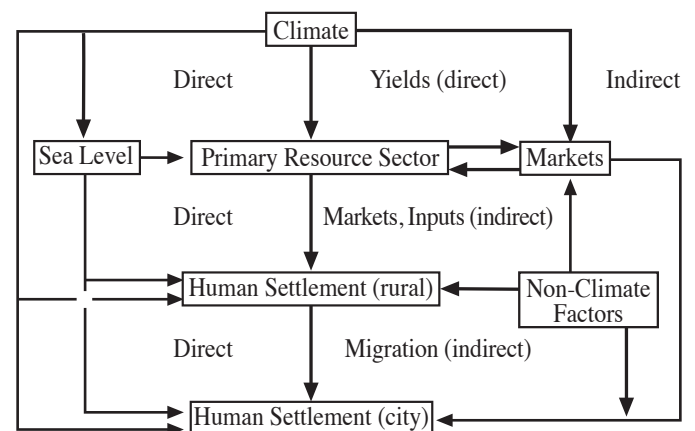

Figure 12-1: Relationship between direct and indirect effects of climate change, sea-level change, and non-climate factors on resource sectors, rural human settlements, and cities.

(IPCC CZMS, 1992; Turner *et al*., 1994). One can reliably predict that certain developing countries will be extremely vulnerable to climate changes because they are both susceptible to the change and already at the limits of their capacity to cope with climatic events. These include populations in low-lying coastal regions and islands, subsistence farmers, populations in semi-arid grasslands, and the urban poor.

12.2.1. Economic and Social Development

12.2.1.1. Population Growth

The population of the world is estimated at about 5.3 billion. At its peak in the late 1960s and early 1970s, the average annual rate of increase in the world's population was close to 2%. Projections suggest that this rate of increase will fall to less than 1% by the second decade of the 21st century. However, the rate of abatement in the growth rate is expected to vary sharply from region to region. For example, whereas the world's population as a whole is expected to grow at 1.3% per year on average between 2000 and 2025, population is expected to grow at 2.1% in low-income countries but at only 0.2% in the Organization for Economic Cooperation and Development (OECD) countries (World Bank, 1991). Further, the differences in birth rates between rural and urban areas have widened, according to the United Nations World Fertility Survey (1986). Regions already struggling to cope with exploding populations can be expected to be exceptionally vulnerable to climate change.

12.2.1.2. Industrialization and Urban Growth

Since 1950, the number of people living in cities has tripled, increasing by more than 1.25 billion (World Commission on Environment and Development, 1987). By 1980, nearly one in three persons was an urban dweller, and one in ten lived in a city with a million or more inhabitants (a "million city"). By 1990, an estimated 42.65% of the world's people were urban residents. It has been estimated that by 2025 60% of the world's people will be living in towns and cities. In many countries, the fastest-growing areas are in coastal regions and estuaries, many of which are vulnerable to extreme events and sea-level rise (Marco and Cayuela, 1992). Already, two-thirds of the world population lives within 60 km of the coast; this is expected to rise to 75% by the year 2010 (WCC'93, 1994). The developed world has heavily concentrated its people in coastal areas (Friedman, 1984; Handmer, 1989; Marco, 1992; Boissonade and Davy, 1993; Lester, 1993; Skinner *et al*., 1993; WCC'93, 1994).

Urbanization has been growing much faster and creating higher urban densities in developing countries than in developed countries (Berry, 1990). Although significant differences exist between countries, in developing countries as a group the urban population is growing much faster than in the industrialized countries. In the developing countries, the urban population is growing by an average of 3.6% per year compared to only 0.8% in the industrialized countries, which are believed to have essentially completed their urbanization process and in some cases are de-urbanizing. The uncontrolled expansion of towns and cities in the developing countries has led to overwhelmed transport, communications, water-supply, sanitation, and energy systems. Urban sprawl preempts other land uses near these towns and cities. Between 1980 and 2000, urban areas in developing countries are expected to grow from about 8 million hectares to more than 17 million hectares. The development policy in most developing countries after World War II favored modernization biased toward the urban-industrial sector, especially manufacturing targeted to satisfy domestic demand. In Latin America, for example, "import-substitution industrialization" registered an unprecedented success between 1950 and 1970; the regional gross domestic product (GDP) grew at an annual average rate of 5%. However, rural public investment was neglected, and the rural labor force was economically marginalized. Excess rural labor migrated to urban unemployment and informal activities (PNUMA/MOPU/AECI, 1989, Part III). Some analyses emphasize the attraction of cities ("pull factor") in the rural exodus, while others point out the aggravation of high rural population growth and the expelling process in rural areas ("push factor"). The latter definitely played a fundamental role in migration. In the last decades, rural life conditions have experienced continuous deterioration in relative and absolute terms, and large sectors of peasants have been excluded from the modernization process (Armstrong and McGee, 1985, Chapters 4 and 5), leaving them more vulnerable to climate variability. Growing scales of urban metabolism (urban demands for natural resources and the increase in the inflow and outflow of materials, products, energy, water, people, and wastes) add to pressures on the environment and could exacerbate the effects of climate change. Particularly salient has been the rapid growth of motorized transportation in urban areas.

