors such as damage to roads and bridges from freeze-thaw cycles, snow removal costs, salt application, and de-icing. Data from cities with similar climates and engineering handbook standards have been used to quantify the relationship (e.g., Walker *et al.*, 1989).

Inland and coastal water transport is particularly sensitive to droughts, floods, changes in water levels, and icing over of ports and waterways. The MINK study (Frederick, 1991) suggested that lower flows in the Missouri River could shorten the navigation season in the United States Midwest from eight months to five months in six of every ten years. Navigation benefits on the upper Missouri, however, are only $14 million/year, and the MINK study was based on a dry, 1930s-analogue climate rather than a forward-looking climate scenario.

In colder regions, the most significant direct impact of warming is likely to be on inland and coastal water transportation. A longer season for Arctic shipping is likely, with a greater number of frost-free days for northern ports and inland waterways such as the St. Lawrence Seaway (Irwin and Johnson, 1988). Inland waterways, however, may suffer loss of depth for greater periods of seasonal drought, reducing their usefulness for commercial shipping (Black, 1990). A survey of the potential impacts on Canadian shipping suggested net benefits to Arctic and ocean shipping due to deeper drafts in ports and longer navigational seasons, but mixed results for lake and river shipping due to the opposing effects of a longer shipping season but lower drafts (Irwin and Johnson, 1988). In Siberia, many rivers are used as solid roads during winter. Warmer winters would require a shift to water transport or the construction of more all-weather roads. Other climate impacts could arise from changes in snowfall or melting of the permafrost (IBI Group, 1990).

Transportation operations are sensitive to the weather. Fog, rain, snow, and ice slow down transport movements and increase risks of accidents. In addition, maintenance costs and the durability of infrastructure are somewhat dependent on weather events. Changes in the frequency and intensity of catastrophic weather events of short duration (for example, hurricanes, floods, wind shear, and surface movements associated with high rainfall) may have significant impacts on the safety and reliability of transportation. Little evaluation of such factors has been attempted.

Transportation operations are also affected by temperature. Fuel economy is somewhat temperature sensitive, primarily because of the time it takes a vehicle to warm up (Murrell, 1980). The impact on overall fuel economy of a few degrees' increase in average temperature, however, is likely to be a fraction of a percent. Vehicle emissions are also affected by temperature, especially evaporative emissions of hydrocarbons (U.S. EPA, 1989). This is potentially significant because formation of tropospheric ozone, for which hydrocarbons are a precursor, also tends to increase with temperature (see Section 11.5.7).

Increased use of air conditioning in vehicles would have a greater impact on overall fuel economy than would the direct effect of temperature change. U.S. automobiles consume 47 liters of fuel to operate air conditioners for every 10,000 km driven (Titus, 1992). Titus suggests that a CO_2 doubling would increase expenditure on fuel by $1-3 billion annually because of more air conditioning, though many of the specific assumptions used to reach this conclusion are not transparent. CO_2 doubling is assumed to be associated with a 3°C temperature rise. A warmer climate would also increase energy demand associated with refrigerated transport and cold storage (Steiner, 1990).

Interruptions to transportation operations can have significant impacts on industry. During the 1988 drought in the United States, industries that relied on bulk transportation of raw materials and finished products by barge on the Mississippi River found that low water kept more than 800 barges tied up for several months. In 1993, by contrast, floods in the upper Mississippi valley disrupted the barge transportation system. To the extent that industry is moving toward just-in-time production systems, it will become more vulnerable to interruptions for these and other reasons. This issue is also discussed in Chapter 17 in relation to financial services.

11.5.2.2. Sea-Level Rise and Coastal Infrastructure

Transportation infrastructure could be lost to inundation in coastal areas when sea levels rise and shorelines recede, although port infrastructure may be rebuilt sufficiently often to avoid such threats. Many airports are located at low levels. The impacts of sea-level rise have been rigorously examined in a few studies. In a detailed assessment of impacts at six sites on the eastern and Gulf coasts of the United States, Daniels *et al*. (1992) found that impacts varied greatly from city to city. For example, under a low sea-level rise scenario, 40% of the transportation, communications, and utilities infrastructure of Galveston, Texas, would be below mean sea level by 2050, and half by 2100. Under the moderate and high sea-level rise scenarios, approximately half would be below sea level by 2050 and all by 2100 (Daniels *et al*., 1992, Table 4.7). A similar study of the Daytona Beach, Florida, area concluded that only about 10% of the transportation infrastructure was subject to inundation (Daniels *et al*., 1992, Table 4.19). The impacts of sea-level rise on transportation infrastructure in low-lying countries such as Bangladesh and Egypt would be massive (U.S. Department of Energy, 1990).

Walker *et al*. (1989) found that considerable damage to roads in the Miami, Florida, area would be caused by a higher water table. If the sea level and water table were to rise by roughly one meter, the subgrade and/or base of many city streets would be subject to a certain amount of saturation given the annual fluctuation in the water table and its proximity to the surface. Structural failure would be caused if a heavy load were to pass over the surface. The cost of raising vulnerable streets in Miami was put at $575/meter for 410 km of road, or $237 million. Walker *et al*. (1989) also found that bridges and causeways that were not inundated would be damaged considerably if not reconstructed. Climate change should be anticipated when constructing or rebuilding transportation infrastructure.

11.5.2.3. Other Infrastructure

Inundation is not the only threat of sea-level rise to transportation infrastructure. Extreme rainfall could have widespread impacts on roads, railways, and other transportation links. As long as rainfall does not become more intense, impacts on urban roads and railways in temperate, tropical, and subtropical zones are likely to be modest. Exceptions could occur in coastal areas where highways and bridges may have to be redesigned for the higher wind pressures of tropical cyclones (Deering, 1994). In mountainous regions, increased intensity of rainfall could increase the risk of mudslides.

11.5.3. Energy Transportation and Transmission

Electricity transmission lines are susceptible to extreme weather events. If the frequency of extreme weather events were to increase, customers would have to accept a less reliable electricity service or pay for the costs of strengthening lines. Storms in Northern Europe in October 1987 led to an average loss of 250 minutes supply to customers of the UK's Central Electricity Generating Board (Electricity Council, 1988). As discussed in Chapter 17, the cost of interruptions to power supply in many service sectors is rising due to the increased use of advanced information and communication technologies. The capacity of electricity transmission lines also drops at higher temperatures. For example, the capacity of the typical line used in the UK falls from 2,720 megavolt-amps (MVA) in winter to 2,190 MVA in summer (Eunson, 1988). Higher temperatures could have minor implications for utilities experiencing a summer peak. Possible thawing of permafrost in Arctic regions may require changes in the design of oil pipelines in order to avoid slumping, breaks, and leaks (Brown, 1989).

11.5.4. Offshore Oil and Gas

Offshore production of oil and gas could be affected to a minor extent by sea-level rise. Royal Dutch Shell has increased the height of North Sea gas platforms above the water level by 1–2 meters to take account of projected sea level rise (National Academy of Sciences, 1992). This will, however, add less than 1% to the total cost of a platform.

Increased wave activity and increased frequency of extreme weather events might have a more significant effect on offshore operations, but little research has been conducted on this topic. Offshore oil and gas production conducted at high latitudes may be assisted by a longer ice-free season (Lonergan, 1989). A recent Canadian study of the Arctic petroleum industry (McGillivray *et al*., 1993) concluded that *global* temperatures rising by 1–4°C over a period of 50 years

and Arctic temperatures rising by two to three times as much would:

- Increase the open water (ice-free) season in the Canadian sector of the Beaufort Sea from 60 to 150 days
- Reduce ice thickness
- Increase the maximum extent of open water in summer from the current 150–200 to 500–800 km offshore
- Increase wave heights (e.g., the proportion of waves in excess of 6 m would rise from 16 to 39%).

As a consequence of reduced ice thickness and more open water, the offshore petroleum industry could experience reduced operating costs. The most critical factor could be ice movement during winter. Increased wave activity, however, would push up design requirements for both offshore structures and associated coastal facilities. In adapting to climate change, the industry would prefer to take a cautious view of these conclusions, discounting the benefits and preparing for increased wave activity (McGillivray *et al.*, 1993).

11.5.5. Thermal Power Generation

The efficiency of electricity generated through both steam and gas cycles would be affected negatively, though in a minor way, by global warming (Ball and Breed, 1992).

Most current thermal electricity generation relies heavily on the availability of cooling water (Smith and Tirpak, 1989; Solley *et al.*, 1988). There is a general trend away from once-through cooling, in which water is returned to rivers, toward evaporative cooling. In the United States, there also is a movement away from river-based power plants toward coastal siting (Smith and Tirpak, 1989). New technologies, such as combined-cycle gas turbines, are reducing the dependence of fossil fuel-fired power generation systems on the availability of cooling water (UK Climate Change Impacts Review Group, 1991). For these reasons, the impact of changes in water availability should be relatively minor.

Power plant output may be restricted because of reduced water availability or thermal pollution of rivers with a reduced flow of water. Events such as these have occurred during droughts in several parts of the world including France and the United States (*Energy Economist*, 1988). Under more extreme temperature conditions, some nuclear plants might shut down to comply with safety regulations (Miller *et al.*, 1992).

11.5.6. Water Availability for Industry

Changing patterns of water activity, particularly at the regional level, are highly uncertain. Industrial manufacturing depends upon water and is affected by its availability in several ways:

- Water is used as an ingredient or processing solvent for pulp and paper, food processing, textiles, and petrochemical refining (see Section 11.6.1).

- Some sectors, such as aluminum and, increasingly, the steel industry, are dependent on electrical energy and in particular on cheap hydroelectricity. Other industries are dependent upon water for process cooling or, indirectly, for cooling water in thermal electric power stations.
- Many industries are dependent upon cheap river and lake barge transportation of bulk raw materials and for shipping finished materials.
- The location of many manufacturers along rivers makes them vulnerable to damage from flooding.

Reductions in rainfall, which are possible during the summer in mid-latitudes, could adversely affect manufacturers in the first three categories by raising the cost of water, energy, and transportation as inputs into their products. Low water levels and higher temperatures could lead to less dissolved oxygen and greater problems with biochemical oxygen demand for industries that utilize water as an ingredient or solvent. This could raise the cost of process water. Efforts to reduce the use of process water through recycling could substantially reduce vulnerability to water shortages.

The global aluminum industry is exceptionally energy intensive and, in 1990, utilized an estimated 280 terawatt-hours (TWh) of electricity (Young, 1992) to convert alumina into 16.3 million metric tons of primary aluminum metal (Plunkert and Sehnke, 1993). Production of aluminum metal is distributed among 41 countries, many of which lack bauxite ore but possess abundant energy resources. The United States is unusual in that only 12.4% of its energy for aluminum production comes from hydroelectricity (Aluminum Association, 1991), whereas most of the other major producers—such as Brazil, Canada, and Ghana—rely almost exclusively on hydroelectricity (Plunkert and Sehnke, 1993). In the six years since 1988, Russian exports have expanded six-fold and now account for 10% of world production (Imse, 1994). Hydroelectricity forms the basis for the development programs and the industrial base of many developing countries. Brazil, for example, now ranks fourth in the world in terms of hydroelectricity production after Canada, the United States, and the former Soviet republics. Developing countries would be particularly hard hit by a reduction in hydroelectricity capacity. Any reduced availability of hydroelectricity could have significant adverse consequences for the industry.

Other industries that might be affected by a decline in regional electricity production are electric arc furnace-based steelmaking, electroplating, and uranium fuel enrichment. Regions suffering a decline in water availability from altered precipitation patterns would see rising water prices. Adaptation would require the development of additional water supply resources, the adoption of less water-intensive processing methods or, alternatively, relocation.

11.5.7. Pollution Control and Climate Change

Some features of climate change could lead to changes in ambient levels of pollution in both air and water. The two

possible impacts that have been given brief consideration in the literature are accelerated rates of ozone formation caused by higher temperatures and possible reductions in water quality caused by lower levels of river flow.

Estimates of the impact of temperature change on ozone formation vary. Gery *et al*. (1987) estimate that a temperature rise of 2–5°C would cause ozone concentrations in several major U.S. cities to rise by 1.69 ± 0.37% for every 1°C of warming. Morris *et al*. (1989) estimate that maximum ozone concentrations over a large part of the United States would rise by 1.45 ± 0.50% for every 1°C of warming. One form of adaptation would be to reduce emissions of ozone precursors. Smith and Tirpak (1989) estimate that, in order to maintain air quality, emissions of volatile organic compounds (VOCs) arising from auto exhausts, organic solvents, and gasoline storage would need to be reduced by up to 2% for every 1% increase in ozone concentration. U.S. VOC emissions for the year 2005 have been estimated at approximately 14 million tons (Pechan and Associates, 1990), suggesting that a 2°C temperature rise would add some $1.4–4.2 billion to annual VOC control costs, assuming abatement costs of $1,900–5,500/ton. As discussed in Chapter 12, there are also severe urban air pollution problems in Eastern Europe and in many cities in developing countries. The losses associated with increased air pollution would therefore be geographically widespread (Cline, 1992).

Maintaining water quality under conditions of reduced river flow would similarly require reductions in the discharge of pollutants. Titus (1992) estimated the impacts of an arbitrary CO_2 doubling on water flows in each of the U.S. states and calculated the cost of maintaining water quality. Across the United States, annual water pollution control costs were estimated to rise by $15–52 billion. Titus concluded that maintaining water quality would have a higher cost than problems directly associated with reductions in water quantity. In other parts of the world, however, river flows could increase and water quality would not be reduced.

11.5.8. Coastally Sited Industry

Many industries are located preferentially in coastal zones that are discussed in detail in Chapter 9. In the energy sector, many petroleum refineries and power stations are located in coastal zones because of ready access to supplies of crude oil and fuel or because of the availability of cooling water. In the UK, all oil refineries and more than half of the thermal power stations are located on coastal sites (UK Climate Change Impacts Review Group, 1991). Sea-level rise could result in additional expenditures at existing sites (Smith and Tirpak, 1989; Nishinomiya and Kato, 1990; UK Climate Change Impacts Review Group, 1991). There is a considerable amount of infrastructural investment (transmission lines, transport routes) associated with existing energy facilities, and any major migration of activity is unlikely.

11.5.9. Tourism and Recreation

Tourism and outdoor recreation is one of the most important and rapidly growing service industries throughout the world. In many countries, tourism is a major source of employment. Countries with economies that are highly dependent upon tourism may face great challenges because the resources upon which tourism rests are regionally, nationally, and globally climate-dependent.

Tourism and recreation are sensitive to climate change because part of the industry is closely associated with nature (National Academy of Sciences, 1992). Some parts of the tourism and recreation industry will necessarily migrate as a result of climate change. The Academy panel concluded that the overall effect for a country as large as the United States would probably be negligible, though specific regions could experience adverse or favorable effects. The question of whether the dislocations or relocations caused by climate change will produce costs over and above those that would have been incurred otherwise is important, but difficult to answer.

Two of the most obvious tourism and recreation facilities exhibiting climate sensitivity are skiing and beach resorts. In general, global warming might be expected to reduce the length of the skiing season in many areas and to affect the viability of some ski facilities. On the other hand, the summer recreation season in many areas may be extended. In some coastal areas, the benefits resulting from a longer season may be offset, however, by the loss of economically important beaches and coastal recreational resources, particularly on low-lying and vulnerable tropical islands.

Several studies have projected shorter skiing seasons as a result of climate change. Aoki (1989) found that skiing activity in Japan was highly sensitive to snowfall. In a study of the implications of an effective CO_2 doubling on tourism and recreation in Ontario, Canada, Wall (1988) projected that the downhill ski season in the South Georgian Bay Region could be eliminated, with an annual revenue loss of $36.55 million (Canadian dollars). This outcome assumed a temperature rise of 3.5–5.7°C and a 9% increase in annual precipitation levels. Some of these losses would be offset by an extended summer recreational season. Lamothe and Periard (1988) examined the implications of a 4–5°C temperature rise throughout the downhill skiing season in Quebec. They projected a 50–70% decrease in the number of ski days in Southern Quebec, while ski resorts equipped with snow-making devices would probably experience a 40–50% reduction in the number of ski days.