12.2.1.3. Poverty

In the 1980s, many developing countries not only failed to keep pace with the industrial countries but saw their incomes fall. The living standards of millions in Latin America are now lower than in the early 1970s; in most of sub-Saharan Africa, living standards have fallen to levels last seen in the 1960s. According to some estimates, the percentage of the world's population living in absolute poverty decreased, at least up to the middle of the 1980s, but the absolute number of poor has increased (United Nations, 1989; Gilbert, 1992). It was estimated that in 1985 1.115 billion people lived in poverty in the developing world. That is approximately one-third of the total population of the developing world. Of these, 630 million were extremely poor (World Bank, 1990). Nearly half of the developing world's poor, and nearly half of those in extreme poverty, live in South Asia, followed in order by sub-Saharan Africa, the Middle East and North Africa, Latin America, the Caribbean, and East Asia (World Bank, 1990). What is particularly relevant for environmental management purposes is that poverty has "urbanized": The number of poor in the world increased 11% from 1970 to

1985, but the number of urban poor expanded 73% worldwide and up to 81% in Africa. Poverty compounds the effects of inadequate drinking water, poor sanitation, and housing in crowded buildings constructed in flood-prone areas and other dangerous circumstances (Habitat, 1992b). In addition, it restricts the ability of communities to invest in practices and technologies that may be more environmentally appropriate. In some cases, poverty restricts access to education and information about better practices that are available. Although extremely serious in themselves, all of these factors are likely to compound any negative impacts of climate change.

12.2.2. Technology

12.2.2.1. Infrastructure

The choices that people make concerning which technology is used to provide a given service may have a dramatic impact on the degree to which a given change in climate will affect human settlements. For example, periodic additions of mechanization in North American agriculture during the last century (e.g, tractors, self-propelled harvesters, center-pivot irrigation) have significantly reduced the number of people engaged in agriculture and the accompanying requirements for their economic and social support services. As a consequence, there are now fewer settlements dependent on agriculture or likely to be directly affected by drought, flood, or other weather incidents. Previous choices of technology may also considerably restrict the options available for adaptation. For example, the ordinary operating life of commercial buildings in the United States is about 80 to 90 years (Pierce, 1994), whereas the life of water-supply systems is around 50 years (Internal Revenue Service, 1994). It follows that climate changes occurring in the first half of the 21st century would affect energy and water-supply systems that will mostly look like today's. The viability of entire transportation systems—for example, the bias that exists toward automobiles in many human settlements throughout the world—is influenced strongly by past technological choices and spatial patterns of settlement that grew up around these choices. This, in turn, has significantly influenced the long-term livability and viability of these settlements.

Standard engineering practice calls for safety standards of drains, culverts, bridges, dikes, and dams. Based on historical data, these are built to withstand 25-year, 50-year, 100-year, or 400-year floods. If rainfall intensity increases with climate change (Pittock, 1994), these structures either would have to be built to a higher standard or a greater probability of damage accepted. A structure strong enough to withstand a 25-year flood in the future might have to be strong enough to withstand a flood now considered to be a 100-year event. Today's structures would have a higher risk of failure. Lowering this risk would require investments that compete for very limited discretionary dollars, especially in many developing countries.

There is a huge unsatisfied demand for shelter in developing countries. Indeed, construction of living space is among the

more energy-intensive activities in some countries, contributing 17% of India's annual carbon dioxide emissions, for example (Tiwari and Parikh, 1993). In addition, in developed countries, existing buildings contribute a large portion of the primary fuel use and greenhouse gas (GHG) emissions. In the United Kingdom and Western Europe, the percentage may be some 50% (Courtenay, 1992). If mitigation of climate change requires large increases in energy costs, the impacts on this sector and on human settlements could be significant.

12.2.2.2. Environmental Management

The manner in which human settlements dispose of their waste, and even the degree to which they declare certain physical outputs of production and consumption processes to be "waste," reflects a series of social choices. The consequences of those choices on the environment varies widely and may be affected by climate change.

For example, the most common method for disposing of solid waste is land disposal, either sanitary landfill or simply disposing of the waste on unused land. Leakage and runoff from landfills and wastes released to surface waters adversely affect the quality of ground and surface waters. In some cases, an incinerator is used to reduce the volume of the organic component (Habitat, 1992a). To reduce the burden on landfills, resource recovery by one of several strategies can be pursued and may be more likely in less-wealthy settlements (Habitat, 1992a). However, if settlements are poor, less-safe technologies may be used for disposal. If climate changes, the assimilative capacity of airsheds may be reduced because of increased prevalence of stagnant-air episodes, while sea-level rise and potential flooding could restrict the availability of land for safe disposal of solid waste. At the same time, demand for disposal areas continues to rise.

12.2.3. Policy

12.2.3.1. Land and Development Policies

The rights and conditions under which land is held (land-tenure systems) can strongly affect the management of this resource and either promote or discourage adaptation to environmental conditions of all kinds. Settlement history has a great deal to say about this, and land-tenure systems can result in mismatches between population and productive land. Some traditional land-tenure systems have adapted to unique climate or cultural systems and have significant survival value (Oguntoyinbo, 1991). For example, in some West African land-tenure systems, tenure goes with the crop, not the land. This system encouraged the growing of perennial crops, such as trees. Subsequent conversion to a fee simple absolute system (ordinary private ownership) encouraged the planting of commercial row crops, the opposite of the intended result (Rayner and Richards, 1994). Communally managed commercial livestock-grazing schemes appear to have worked better in Africa than fenced-ranching

schemes, in that they permit freer adjustment to spatial variability in rainfall (Thompson and Wilson, 1994). In Mexico, *ejido* usufruct land-tenure systems (now undergoing privatization) have been used, in part, to combat the consequences of variability in rainfall (Thompson and Wilson, 1994) but have been more vulnerable to routine drought and generally show chronic low yields in comparison with private lands that are generally in more favorable locations and can attract higher investments in seed, fertilizer, and water supply (Liverman, 1992). This situation has encouraged rural-to-urban migration. In Nepal, forests were historically managed locally by the community. When the state forest-management system was established, both land tenure and management passed to Kathmandu, and deforestation resulted. A mixed system of state ownership and local control seems to have improved forest management (Thompson, Warburton, and Hatley, 1986). In all cases, local knowledge has proved important.

Some land uses can themselves increase flood hazard by lowering the ground level through drainage (Tooley, 1992) and water extraction (Hadfield, 1994). Deforestation exacerbates runoff, and dams prevent the accumulation of silt on river deltas (Clark, 1991; Kreimer and Munasinghe, 1991). Local flooding can be made worse if much of the settlement's surface area is paved (Berry, 1990; Henri, 1991; Marco and Cayuela, 1992), even in years of great drought (Handmer, 1989).

Government actions (such as zoning practices in flood plains to limit settlement) can reduce adverse interactions between development and climate. However, governments may lack the governance capacity or will to adequately regulate land uses and respond to hazards (Beatley, 1994) or may face sometimes-irreconcilable duties to make settlements both affordable and safe. This quandary manifests itself in floodplains in the conflict over making flood insurance affordable and available without, at the same time, encouraging settlement in areas that have to be defended at great cost (Arnell, 1983; Henri, 1991; Murray, 1991; Denlea, 1994). In addition, government infrastructure investments and other actions can themselves create unfavorable environmental outcomes. In Mexico, Australia, and India, for example, government investment in irrigation has sometimes resulted in high soil salinity and difficulties for the farm communities (Liverman, 1992; Leichenko and Westcoat, 1993). Water-management projects established to cope with frequent drought or flooding have also created poorly assimilated refugee populations. For example, the creation of Lake Kariba, between Zambia and Zaire, has marginalized the Tonga people (Magadza, 1991). Numerous other examples are cited by Gleick (1992). Many of the adverse environmental consequences of urban slums occur because residents lack clear legal tenure and because of the lack of land-use controls.

Most fundamental environmental problems of settlements themselves cannot be tackled unless city governments have the capacity (power, resources, and technical expertise) to intervene in the urban land market. While land-use planning and controls can be problematic everywhere, in many developing countries in particular this lack of capacity, lack of land-use controls, and lack of legal alternatives to unauthorized settlements creates a haphazard,

sprawling pattern and density of development that will not allow cost-effective infrastructure and service provision. It also promotes illegal housing on dangerous land sites, sprawl over prime agricultural land, and degradation of the natural landscape (Hardoy and Satterthwaite, 1984; Gilbert, 1992). Even when planning norms exist, they may be weak or unconnected with the way in which land is actually appropriated. In some big urban settlements like Mexico City, planning did not have stipulations to regulate the land market, nor was it associated with concrete programs for addressing priority needs and problems, such as housing and services (Aguilar, 1987; Aguilar and Olivera, 1991).

12.2.3.2. Migrant and Refugee Populations

Conflict between groups in society can exacerbate the effects of climate, creating refugee problems of major dimensions. Such conflict has occurred on the Horn of Africa for 20 years, where successive civil wars in Ethiopia, Eritrea, Somalia, and Sudan have repeatedly disrupted both agriculture and food-delivery systems. Human settlements in many rural areas have been abandoned, and thousands have succumbed to famine and disease (Tolba *et al.*, 1992). Adverse climate conditions may compound the plight of refugees (Newland, 1994).