Because many recreational activities and related facilities are associated with coasts and beaches, sea-level rise may be of special concern to the recreational and tourist industries. Boathouses, residential plots and houses, public buildings, and structures are increasingly under threat due to sea-level rise. The low-gradient recreational beaches characteristic of much of the Atlantic and Gulf coasts of the United States are very vulnerable to erosion. Titus *et al*. (1991) estimate that the cost

of sand required to protect major United States recreational beaches from a 50 cm sea-level rise would be $14–21 billion. In addition, elevating infrastructure would cost another $15 billion on the Atlantic coast alone. Several U.S. states have prohibited seawalls on the ocean coast. Texas, Maine, and South Carolina allow public beaches to migrate inland with the shoreline. Property owners must take the risks of an eroding shoreline into account. Sea-level rise could affect fixed waterfront facilities such as marinas and piers. There could be increased erosion of beaches backed by sea walls, leading to a lowering of the beach level and subsequent undermining of the walls. Recreational habitats such as sand dunes, shingle banks, marshlands, soft banks, soft earth cliffs, and coral reefs would also be affected.

A small number of national studies of the potential impacts of climate change on tourism have been conducted. Higher temperatures are likely to stimulate an overall increase in tourism in the UK, with the greatest impact being on holiday activity and some forms of outdoor recreation (UK Climate Change Impacts Review Group, 1991). An increase in sea temperature would increase the pressures of tourism on UK beaches, while coastal erosion may reduce beach area (Baker and Olsson, 1992). A study by the Tokyo District Meteorological Observatory (1986) found that warm springs, falls, and winters, the absence of a rainy season, and very hot, dry summers have a favorable impact on tourism. On the other hand, typhoons, cool and rainy summers, extended periods of rain in the early summer, heavy snow, and cool springs were found to create unfavorable conditions.

11.6. Economic Activity Dependent on Climate-Sensitive Resources

Agroindustry, biomass production, and renewable energy sources depend heavily on climate-sensitive resources and therefore are potentially vulnerable to climate change.

11.6.1. Agroindustry

The impacts of climate change on the primary products of agriculture, forestry, and fishing are carried over to the food and drink sector, industries dependent on forestry products such as pulp and paper, and other sectors, notably textiles. The food and beverage industry is almost completely dependent on agricultural products, with the exception of mineral waters and some soft drinks. The textile and clothing industry is slightly less dependent due to synthetic fibers. In this chapter, these sectors are described collectively as *agroindustry*.

Many assessments of the impacts of climate change on specific crops and on agriculture as a whole have been carried out (Chapter 13). The few conceptual or empirical studies of agroindustry suggest that the sector is indeed vulnerable to climate change. Most of the assessments refer to developed rather than developing countries. Agroindustry, however, is relatively

more important in economic terms in developing countries. Moreover, even in the case of industrialized countries, analyses focus on only a few countries, notably the United States. The narrow range of studies carried out is unfortunate because it is virtually impossible to define generic thresholds for the impact of climate variables on agroindustries, even when the same product is derived from the same raw material.

11.6.1.1. Economic Impacts on the Food Industry

11.6.1.1.1. Agriculture-agroindustry linkages

The literature on the impacts of climate change on agroindustry has advanced little since the IPCC Supplement (IPCC, 1993). The U.S. MINK study addresses the linkages between agriculture and agroindustry at a regional level (Rosenberg and Crosson, 1991). Scheraga *et al.* (1993) have examined the consequences of higher agricultural prices resulting from CO_2 doubling using a general equilibrium model. Kane *et al.* (1992) have assessed the economic effects of CO_2 doubling on agricultural commodities at a global level. Some national studies exploring the linkages between primary agricultural products and subsequent processing also have been conducted (UK Climate Change Impacts Review Group, 1991; Antal and Starosolzky, 1990; Comisión de Cambio Climático, 1991). Most of these studies are concerned only with the impact of changes in the mean values of climatic variables on agriculture and agroindustry. Extreme weather events, however, can also carry climate impacts from the primary agriculture sector to agroindustry. The resource base of agroindustry is particularly vulnerable to droughts and tropical cyclones. Such cyclones can also severely damage industrial infrastructures, mainly small and medium-sized factories.

The MINK project (Rosenberg, 1993; Bowes and Crosson, 1993) quantified the links between agricultural production and processing industries. A climate similar to that of the 1930s was superimposed on current and projected patterns of economic activity. The work indicated strong linkages between the regional meat packing industry and feedgrain production and between soybean cultivation and oil production. More than 80% of the outlays by soybean oil mills are accounted for by purchases of oil-bearing crops.

The overall effect of the expected decline in feedgrain production on the regional economy depends on the extent to which the decline affects domestic or export markets. The decline could be as much as 6–10% if drops in production were to affect only domestic markets through the impact on the local meat-packing industry. The authors believe, however, that the economic impact would be closer to 0.6–1.0% because of adaptation on the part of farmers, the possible benefits of higher CO_2 concentrations, and the likelihood that reduced grain output would primarily affect export markets. The higher production costs in MINK under the 1930s climate would weaken the region's competitive position in world grain markets. Over the long term, some animal production might shift to other

grain-producing regions less affected by climate change. This could induce a decline in meatpacking in MINK, because these activities tend to be near animal production (Bowes and Crosson, 1993).

Scheraga *et al*. (1993) used a general equilibrium framework to explore the impact of a fairly extreme change in climate on agricultural production costs and the prices of goods and services that use agricultural commodities in the United States. The effects of selected climate impacts on the gross national product (GNP), consumption, investment, and the sectoral composition of output were assessed. A projected decline in crop yields was assumed to raise agricultural prices by more than 20% by 2050. This has an indirect effect on prices in other sectors, as shown in Figure 11-2. The largest price increases occur in agroindustry, notably the food sector, causing food and tobacco output to decline by 10%. Scheraga *et al*. (1993) calculated that the economic burden of climate change would fall disproportionately on lower-income households, which spend a large share of their income on food. This consequence of climate change, applicable to U.S. conditions, could be even more pronounced in developing countries.

Kane *et al*. (1992) examined the impacts of a doubling of atmospheric CO_2 concentrations on world agriculture and the indirect impacts on agroindustry. The study assumed increased precipitation and warming in the high northern latitudes coupled with drying in continental interiors. This work emphasized the importance of trade effects as a result of changes in the relative importance of the agricultural and industrial sectors and the direction and magnitude of the world price effects. Under two scenarios, prices of the main commodities used in food-related agroindustry were projected to rise by between 1 and 37%. The study projected only modest impacts on national economic welfare, which depends on changes in the yield of domestic agriculture, changes in world commodity prices, and the relative strength of the country as a net food importer or exporter. The benefits to producers will be larger than the losses to consumers if the country, like the United States, is a large exporter. This conclusion emphasizes the vulnerability to climate change of agriculture and agroindustries in the majority of developing countries. Rosenzweig and Parry (1994) also note that many cereal-producing countries in the tropical and sub-tropical zones appear more vulnerable to the potential impact of global warming than are countries in temperate zones.

The link between agriculture and agroindustry has been explored qualitatively in a number of country studies. In the UK, a rise in temperature coupled with increases in rainfall would accelerate the rate of deterioration of food and would change crop production patterns. Reduced rainfall, possible in summer, would reduce production, increasing raw material costs and requiring the import of more raw materials for the food industry (UK Climate Change Impacts Review Group, 1991). In Hungary, an increase in droughts would lead to a decrease in the yield of pastures, which would reduce the economic viability of cattle stocks and the associated meat processing industry (Antal and Starosolzky, 1990).

11.6.1.1.2. Impacts on specific food products

From the literature it is possible to draw more specific examples of the possible indirect impacts of climate change for grain, sugar cane, and fish products.