As land and water resources bear increased population and development burdens, disputes over resource use become increasingly acute and may themselves become a source of conflict. For example, in northwest Mexico, the water rights in the Cucurpe area have sometimes become a cause for violence (Liverman, 1992). In the Middle East, Jordan, Israel, and Syria have had great difficulty resolving issues over the distribution of both groundwater and surface waters of the Jordan River Valley (Lowi, 1992; Suhrke, 1993), which contributes to the political instability of that region. Environmental degradation has been a major source of internal social and economic conflict and migration within China (Smil, 1992). Similar (though less extreme) difficulties have attended the distribution of Colorado River water in North America (Glantz, 1988) and Euphrates River water among Turkey, Syria, and Iraq (Gleick, 1992).

In some cases, climate-related environmental disaster has created significant refugee populations, while in other cases the management of resources to prevent disaster has created the problem. These refugee populations are often either socially marginalized or become a source of conflict (Suhrke, 1993). For example, repeated flooding in Bangladesh has resulted in migration of thousands of Bangladeshis to India, where ethnic conflict has resulted (Homer-Dixon *et al.*, 1993; Hazarika, 1993).

12.3. Impacts and Ranges of Sensitivities to Climate Change

12.3.1. Population Migration

If future climates resemble those projected by the general circulation models, wetter coasts, drier mid-continent areas, and

sea-level rise may cause the gravest effects of climate change through sudden human migration, as millions are displaced by shoreline erosions, river and coastal flooding, or severe drought (e.g., Xia Guang, 1991). In the developing world, many areas to which people might relocate are likely to have insufficient support services to accommodate the new arrivals. Other consequences can include ethnic tensions and regional overpopulation.

Less dramatically, long-term problems with land fertility arising from the interaction between climate and social and agricultural practices produce rural–rural and rural–urban migration. It is known, for example, that a large number of the rural–rural migrants in Nigeria originate in the very densely populated areas where soils are impoverished and have also been destroyed by erosion (Udo *et al.*, 1990). Other things being equal, more-intense rainfall accompanying climate change could accelerate these soil-erosion and leaching processes.

Where social safety nets do not intervene and where land uses and techniques are inappropriate, mid-continental droughts have contributed to similar migrations in developed countries (Riebsame, 1990).

In much of the developing world, perhaps 90% of the migrants do not have the special skills that would attract a salary high enough to enable them to live in a better-designed and built urban settlement. Consequently, they end up living in informal peri-urban settlements with some serious infrastructure problems, ranging from unhealthy environment and water supply to difficult access to energy, transportation, communications, and shelter. About one-third of the population in many developing-world cities lives in these informal settlements. Some can be enormous. Ciudad Netzahualcoyotl, the large informal settlement of the 1970s (now a more regular, permanent city) in the Valley of Mexico had more than 1.2 million inhabitants in 1990, according to the Population Census. A newer informal settlement that mainly developed during the 1980s is Valle de Chalco, with an approximate population at the beginning of the 1990s of 400,000 inhabitants (Aguilar and Olivera, 1991; Hiernaux, 1991).

12.3.2. Energy

Generally, studies have shown differing location-specific overall aggregate energy impacts, depending on how much energy use is related to residential and office heating and cooling. Climate warming will increase energy consumption for air conditioning and, conversely, lower it for heating. This result was discussed in the 1990 and 1992 assessments for developed countries. This section confirms those earlier findings and adds some insights on the developing and newly industrialized countries. Because agriculture, transportation, and industry all have been allocated their own sections in this report and because Chapter 22 provides considerable background on fuel use in residential and commercial buildings, this section primarily focuses on energy demand in the residential and commercial sectors as influenced by climate change. Change can

be expected in climate-sensitive sources of energy such as hydroelectric power, biomass, solar, and wind. Those resources are discussed in much greater detail in Chapter 11.

12.3.2.1. Demand

Space conditioning of buildings is one of the most climate-sensitive uses of energy—especially the use of electricity for residential and commercial air conditioning, and electricity plus other fuels for space heating. Although usually smaller in total magnitude of energy demand, the use of electricity and fuels for irrigation pumping and the use of fuels for drying of agricultural crops also can be significant weather-sensitive demands in some regions (Scott *et al.*, 1993; Darmstadter, 1993). Climate change has negligible direct effect on vehicle performance, but transportation activities are sensitive to immediate impacts from weather and may be indirectly sensitive to gradual shifts in human activities as they respond to climate change and to greenhouse and environmental strategies. For example, if warming should accelerate urbanization tendencies caused by adverse effects on the rural resource base, additional urban congestion could reduce vehicle performance in cities. This performance decline provides incentives for transportation modal shifts (to public transit, for example).

Changes in population, wealth and activities of the population, energy prices, cost and characteristics of technologies used, and daily and seasonal operational patterns for these technologies help drive urban energy demand. For example, discrete zoning of residential and commercial areas may cause higher levels of transportation use (Matsuoka *et al.*, 1992). D.W. Jones (1991) found that urbanization was an important determinant of energy demand, though less important than per capita income and industrialization. Mechanization of food delivery and journey to work are major factors. Because the effects of climate change appear to be small in comparison with potential changes caused by these other factors, adjustments can be made to accommodate climate change at small to moderate cost (Linder and Inglis, 1989). A special consideration in considering the effects of urbanization on energy use is the urban "heat island" effect, in which the replacement of vegetative ground cover in urban settlements with structures, streets, and similar surfaces causes outdoor temperatures within these settlements to be several degrees higher than they otherwise would be (Boodhoo, 1991). Energy consumed for air conditioning may increase heat-island effects (Hanaki, 1993). Heat-island effects and actions to reduce them are further discussed in Chapter 22 in the context of the extra energy that must be expended in buildings to counteract heat-island effects.

The sensitivity of space-heating and air-conditioning demand to climate may be estimated in two ways: (1) by using statistical relationships between demand and climate variables of the type routinely used by energy suppliers in carrying out short-run demand forecasting (an analog approach) and (2) by using underlying physical parameters, such as heating or cooling degree-days, to make estimates based on the physical

characteristics of buildings (UK Climate Change Impacts Review Group, 1991). In general, the analogue approach results in a lower estimate of climate sensitivity because it takes account of the fact that building occupants may, through autonomous adaptation, adjust their comfort levels. On the other hand, the analogue approach does not take account of some forms of long-term adaptation, notably the modification of building design and space-heating or air-conditioning systems to take account of changed climate conditions (UK Climate Change Impacts Review Group, 1991). In temperate-zone developed countries, investigators have observed that the net balance of energy demand depends largely on the balance between cooling and heating in the residential and commercial sectors (Linder *et al.*, 1987; Scott *et al.*, 1993; Rosenthal, Gruenspecht, and Mann, 1995). In the commercial sector, air conditioning accounts for a greater proportion of final energy demand, partly because of internal heat gains from lighting, office equipment, and occupants. Generally, in cool areas with limited air conditioning, space-heating fuel use and electricity demand for heating (and, sometimes, total electricity demand) would likely decline (Stokoe *et al.*, 1987; Singh, 1988; Mundy, 1990; Aittoniemi, 1991a, 1991b; UK Climate Change Impacts Review Group, 1991; Scott *et al.*, 1993). Where cooling is already more important than heating or may become more important, the increase in cooling demand will be greater than the decrease in heating demand (Loveland and Brown, 1990).

In developed countries, increases in commercial building space, space conditioning, and office automation drive much of the overall increase in energy demand and an increase in electricity's share (Nishinomiya and Kato, 1989; Herring *et al.*, 1988), while energy-efficiency codes and varieties of green labeling have reduced energy demand. In some cases, climate warming can be expected to further increase both peak and total annual electric power consumption (Linder *et al.*, 1987; Linder and Inglis, 1989; Niemeyer *et al.*, 1991; Nishinomiya and Nishimura, 1993). However, primary energy demand can still either fall (Nishinomiya and Nishimura, 1993) or rise (UK Climate Change Impacts Review Group, 1991), depending on local conditions.

The relationship between cooling energy and temperature appears to be nonlinear because of latent heat of water condensed by active system cooling equipment and lost efficiency of passive and natural ventilation at high temperatures (Millbank, 1989; Hulme, Haves, and Boardman, 1992; Scott, Hadley, and Wrench, 1994). Huang *et al.* (1987) showed better cooling correlations using degree-hours, latent enthalpy hours, latent cooling loads, and adjustments for natural ventilation. In more recent unpublished work, Huang has shown that a uniform 1.7°C increase in temperature causes about a 12% to 20% increase in cooling loads in cities in newly industrialized or developing countries with hot climates. In cities with cooler climates (e.g., Mexico City, Sao Paulo, Beijing), the estimated increases in cooling loads are larger in relative terms but smaller in absolute terms. Cities in warmer climates may experience large relative decreases in their very small heating loads of 50% or more, virtually eliminating the requirement to heat.

Research in developing countries has shown that appliance use in general (OTA, 1991; Figueroa, Ketoff, and Masera, 1992) and air-conditioning saturation in particular depend on urbanization and income levels. Meyers *et al.* (1990) credited the rapid growth in residential energy use in developing and newly industrialized countries to an increase in the number of households and electrification. Market penetration of air conditioners is still low in most countries, but once they become affordable their proliferation can be very rapid, particularly in hot climates. This has happened in the Philippines, Malaysia, Thailand, Taiwan, and Brazil, which also have humid climates (Schipper and Meyers, 1992). In Taiwan, air-conditioner market penetration more than doubled (12% to 29%) between 1979 and 1989, while in Korea, which has a relatively short summer, it grew from zero in 1976 to 9% in 1989. In comparison, the market penetration of air conditioning in Japan is close to 60%. Similar findings are reported by Sathaye and Tyler (1991) and Parker (1991). Urbanization, rising incomes, and warmer climates could combine to increase both air-conditioner market penetration and cost per unit.