Grains constitute the world's staple food. In terms of agroindustries they are used in the production of bread, flour, meals, and pasta and form an essential input to the meat processing and dairy industries through animal production. Rosenzweig *et al*. (1993) conclude that climate change will lead to a decrease in cereal production, mainly in developing countries. Warming, coupled with drier climates in the interior of continents in the northern middle latitudes, predicted by most climate models, could have negative impacts on crops and livestock in the United States, Western Europe, and southern Canada, which are the most important grain-producing areas of the world (Kane *et al*., 1992). Increased precipitation and warming in the high northern latitudes, however, could enhance agricultural production potential.

The northward shift of the North American corn and wheat belt, as a consequence of drier conditions in the Midwest, could bring benefits to Canada, increasing its grain production and export capacity (Smit, 1989). Any shift in the corn belt also would entail large social and environmental costs. Some communities, industries, and the associated physical infrastructure could cease to be viable and might need to be relocated (U.S. Department of State, 1992). Affected agroindustries might include the production of ethanol and sweeteners, both of which are currently expanding.

World sugar production is 100 million tons per year, 60% of which is derived from sugar cane and 40% from sugar beet (UN Statistical Office, 1993). Sugar cane is also used to manufacture distilled alcoholic beverages and ethanol for motor fuel. According to Leemans and Solomon (1993), the distribution of sugar cane in a warming world could be quite similar to that at present, with the possibility of some expansion of the cultivated area. Yields per unit area could be increased by 3.4% and global production by 16.2%. This is based on the assumption that agroindustry associated with sugar cane will be developed intensively for energy production. The expansion of sugar cane for use as an energy source would be aided by the successful development of biomass gasification technology coupled to gas turbines (Larson, 1993). The greater use of sugar cane could form part of climate change mitigation strategies because this would contribute to reductions in greenhouse gas emissions (Acosta and Suarez, 1992; Macedo, 1991).

Sugar cane is produced in a large area of the world extending from 37°N to 31°S. Within that belt there are huge climatic differences (Blume, 1985). Consequently, local conditions must be addressed in assessing climate change impacts. This underlines the impossibility of defining generic thresholds for the impact of climate variables on agroindustries. A study of the productivity of Cuban sugar mills has shown that temperature and, to a greater extent, rainfall patterns are the principal climatic factors
Figure 11-2: Percent change in sector supply prices (top) and domestic output (bottom) for the year 2050, as a consequence of projected decline in crop yields (Scheraga *et al.*, 1993).

influencing sugar production (Comisión de Cambio Climático, 1991). The sugar industry could also be threatened by an increase in the frequency and intensity of hurricanes. Central America, the Caribbean, and Fiji have recently been struck by a number of severe hurricanes that damaged sugar production.

Citrus fruits are the basis for the large-scale production of beverages and other agroindustrial products. The impact of extreme climate events has contributed to important changes in the map of world citrus production. Frosts have a dramatic impact on the production levels of citrus (Buzzandi, 1979). Between 1957 and 1985, the citrus industry in Florida was subject to periodic freezes resulting in widespread production losses (Bulger, 1985; Miller and Glantz, 1988). The freezes in 1980–85 reduced seasonal orange production by about 50%. Those impacts helped to consolidate the expansion of agroindustry based on citrus fruits in Brazil, which was able to increase its exports during a period of rapid industrialization (Castello and Carvalho Filho, 1992).

Climate change would affect fish processing through both the availability of resources and impacts on storage systems. Fish processing comprises the freezing, salting, and drying of fish and the manufacture of fish jelly products, canned products, oil and fat, feed, and fertilizer. Seaweed is also economically significant in some parts of the world. The largest pressures on fish processing in some parts of the world will arise from overfishing and reduction in stocks. Fish jelly products and frozen fish, however, are sensitive to temperature change. Since fish processing industries are usually located along the sea coast, facilities are vulnerable to sea-level rise. For example, Stokoe (1988) notes that fish processing facilities in Canada's Atlantic provinces have a capital value of $1 billion (Canadian dollars), and most are situated at or near the water's edge. They could be vulnerable to inundation or damage as a result of sea-level rise. Reductions in precipitation could reduce potable water needed for fish processing. This is currently a problem due to climate variability, and significant permanent changes could cause additional difficulty.

Higher temperatures and sea-level rise could reduce catches of cod, tuna, and green hata in the Gulf of Tonkin, although the profitability of the shrimp industry could rise due to increased production (Nguyen *et al.*, 1993).

11.6.1.1.3. Key issues for the food industry

The conclusions of the small number of country studies and more general studies can be drawn together:

- Impacts on the food industry depend mainly on changes in the availability and price of agricultural products. Therefore, adaptation measures in agriculture are the key to diminishing any negative impacts on agroindustry.
- Climate change could have a severe impact on regions or countries dependent on single crops. Diversification of economic activity could be an important precautionary response.

- The impacts of climate change for agroindustry will be more pronounced in developing countries than in developed countries because many are located in more vulnerable zones and because their capacity for adaptation is lower.
- The burden of climate change may affect lower-income households disproportionately.
- Climate change could cause a loss of competitiveness in agroindustry in specific countries or regions, especially in developing countries. This could affect the viability of communities, industries, and associated physical infrastructure, resulting in relocation and/or large social and economic costs for the affected regions. On the other hand, some countries or regions might benefit.

11.6.1.2. Industry Dependent on Forestry

Many industrial sectors are dependent on forest products, including wood and timber, pulp and paper, rubber, and pharmaceuticals. Other forest products include nuts and oils. A recent analysis of the potential for products other than timber from a region of the Amazon concluded that their annual market value could be double that of timber itself (Peters *et al.*, 1989). Many forest products originate in developing countries where the commodities play a large role in the local and national economies. The sensitivity of forestry to climate is discussed in Chapter 15.

Forests provide major components for the construction of buildings in most parts of the world. Substantial amounts of furniture and a lesser proportion of other home utensils are manufactured from wood. In Europe, Russia, and North America, indigenous forests support major domestic timber industries. In many developing countries in the tropics, wood is a common property resource used as the predominant building material and for manufacturing agricultural/domestic tools and implements. Significant losses of forests in the North due to climate change would have major economic consequences. In the South, such losses could affect livelihoods, especially in rural areas.

The pulp and paper industry now relies most heavily worldwide on a combination of virgin forests and tree plantations as its source of fiber. Forests with rotation times of 30–50 years or longer are particularly vulnerable to climate change. In North America, the original Canadian boreal forest is still a principal source of newsprint, although short-rotation pine plantations harvested every 20 years in the southeastern United States contribute an increasing share. Europe relies upon boreal plantations in Scandinavia and coniferous plantations in Germany. The vast taiga of Siberia has supplied pulp and fiber for Eastern Europe in the past, but those traditional market relationships have been disrupted. Recent work has raised concern that the very slow regeneration time of the Siberian taiga could lead to major long-term deforestation of the region. Models suggest that changes in albedo accompanying climate

change could produce significant *cooling* in the region that would further diminish regrowth.

In industrialized countries, forests are likely to remain the primary source of raw materials for paper manufacture. In developing countries, the per capita demand for paper is still growing rapidly. Some developing countries may need to utilize other sources of raw materials. In 1989, 161 paper mills worldwide utilized bagasse (dry residue) from sugar cane (Silverio *et al.*, 1991). Mexico produced 8.5% of its paper from bagasse in that year (Atchison, 1989). China and other Asian countries use rice stalks in traditional paper making, and there is also the potential for utilizing cellulose fiber from other annual plant sources for pulp. Annual crops such as these are far less vulnerable to climate change.