12.3.2.2. Supply

Understanding the effects of climate on hydroelectric, biomass, solar, and wind energy is particularly important because renewable energy sources are playing a significant role in the energy planning of many countries. This could become an increasingly important concern in developing countries, many of which are facing serious economic pressures from the need to import conventional energy resources.

Although cooking usually is a more important end use than heating, woodfuels are particularly important in developing countries because of their (typically) low cost and the simplicity and low cost of the end-use technology (Hall *et al.*, 1993). Among the largest potential impacts of climate change on the developing world are the threats in many areas to fuelwood and charcoal, which are principal sources of energy in most sub-Saharan African nations and many other developing countries. For example, cities and towns place large demands on adjacent and distant forests. Bamako, the capital of Mali, is supplied by a zone with a 100-km radius (Simmons, 1989), but most of the 612 tons per day arriving in Delhi, India comes from 700 km away in Madya Pradesh (Hardoy *et al.*, 1992), and charcoal from northern Thailand is exported to Bangladesh (Tolba *et al.*, 1992). Locally, firewood removal can be very important. Wood is known to be scarce around Kinshasa in Zaire, Brazzaville in the Congo, Nairobi in Kenya, Niamey in Niger, Ouagadougo in Burkina Faso, and in much of Nepal (Williams, 1990). More than 90% of the energy in some African countries depends on biomass (fuelwood). Even if climate does not change, the combination of population growth and a declining resource in some cases will bring cost pressure to change the fuels for cooking and heating from wood and charcoal to other fuels (see Chapter 11). Because of uncertainties in water-resource projections derived from current climate models, providing reliable regional projections of future moisture conditions in these

countries is very difficult, although researchers are working on the problem (e.g., Magadza, 1993). Analysis of this situation should be a top priority for energy planners. Further details are provided in Chapter 11.

Many developing countries and some developed countries depend significantly on hydroelectric power (World Resources Institute, 1992). Even constant per capita electricity consumption implies that without major additions from technical potential, hydropower could decline significantly as a source of power by the early part of the next century. Management of some hydroelectric power systems could be significantly complicated by reduced snowpacks, which change the seasonality of storage and supply, and greater flood intensities if rainfall increases. Geographically extensive hydroelectric systems may be surprisingly unaffected despite climate sensitivity of some components (Sias and Lettenmaier, 1994). Rising electricity consumption and (perhaps) declining future capability resulting from climate change could force some nations to rely increasingly upon fossil fuels. For additional details concerning the effects of climate change on energy supply, see Chapter 11.

12.3.3.   *Air Pollution, Waste Management, and Sanitation*

Climate change does not directly lead to air, water, or soil-column pollution. However, if changes in climate significantly alter local and regional weather patterns, underlying trends in pollution damage may change nonlinearly. This issue received only brief attention in the 1990 and 1992 assessments. Global monitoring of urban air quality in cities indicates that nearly 900 million people are exposed to unhealthy levels of sulfur dioxide (SO_2) and more than 1 billion are exposed to excessive levels of particulates (Schteingart, 1988). While cities such as Manchester, London, Tokyo, and Frankfurt have seen great improvements in air quality (especially SO_2), other cities in the low latitudes have increased SO_2 levels. Moreover, photochemical smog produced by the reaction of sunlight with ozone and photochemical oxidants, such as peroxyacetal nitrate (PAN) from nitrogen oxides (NO_x) and hydrocarbon emissions, is particularly prevalent in cities in semi-arid regions, such as Los Angeles, Tehran, and Mexico City. In British cities, NO_x is probably of more concern now than sulfur oxides (SO_x). Warming can exacerbate the formation of smog. Global warming appears likely to aggravate tropospheric ozone and other air-quality problems in polluted urban areas, which in turn may increase human respiratory disease. In developing countries, much of the pollution problem comes from small and numerous sources rather than large industrial sources (Parikh, 1992).

Rapid industrialization and high urban growth rates have engendered major air-pollution problems in urban centers (e.g., Brazil, Chile, Mexico, Malaysia, Indonesia, Thailand). In Mexico City, for example, severe pollution stems from 36,000 factories and 3 million motor vehicles emitting 5.5 million tons of contaminants per year (Schteingart, 1988), leading in part to high blood levels of lead in newborns (Schteingart, 1989). Box 12-1 describes the complexity of interacting urban growth and

air pollution problems of the Basin of Mexico (Mexico City and surrounding urban area). Similar problems are caused by private diesel buses in Santiago, Chile (Crawford, 1992) and by the use of smoky, high-sulfur coal briquettes in domestic stoves in Chongqing, China (Wang *et al*., 1994). In all of these cases, if climate change were to add to the number of air-stagnation periods, the effects on human health and economic productivity (from pollution itself or from emergency countermeasures) would be more severe.

Many landfills, abandoned industrial waste dumps, agricultural chemical residues in soils, and polluted river and lake sediments pose long-term potential chemical "time bombs." A chemical time bomb is defined as a time-delayed, nonlinear response of soils, sediments, and groundwaters to stored pollutants under changing climate and land-use conditions (Hejkstra *et al*., 1993). The metabolism of human settlements is responsible for these potential chemical time bombs—some of which, such as landfills and old industrial sites, lie directly in urban areas. Hydrological modifications, especially if rainfall intensities increase following climate change, could lead to more rapid leaching from old landfills that are not watertight, affecting groundwater tables and thus drinking-water supplies. Land-use modifications driven by changes in water availability or altered economic situations could lead to changes in ground cover that mobilize toxic residues in soils (Hesterberg *et al*., 1992). In forests, an increase in temperature and a reduction in transpiration by trees leads initially to increased mineralization of organic matter, followed by nitrification and mobilization of hazardous substances (Mayer, 1993).

The rapid urbanization of low-lying areas in many developing countries has resulted in poor sanitary conditions and low water quality. In many cases, this degradation is exacerbated by natural climatic phenomena. For example, in the rapidly growing coastal cities of Lagos, Port Harcourt, and Warri in Nigeria, wastewater and sewage are discharged into open wayside gutters. Flooding during the rainy season produces an unhealthy and noxious environment (Udo *et al*., 1990). Since these areas are also subject to sea-level rise and perhaps more intense and extended coastal storms under climate change, the triple effects of urbanization, poverty, and climate change could make the environment in cities like these dangerous for human health.

12.3.4. *Infrastructure*

Except for a reduction in the degree of expected sea-level rise and more emphasis on extreme events, little has changed in our understanding of this issue since the 1992 assessment concerning direct impacts of climate. However, the indirect impacts of climate and socioeconomic change were not discussed in earlier assessments. Although bridges, roads, and buildings can have a physical lifetime of several hundred years when properly maintained, urban infrastructure often has a rather short lifetime because population, urban activity, and other factors often change significantly within shorter time periods than the physical lifetime of the structure. Such socioeconomic change

Box 12-1. The Challenge of Urban Growth and Air Pollution: Mexico City

The metropolitan area of Mexico City (AMCM) consists of more than 2,000 square kilometers, comprising the Federal District (where the government seat is) and 21 adjacent municipalities in the State of Mexico. Growth of 5% per year from 1940 to 1980 and 2% per year for the last 10 years has resulted in 15 million inhabitants in 1990, making the AMCM one of the largest cities of the world. As the country's political, economic, industrial, and social capital, Mexico City contains about 20% of the national population, provides 47% of all jobs in industry, and generates 48% of public investment in social welfare (Aguilar and Sanchez, 1993). It also contains 30% of all the industrial plants in the country (a total of 38,000), which contribute 20% of Mexico City's pollution, and has about 2.5 million motor vehicles that consume about 14 million liters of gasoline and 4 million liters of diesel fuel per day, generating 75% of the pollution in the city (Departmento del Distrito Federal, 1987).

Mexico City's location in a deep valley at approximately 2,300 meters above sea level creates a natural isolation and contributes to frequent thermal inversions (especially in winter), preventing the dispersion of pollutants. Ecological damage has been aggravated by the lack of measures to protect the local environments. GCMs are silent on the question of local winter temperature inversions, but more frequent or persistent inversions would worsen the Mexico City air quality, while less frequent inversions would improve it.

A comprehensive program of action was announced in 1990 to rationalize urban transport, improve the environmental qualities of fuels burned, install pollution-control equipment, and regenerate natural areas (Mendez, 1991). Some of the main actions taken in this new program also would reduce emissions of greenhouse gases:

- Emission of atmospheric pollutants was controlled in service facilities, such as public baths, dry-cleaning shops, and laundries. These places frequently did not comply with technical standards because of their old equipment and a notorious lack of maintenance.
- Industries in the basin were inspected regularly and systematically to verify the correct functioning of their now-mandatory pollution-monitoring and emission-control equipment.
- Checking vehicular exhaust emissions became mandatory in late 1989. From 1991 onward, the regulation was changed to compulsory verification every six months for heavy-use vehicles and yearly for all other vehicles.
- The use of each car was banned one day of the week, according to the numbers on the license plate, to reduce the circulation of vehicles by approximately 500,000 cars, on average, during working days.
- In 1991, unleaded gasoline and catalytic converters became obligatory in all new cars. However, the lower levels of lead increased the amount of unburned oil residues—which, in turn, increased the ozone formed in the air of the city during daylight hours (Bravo *et al*., 1991).
- The two thermoelectric plants in the basin increased their consumption of natural gas as a substitute for oil.