The main source of natural rubber is the rubber tree, grown principally in Southeast Asia at latitudes below 10°N. More than six million hectares of land were used to produce 4.8 million tons of natural rubber in 1987 (UNIDO, 1993). Extreme temperatures can kill the tree, and relative humidity below 60–65% decreases the production of rubber resin (Tran *et al.*, 1979; Pham, 1973; Le, 1988). Excessive humidity or rainfall would encourage disease and pests (Tran *et al.*, 1979; Tayhieu Station, 1969; Chee, 1977). An increasing frequency of typhoons and tornadoes could cause significant damage to rubber plantations in countries such as Indonesia, the Philippines, Thailand, and Vietnam (Enquête Kommission, 1991; IPCC, 1990a; Tran, 1990). In Malaysia, the main rubber-producing country, yields could decline by 15% under a CO_2 doubling scenario associated with a regional temperature rise of 1–2°C and a 10% increase in rainfall (Asian Development Bank, 1994). Yield loss could rise to 25–40% due to the effects of temperature on the viscosity of resin when the tree is tapped. In Indonesia, the Philippines, coastal South Asia, and Indochina, warming for a CO_2 doubling could be in the range 0.5–3.0°C (CSIRO, 1992a). Adaptation to climate change could involve preparing for new developments outside the 10°N latitude zones. Plantations could be protected from high winds and colder winds by planting dense buffer trees to act as windbreaks. Increased irrigation could be used in Africa and parts of Asia, which might become drier. All of these measures could push up the cost of natural rubber and encourage substitution of synthetic material. This would damage the economies of rubber-growing countries.

Climate change could reduce biodiversity in forested regions, which in turn could reduce the availability of pharmacologically active natural products derived from plants, bacteria, and animals (Wilson, 1992). A quarter of the prescription pharmaceutical drugs dispensed in the United States between 1959 and 1973 had plant-derived active ingredients (Farnsworth and Socjarto, 1985). Plants provide 15–20% of pharmaceuticals in Japan and provided 35–40% in West Germany before unification (Principe, 1989a). The total market value of plant-derived pharmaceutical drugs was an estimated $43 billion in the Organisation for Economic Cooperation and Development (OECD) countries in 1985 (Principe, 1989b).

While it is difficult to make precise links between climate change and species loss, attempts to identify climate-altered conditions that might lead to extinction have been made (Gates, 1993; Wyman, 1991; Rose and Hurst, 1992; Emanuel *et al.*, 1984). Each of these studies predicts major relocation of species and ecosystems. Many species, especially trees, are unlikely to be able to migrate successfully if climate change occurs rapidly.

Surveys suggest that the tropics remain the most potentially productive source of future drugs, especially the Amazon (Peters *et al.*, 1989) and Costa Rica (Tangley, 1990). Most of the focus to date has been on the commercial potential of drugs for markets in industrialized countries, but populations in tropical countries might be disadvantaged if local species upon which they have come to depend for medication were to disappear because of climate change.

11.6.1.3. Textiles

Four fibers form the basis of the textile industry: cotton, wool, cellulosic fibers (rayon), and synthetics. Other fibers—for example, silk and linen—make up a small fraction of the total. Climate has little effect on synthetic fibers, but industries that rely upon natural fibers will be affected in a variety of ways by climate change.

Warming is likely to increase the risk of disease vectors and insect pests for cotton, sheep, and the forest sources of cellulose (Smith and Tirpak, 1989). Altered water availability is most serious for the growing of cotton, which is heavily dependent on irrigation in Central Asia, Egypt, and other parts of the world. Altered precipitation patterns could diminish the usefulness of large reservoirs and water distribution systems. Sheep are most often raised on marginal, drier lands such as in Australia, which accounts for nearly 70% of the world trade in wool for apparel (*Economist*, 1992). The boundaries of suitable grazing regions are likely to shift under any significant alteration of climate. Since many tree species are suitable for producing cellulosic fibers, they are much less vulnerable to altered precipitation patterns.

All fibers require massive amounts of water for processing and dyeing. One ton of wool requires an estimated 200,000 liters of water from shearing to the finished fabric (Watson, 1991). Cellulosic fibers require substantial amounts of water in the pulpmaking process, and cotton and wool require substantial amounts for cleaning. Synthetic fibers require relatively little water after the petroleum refining stage. Approximately 70% of water use is associated with the dyeing of finished cloth (Watson, 1991). Recycling could reduce the degree of dependence on water.

If precipitation patterns were to shift significantly, the production of finished cloth and industrial fibers might shift away from regions that were becoming drier. There might also be a shift toward synthetic and cellulosic fibers, which

are less vulnerable. Apparel, carpet, tire cord, and other industries dependent on textile fiber are relocating in response to changing labor markets. This suggests that textile industries located close to supplies of raw materials might respond rapidly to climate-induced changes in availability. While global production might not be greatly altered, the loss of industries might have significant local effects.

11.6.2. Biomass

Biomass is estimated to account for 12–15% of global primary energy consumption (World Energy Council, 1993b; Hall *et al.*, 1993). After oil, coal, and natural gas, biomass is the world's most important source of energy. Trees are the most important source (64%) of biomass fuels in both urban and rural areas. The remainder consists of animal dung and crop residues used in the countryside. A total of 88.5% of wood biomass is used as firewood and the rest as charcoal (Smith *et al.*, 1993). Biomass is the most important source of energy in developing countries, where it accounts for 38% of consumption (Hall *et al.*, 1993). In some of the least industrialized countries, where there is limited access to electricity grids, 90% of energy needs is met by biomass. Financial constraints may also force people to use biomass in cities (see Chapters 12 and 22). Biomass in the domestic sector is used primarily for cooking, although it is also used for space heating in regions with cold winters—for example, Nepal and northern China. Biofuels are transported to cities by draft animals and lorries, sometimes over long distances. In the Sahelian countries of Africa, biofuel trade is a well-organized sector with impressive turnovers (Sow, 1990). Biogas generated by anaerobic fermentation is used mainly in the Asian countryside. According to Dutt and Ravindranath (1993), more than four million family house generators have been installed in China and one million in India. The numbers are growing rapidly.

In industrialized countries, biomass accounts on average for 2.8% of primary energy consumption (Hall *et al.*, 1993). The share is, however, 13% in Scandinavia and 5% in France and the United States (Corté, 1994; and FAO, 1994). In industrialized countries, most biomass is used for household heating in rural areas and small towns. For example, this accounts for 81.5% of biomass consumption in France (Barbier *et al.*, 1994). Usually, fuelwood is burned in stoves in the industrialized countries, though woodchips are becoming more popular for district heating in Austria and Scandinavia. Large amounts of biomass are collected directly by users, bypassing the market system (Riedacker and Robin, 1987).

In both developing and industrialized countries, agroindustries use large amounts of biomass wastes for energy generation. Cogeneration is important in the sugar cane industry in the United States, Cuba, and Mauritius (Turnbull, 1993). These industries do not generally need to buy extra biomass to meet their energy demand. In developing countries, biomass, mainly fuelwood, is also used for drying tea and tobacco, for processing food, for cremation, and for public baths. There is an increasing demand for biofuels in small industries in countries such as India and Brazil (La Rovere, 1994). Large amounts of charcoal based on eucalyptus are used in Brazilian steel mills (Sampaio, 1994).

Biomass is also used for transportation fuels. In Brazil, liquid biofuels accounted for 18% of transportation fuel in 1987 (Goldemberg *et al.*, 1993). There are about fifty facilities manufacturing ethanol fuel from grain, mainly maize, in the United States. In 1987, this accounted for 8% of the U.S. gasoline market (Wyman *et al.*, 1993). Zimbabwe also has started to produce ethanol from sugar cane.

11.6.2.1. Impacts of Climate Change on Domestic Biomass

Fuelwood supply depends very much on forest area and the quantity and pattern of rainfall. As deforestation proceeds around cities in developing countries, mainly to provide more cropland, fuelwood has to be transported greater distances (see also Chapters 12 and 22). Forest yields are likely to be reduced with decreasing rainfall. Thus, in dry and densely populated areas, fuelwood may become more scarce due to a combination of population growth and climate change. The projected deficit of demand over supply could be most critical in tropical Africa (see Chapters 1 and 15).

The growth of annual and perennial plants is likely to increase with CO_2 enrichment and higher temperatures. Forested areas may expand northward, increasing resources in industrialized countries. Biomass resources are expected to increase in Italy (Bindi *et al.*, 1994), for instance, but this depends on the precise nature of any climate change as well as on the crop and the crop system used (see Chapters 1 and 13). Except in regions with reduced rainfall, future biomass supply in industrialized countries is likely to exceed the present demand. As discussed in Chapter 19, more intense biomass production to substitute for fossil fuels may become an important mitigation option in countries with good rainfall regimes. This would also be the case in Latin America and tropical Africa.

Biomass can be converted to methane gas through anaerobic conversion in digestors. The rate of methane production increases at high temperatures and may be interrupted in winter, for example, in North China (Rajabapiah *et al.*, 1993). Global warming may therefore lengthen periods during which high yields can be obtained and extend the areas in which biogas can be produced without heating the digestor, for example, in households.

11.6.2.2. Impacts of Climate Change on Industrial Biomass

The impact of climate change on the availability of agricultural wastes for electricity production and cogeneration will be similar to the impact of climate change on the supply of food and agricultural raw materials. Industries and biofuel production dependent on brought-in supplies of annual biomass crops

are more vulnerable. Raw material is more costly to transport than is food.

Large fluctuations in the yield of biomass energy systems could have greater impacts on system reliability and costs than might be estimated by extrapolating experience gained from food crops (Hillman and Petrich, 1994). In 1993, ethanol production from sugar cane in Zimbabwe stopped completely due to an extreme drought. The impact of extreme events on industries dependent on wood biomass are likely to be less dramatic.

11.6.2.3. Adaptation to Gradual Change

In general, decreasing rainfall will lower biomass production, particularly in the low latitude countries. Changes in rainfall intensity and evapo-transpiration will also be relevant. In some tropical and semi-arid countries, adaptation may become necessary before climate change becomes perceptible because of population growth and deforestation around cities. Adaptation could take the form of either switching to new fuels or more efficient production and conversion of biomass.

As forests become more scarce, increasing amounts of fuelwood may be derived from trees planted on private land. Countries that face fuelwood or charcoal shortages and cannot afford or do not want to switch to imported fossil fuels could develop small-scale projects to test the feasibility of new biomass conversion and production techniques. Adaptation will be especially necessary in areas with low land availability or low growth potential—for example, arid and semi-arid regions. Biofuel supply from trees, shrubs, grass, or crop residues can be increased or maintained by the following means:

- Better management of natural resources by giving local populations a stake in sustainably grown forests (Bertrand, 1993)
- Planting more trees on agricultural land and establishing better prices for biofuels derived from these plantations to provide rural incomes and incentives to grow more biomass
- Carrying out research to identify higher yielding species, preferably trees and shrubs, that are easy to propagate and are better adapted to extreme conditions like droughts and acidic or saline soils (Riedacker *et al.*, 1994)
- Increasing the productivity of agricultural land.

More details about these measures are provided in Chapters 1, 13, 15, and 25. There are many technologies that can contribute to the improved conversion of biomass (Antal and Richard, 1991; Mezerette and Girard, 1990).

11.6.2.4. Adaptation to Extreme Events

Energy systems based on a mixture of biofuels and fossil fuels are likely to be less vulnerable to climate change than systems based on a single biofuel. Options that reduce vulnerability include injecting gas derived from biomass into natural gas networks, gasohol (a mixture of gasoline and ethanol), or methanol, which can be derived from biomass, natural gas, or coal. Electricity generation plants that can use either perennial or annual crops also will be less vulnerable (Larson, 1993).

11.6.3. Renewable Energy

As discussed in Chapter 19, the accelerated development of renewable energy systems—for example, solar energy and wind—could help to mitigate emissions of greenhouse gases. Mitigation strategies are likely to have the largest impact on the development of renewable energy, but climate change could modify the potential to some degree:

- By increasing or decreasing the flow of the renewable energy resource being used (e.g., hydroelectric potential)
- By affecting the technology used to collect or convert the resource into a useful form, generally in ways that increase system costs or reduce performance (e.g., if high winds damage photovoltaic installations)
- By affecting willingness to develop renewable energy systems, if climate change places stress on ecosystems or reduces the value of the resource.

Renewable energy systems tend to be developed first at locations that have the best resources and that can be developed to yield useful energy at the lowest cost. Climate change might, at favorable locations, increase the availability of some renewable resources. Others, such as solar radiation, are affected only by changes in cloudiness. Developers of renewable energy systems tend to match equipment carefully to the characteristics of the site, taking account of factors such as the flow of the renewable resource. This both increases the amount of the resource used and reduces the delivered cost of energy. A change in climate can reduce the quality of the match between installed technology and a site's resources, thereby increasing cost, wasting resources, or reducing performance. Hillsman and Petrich (1994) provide a comprehensive review of the possible impacts of climate change on renewable energy systems. Any negative effects of climate change on the operation and cost of renewable energy systems need to be set against positive benefits arising from their role in GHG mitigation strategies.

11.6.3.1. Impacts on Resources

11.6.3.1.1. Hydroelectricity

Hydroelectricity is currently the most exploited renewable energy resource around the world. The principal pathways through which climate could affect hydroelectric resources are through a change in precipitation or the conditions (temperature, insolation, wind, humidity) that affect evaporation from reservoirs. Precipitation can change in quantity, seasonality, and form (for example, snowfall versus rainfall). The percentage of a basin's

supply lost to evaporation from reservoirs or lakes depends not only on how much of the basin they cover but also on temperature, wind, and humidity, as well as vegetation cover and the location of a basin's reservoirs in relation to precipitation sources (Cohen, 1987a, 1987b). In an arid region, a change in temperature alone might have less effect on evaporation than it would in a more humid one. All else being equal, reductions in precipitation should also tend to reduce humidity and therefore increase evaporation. An increase in transpiration from vegetation can also reduce the net supply of water to a basin.

An analysis of hydroelectric generating potential in the James Bay region of Quebec under two climate scenarios estimated that an increase in precipitation would outweigh an increase in evaporation, and that generation could increase 6.7–20% (Singh, 1987). Possible responses to decreased production include reliance on other generating sources or the use of demand-side management (*Energy, Economics and Climate Change*, 1992).

Fitzharris and Garr (1995) conclude that changes in precipitation patterns resulting from climate change could result in increased hydroelectric production in the South Island of New Zealand, arising at more useful times of the year. Lettenmaier *et al*. (1992) estimate that a 2–4°C warming in Northern California would reduce snow accumulation and shift peak runoff from spring to winter. This would result in a closer match between runoff and peak power demand in the region, but, on the other hand, water supply would become less reliable. More efficient reservoir management alone could not mitigate the additional risk of floods, and additional reservoir storage for flood flow would be needed (Lettenmaier and Sheer, 1991). Such a response might increase the potential for hydroelectric production during floods but affect the availability of the reservoir system to meet other demands, such as those for irrigation. Where water storage is dominated by snowmelt rather than by reservoirs, river basins are likely to be more sensitive to temperature shifts than to hydrological changes (Lettenmaier and Sheer, 1991).

11.6.3.1.2. Wind

Wind energy depends in part on the temperature gradient from low latitudes to high (Grubb and Meyer, 1993). Estimates of potential climate change based on general circulation models have suggested that the high latitudes should warm relatively more than the tropics (IPCC, 1990a). By itself this would reduce the temperature gradient and global wind resources. The wind resource at some sites, however—such as Altamont Pass in California—is determined largely by a combination of local topography and location, so that the resource there might display less direct sensitivity to changes in global circulation patterns. For existing wind installations, a change in the direction of the prevailing wind also could have a significant effect, depending on the orientation of the array.

Established wind energy systems are potentially vulnerable to changes in the local wind regime because wind energy flux varies with the cube of wind velocity (Cavallo *et al*., 1993). Windspeeds above average contribute disproportionately to wind generator output. A changed frequency of higher windspeeds would have the greatest impact on output. Baker *et al*. (1990) analyzed long-term wind records at good but undeveloped wind sites and estimated that a 10% change in wind speeds could change wind energy yields by 13–25%, depending on the site and season. In general, if climate change manifests itself as greater variability in wind speeds, then wind energy production will tend to magnify this variability. An increase in wind resources would cause a disproportionately large increase in energy capture, while a decrease would cause a disproportionately large decrease.

Air density decreases with increasing temperature (Cavallo *et al*., 1993), but an average increase of several degrees at a developed site should reduce output by at most 1–2%. In the high latitudes, where global warming might be more pronounced, air density and hence output could decrease to a greater extent (IPCC, 1990a).

11.6.3.1.3. Other renewable energy sources

Solar thermal and photovoltaic (PV) energy systems are dependent on local conditions (Radesovich and Skinrood, 1989; De Laquil *et al*., 1993). Systems that concentrate sunlight, using either mirrors to reflect it or lenses to refract it, require direct sunlight. Increases in humidity, haze, or cloudiness reduce the effectiveness of concentrating systems (Kelly, 1993). Global climate change may alter cloud regimes, leading, possibly, to more clouds and less direct solar radiation (Enquête Kommission, 1991). Cloudiness has recently increased over Europe, North America, India, and Australia as a whole (IPCC, 1990a) but has decreased in Southern Australia and in the Sahel (CSIRO, 1992b).

Flat-plate PV systems utilize both direct sunlight and diffuse light scattered by clouds or humidity. Electricity from a flat-plate system in a region with relatively poor conditions might be 40% lower than that from an identical system in a region with excellent conditions (Zweibel and Barnett, 1993). This range is probably much greater than the difference produced by a gradual change in climate. Photovoltaic cells lose about 0.5% of their efficiency per °C above their rated temperature (Kelly, 1993).

Ocean energy systems comprise a variety of technologies, including tidal barrages, wave energy systems, and ocean thermal energy conversion (OTEC). There are few plans to develop ocean energy systems, though their use might grow in the longer term. It would be essential to take account of projected sea-level rise over the very long design life of tidal barrages (UK Climate Change Impacts Review Group, 1991). Wave energy resources at any particular site depend on global wind patterns to generate waves, nearshore winds that affect wave size, and nearshore seabed conditions that affect the refraction and reflection of waves (Cavanagh *et al*., 1993).

Geothermal resources may be affected by a change in precipitation patterns where the steam resource depends on an aquifer recharged by surface water or precipitation. An assessment of the potential effects of climate change in New Zealand (Mundy, 1990) suggests that increased rainfall could increase the recharge of groundwater for most geothermal fields.

11.6.3.2. Impacts on the Value of Resources

Several renewable energy resources, especially PV systems, often have high value because they are dependable when demand for energy is highest. Some changes in climate could shift demand peaks or change energy yields, thus altering the value of affected systems.

The use of some renewable energy resources must be balanced against other potential uses. For example, in hydroelectric systems, energy production may compete with demands for water to provide wildlife habitat, irrigate crops, maintain navigation, and support recreation. In coastal ocean energy systems, energy production may compete with demands to protect wildlife habitat or support recreation. Climate change could lead the public to place greater value on the nonenergy uses of these resources, leading to a decline in energy production.

11.6.3.3. Impacts on Performance

Climate change could affect renewable energy technologies by changing the performance and the degree of damage incurred during extreme weather events. Adapting to these impacts could alter operation and maintenance costs. The economic impacts, however, are likely to be much lower than those deriving from climate mitigation policies designed to promote renewable energy. The main climate impacts are:

- For hydroelectric systems, precipitation patterns and climatic impacts on vegetation of the watershed could affect rates of siltation and reservoir storage capacity.
- Dust, insects, or ice can reduce wind energy production by about 8% (Lynette, 1989; Lynette and Associates, 1992). Light rainfall may clean the blades and increase energy yields by up to 3%, but heavy rain can reduce energy output by increasing turbulence (Baker *et al.*, 1990).
- Severe weather (tornadoes, hurricanes, snow, and ice) can damage wind machines (Jensen and Van Hulle, 1991), though the use of variable-speed wind turbines shows great promise for reducing this source of vulnerability (Lamarre, 1992).
- Soiling of the reflective surfaces of heliostats through dust can reduce energy capture by solar thermal systems by up to 8% when there is little rainfall (Radesovich and Skinrood, 1989). Efforts to reduce system costs have led to the development of larger heliostats that are more susceptible to wind damage.
- Soiling also affects PV systems (Goossens *et al.*, 1993). Moisture from storms or dew, lightning strikes, overheating, and voltage surges from cloud-induced transients can cause damage to electronic components (Conover, 1989; Kelly, 1993; Boes and Luque, 1993; Smith, 1989). An increase in peak windspeed or in the frequency or severity of storms would require the structures necessary to support PV collectors to be strengthened (Kelly, 1993).
- Ocean energy systems would be susceptible to storm damage (Cavanagh *et al.*, 1993).

11.7. Need for Future Assessments

Many elements of the industry-transportation-energy system are sensitive to extremes of climate rather than average conditions. The impacts of many variables also are specific to geographical regions. If work on the potential impact of climate change on the industry, energy, and transportation sectors is to develop beyond a simple identification of sensitivities, then it will be necessary to generate climate scenarios that cover a wider range of climate variables, including extreme events, and refer to changes at the regional as well as global levels. The capacity to produce such scenarios does not yet exist. Several types of climate impact in the industry, energy, and transportation sectors appear to merit further research.

Developing Country Studies

A number of comprehensive studies of the impacts of climate change on developed countries have been published. Extending this type of work to cover a wider range of developing countries, which are likely to be more sensitive to climate, should have a high priority. Agroindustries merit special attention, given the dependence of many developing countries on agriculture and derivative sectors. Very few studies have been conducted that trace the indirect effects of changes in agricultural activity on associated agroindustries. With a few exceptions, only casual inferences have been drawn concerning the secondary impacts of agricultural productivity on industrial output and employment. This problem can be addressed through economic models that characterize the relationships between agriculture and industrial activity. The linkages between marine ecosystems, fisheries, and fish-processing industries similarly need to be assessed.

Studies at the System Level

Much of the climate sensitivity exhibited by the industries examined in this chapter arises not because of the direct impacts of climate on an activity but because of interdependence *between* activities through either climate-sensitive markets or the use of raw materials and resources that are themselves climate sensitive. Studies that increase understanding of these interdependencies and the indirect consequences of climate change throughout the economic system are an essential complement to studies that focus on specific sectors and activities.

Energy Demand

There is a need for studies that assess the impacts of climate change on energy demand and the impact of GHG mitigation measures within a unified framework. The adoption of mitigation measures such as energy efficiency, renewable energy, or biomass production may influence the vulnerability of the energy system to climate change while, at the same time, the direct impacts of climate change may influence the degree of mitigation action required to attain specific GHG emission objectives. No studies addressing this topic have been identified.

Also, although there have been many studies of the impact of climate on energy demand, there is still considerable uncertainty about the possible links between the adoption of new air-conditioning systems and climate change, particularly in temperate climates where the use of air conditioning is currently marginal.

Transportation

More assessment of impacts on transportation infrastructure and operations is needed. It is especially important to extend studies to developing countries and countries with economies in transition. Issues other than submergence as a result of sea-level rise should be considered. The impacts of temperature, precipitation, and extreme events on both infrastructure and operations should be included.

Transportation issues should be addressed within the wider framework of changes in human settlement patterns. The question of the impacts of climate change on regional transportation systems via the redistribution of population and economic activities has been neglected. There is a need to develop and refine an assessment methodology by adapting existing transportation models. Eventually, such models would be employed to evaluate scenarios of regional growth derived from climate change impact studies of migration, agriculture, industry, and other sectors to determine changes in transportation demand and impacts on transportation networks.

Adaptation

The literature referring to industry, energy, and transportation focuses largely on sensitivities and impacts and is weak on questions of adaptation. There are some areas where research on adaptation could be appropriate. Infrastructure associated with some large-scale renewable energy projects, transportation systems, and buildings has a very long lifetime. It may be necessary to anticipate climate change by assessing how demand for facilities may be affected by climate in the long-term and how climate might influence technical aspects of design. The development of climate guidelines is necessary for the construction and location of coastal structures such as sea-walls, harbors, jetties, piers, and causeways that have long lives (Hameed, 1993). Such guidelines would also assist with the design of new buildings, particularly with respect to their energy use characteristics. Improved monitoring of coastal zones, covering sea level, tidal and wave patterns, weather, marine ecosystems, coral reefs, coastal geomorphology, and sedimentology also is required (Crawford, 1993).

CONTENTS

EXECUTIVE SUMMARY

Climate change will occur against a background of other non-climate environmental factors and socioeconomic factors that could either exacerbate or mitigate the effects of climate change. These other factors may, in many cases, dominate climate change. As compared with the 1990 or 1992 IPCC assessments of impacts, this discussion emphasizes the multiple and interactive pathways by which climate change exacerbates or mitigates the effects of other events that nations may find important. These interactions could occur in unexpected ways, with small changes having disproportionately large outcomes. The major conclusions follow.

Impacts on human settlements from climate change may be indirect, as well as direct. Direct effects of sea-level rise and extreme events are known to be important in coastal zones and island nations. However, many of the impacts on human settlements from climate change are likely to be experienced indirectly through effects on other sectors (for example, changes in water supply, agricultural productivity, and human migration). We have high confidence in the importance of these indirect effects because they depend on well-known mechanisms of social interaction rather than data specific to the climate of the future.

Thresholds beyond which impacts escalate quickly are unique to individual local situations and tend to depend on the degree of adaptive response. For example, the impact of sea-level rise on coastal communities critically depends on the degree to which human lives and assets can be protected, insured, or shifted to new locations that are unthreatened. As discussed in 1990 and 1992, the human settlements most vulnerable to climate change are likely to be in locations already stressed by high rates of population growth, urbanization, and environmental degradation. However, in addition to islands, coastal communities, and communities dependent on marginal rain-fed agriculture or commercial fishing discussed in the previous reports, vulnerable settlements include large primary coastal cities and especially squatter settlements located in flood plains and on steep hillsides. We have medium confidence in this result. The consensus is strong concerning the principle, but the data supporting it apply mainly to analogous circumstances.

Non-climate effects may be more important than climate change. Local environmental and socioeconomic situations are changing rapidly for reasons other than climate change. Worldwide, population growth, industrialization, urbanization, poverty, technological change, and government policy could overwhelm any effects of climate change. We have low confidence in this finding because the result is a matter of some controversy and there is insufficient data on climate-change effects on human settlements relative to those of other disturbances to resolve it.

A significant potential for noncoastal flooding (river basin and local urban flooding) is expected if precipitation intensity increases as a result of climate change. The IPCC Working Group I volume (Chapter 6, *Climate Models–Projections of Future Climate*) states that precipitation intensity may increase and that several models now project increases in higher-rainfall events. If intensity increases, the risk of flooding to settlement infrastructure could be very widely distributed across the planet, not just in coastal zones. One particular problem in providing estimates of damage is specifying the extent of future human intrusion into disaster-prone areas. We have low confidence in this finding because the consensus of climate modelers concerning the effects of climate change on intense rainfall events does not extend to regions and localities and because the degree of adaptation is likely to be important.

Health risks are potentially very large, especially in the informal settlements on the fringes of megacities of the developing world, but the probabilities are difficult to estimate. Current patterns of urbanization, extended into the next century, suggest that the most vulnerable human populations may become even more vulnerable. Economic and environmental refugees may introduce a number of exotic diseases into temperate-zone human settlements. Increased climate variability and associated extreme events can add new breeding sites and new bursts of activity for vector-borne diseases. This finding relies on the best thinking of the community of epidemiologists, but our confidence in the finding varies with the particular disease and location and because necessary supporting environmental data are adequate in some cases and extremely sketchy in others (see also Chapter 18).

Some other important findings are as follows:

- **Migration**—Many of the expected impacts in the developing world will occur because climate change may, by reducing natural resource productivity in rural areas, accelerate rural-to-urban migration, exacerbating already crowded conditions in the cities and further depleting the labor force of the countryside.
- **Water and Biomass**—Global warming can be expected to affect the availability of water resources and biomass, both of which are major energy sources

in many developing countries. Water and biomass resources are already under stress in many of these areas as a result of rising demand. Loss of water and biomass resources may jeopardize energy supply and materials essential for human habitation and energy production.

- **Energy**—Increasing human population and wealth provide a rising energy-demand baseline against which the consequences of changing climate will be played out. Energy demand will be affected by warming, but the direction and strength of the impact will depend on the extent of demands for space heating or cooling and the role of climate-sensitive sources of demand, such as irrigation pumping. Many of the largest increases in baseline demand will occur in developing countries, although not necessarily the largest changes as a result of climate.

- **Adaptation**—Many adaptive mechanisms are available to address each of the potential direct and indirect impacts of climate change on human settlements. The cost and effectiveness of each depend upon local circumstances.

12.1. Introduction

12.1.1. Why Human Settlements

A potentially important way in which climate change could affect human beings is through its effects on human settlements. Settlements, especially cities, have a central role in civilization as the primary generators of human wealth and the engines of social interaction and change. Whether explicitly acknowledged or not, environmentally appropriate economic and social development in settlements is a major goal of national environmental policy throughout the world. According to the United Nations Centre for Human Settlements, a human settlement can be judged on four criteria: (1) the quality of life it offers to its inhabitants; (2) the scale of nonrenewable resource use (including reuse); (3) the scale and nature of the use of renewable resources and the implications of the settlement's demands for sustaining production levels of these resources; and (4) the scale and nature of nonreusable wastes generated by production and consumption activities, the means by which these are disposed of, and the extent to which wastes affect human health, natural systems, and amenity values (Habitat, 1992a). Climate change could affect the sustainability of human settlements either by directly affecting the quality of life in settlements (e.g., by changing the probability of floods or the effects of air-pollution episodes), by modifying the effects of the settlements on their surrounding environments (e.g., by changing the demand for water or changing the assimilation capacity of wetlands), or by changing the economic underpinnings of the settlement (e.g., by changing the productivity of croplands, forests, or fisheries on which the settlement depends).

The 1990 and 1992 IPCC assessments dealt only with the direct effects of climate on human settlements, primarily infrastructure issues. The more subtle effects of human-settlement metabolism may be more important in some instances. Moreover, consideration of the indirect effects of climate change shifts the focus of attention from a narrow and necessarily speculative concern over future impacts on infrastructure to the more general pressing problems of economic and social development. Included in development could be an adaptation policy that includes a variety of adaptive mechanisms.

12.1.2. Guide to the Chapter

This chapter begins with a discussion of the non-climate environmental and socioeconomic factors that are expected to interact with climate change and sea-level rise (see Figure 12-1) in producing effects on human settlements. Some of the non-climate effects (e.g., urbanization or pollution) are likely to be significant enough in many cases to dominate the effects of climate alone but in any case could exacerbate climate effects. The chapter then discusses the possible impacts of climate on various sectors that might be affected (e.g., population, energy demand and supply, infrastructure, and water supplies). Some of these sectors have chapters of their own; however, this chapter emphasizes not only the direct effects of climate on human

settlements but also the relationships between human settlements and these other, more directly affected, sectors. Finally, this chapter discusses adaptive responses to climate change—both those that may be taken autonomously by human settlements in response to climate change and other stresses and those that may be undertaken as a matter of deliberate adaptive policy by governments. Some readers will be disappointed that the chapter contains very few quantitative estimates of impact. This is by design. The very variety of human settlements and complexity of their environmental circumstances assure that almost any impact estimates will be local in scope and that both the absolute and relative importance of the various effects will be different in almost every circumstance. Except for sea-level rise, where some international estimates exist, the few estimates in the literature of the impact of climate change on human-settlement infrastructure and inhabitants are local and regional in scope. No study has yet attempted the difficult aggregation of climate and non-climate effects required for a proper analysis. Thus, the quantitative estimates provided in the chapter should be regarded as illustrative and anecdotal in nature.

12.2. Non-Climate Factors

A major difficulty in determining the impact of climate change on human habitat is the fact that many other factors, largely independent of climate change, are also important. In many cases, these other factors are far more important than climate change in terms of the risk they pose for human settlements. These non-climate factors will also increase the vulnerability of some regions to climate change. The most important of these factors include population growth, urbanization and industrialization, technology choices, and government policies. Other social factors, such as cultural clashes and warfare, also play a role. Vulnerability of settlements has to be judged on the basis of the susceptibility of the settlement's resources to damage via climate change, conditioned by the resilience of the resources and the technical, institutional, economic, and cultural capabilities of the settlement to cope with or manage the change