Despite all these measures, atmospheric pollution has remained dangerous to human health. Public officials acknowledge that employment and productivity in the urban economy is still a priority over environmental preservation (Mumme, 1991). Furthermore, some industrial plants have yet to install antipollution devices. Because of the high cost involved, these plants will depend on state credit programs that are to be implemented in future years to afford these devices.

Additionally, because of the ban on using cars once or twice in a week, some people have bought a second or third car in order to drive on all working days. This has increased the number of the private vehicles by about 20%, as well as the consumption of gasoline. Catalytic converters are optional for used cars, which represent most of the private vehicles in the urban areas. As a result, atmospheric pollution has remained at critical levels in the past five years. Not only have some individual pollutants frequently exceeded what are considered the healthy limits, as is the case with ozone, but the overall air-quality index (abbreviated in Spanish as IMECA) has surpassed 100 points—the air-quality norm recommended by the World Health Organization during most of the year. This fact indicates that at least some pollutants are well above the healthful limit and that long periods of exposure to high pollution levels are notable.

requires renewal or alteration of infrastructure. Adaptation to climatic change becomes an important factor in the design of infrastructures with long lifetimes.

A significant component of the increase in costs associated with risks to infrastructure occurs because the "built environ-ment" has become more valuable over time as investments have occurred. Although some infrastructure has become better designed against natural hazards, risks to infrastructure could increase over time, even without climate change. As with population, human settlement infrastructure has increasingly concentrated in areas vulnerable to flooding, fires, landslides,

and other extreme events. Much of the increase in the value of these physical assets has come because of rising per capita wealth (Stavely, 1991; Central Statistical Office, 1994). These assets are often housed in lightly constructed residential property, which in the case of Hurricane Andrew in Florida accounted for 65% of all insured losses (IRC, 1995). Use of modern construction materials (e.g., aluminum sheeting used for roofing) and aesthetic design features without sufficient understanding of their appropriate use has compounded the damages of extreme events. Modern buildings are difficult to repair if structural pillars are damaged (Jakobi, 1993), and exterior and contents damages also can add up to severe losses (FEMA, 1992). Although the amount or proportion of national physical assets exposed to climate hazards is not readily available, it is known that in the United States about $2 trillion in insured property value lies within 30 km of coasts exposed to Atlantic hurricanes (IRC, 1995); in the Netherlands $186 billion lies in the hazard zone. The corresponding total in Japan is $807 billion (WCC, 1993, 1994), and in Australia, $25 billion (uninsured) (Peele, 1988). Elsewhere, the value of exposed assets is not well known, but Hohmeyer and Gartner (1992) updated a 1971 estimate to give $22 trillion. This value may have doubled due to economic growth since the 1970s. Insured values are usually considerably less than total values because of the difficulty and expense of obtaining coverage.

Climate can directly affect infrastructure via atmospheric processes, fire, and flood. Some researchers have found, for example, that return periods for major flood events may increase fourfold by the year 2070 (Gordon *et al.*, 1992; Smith, 1993; Whetton *et al.*, 1993; Bates *et al.*, 1994); that is, the 100-year flood would become the 25-year flood. If so, design and safety standards would have to be revised for culverts, drains, bridges, dikes, and dams. Moreover, existing infrastructure would be more vulnerable to failure (Minnery and Smith, 1994). Lake levels in many regions in the world are known to fluctuate under current climate conditions, in some cases changing more rapidly than settlements can adapt to easily (Dejoux and Iltis, 1992) or influencing water quality (Gafny and Gasith, 1989, 1993). This fluctuation occurs both because of varying precipitation and runoff and because of variations in human withdrawal of water for a variety of purposes. Climate change could add to the list of variables affecting lake levels.

Protection of infrastructure from extreme rainfall events, river flooding, landslides, and coastal flooding could become a more serious problem with climate change, in some cases pointing toward retreat from hazardous areas. As noted in Chapters 9 and 17, many inhabited areas in the world, especially those in coastal zones, are already sensitive to flooding, landslides, and wind damage under existing climate (e.g., see Ojo, 1991). Some coastal areas, most notably river deltas, face relative sea-level rise already due to geological factors; withdrawal of oil, natural gas, and water from geological formations underlying the delta regions; and sediment impoverishment because of water and flood control works. Coastal zone agriculture, coastal mangroves, and coral reefs are important to human settlements in some parts of the world (Morgan, 1993; Yoshino, 1993) and are

sensitive to sea-level rise. Based on a population-at-risk concept (populations subject to annual flooding), a 1-meter sea-level rise, and year 2020 populations, Hoozemans *et al.* (1993) note that very large populations are sensitive to sea-level rise in Bangladesh, China, Egypt, India, Mozambique, Pakistan, and Vietnam. Others note particular locations at risk, like Jakarta, Indonesia (Sari, 1994). Excluding Mozambique and Vietnam, projected aggregate annual costs of protection were $290 million for these countries, less than 1% of their gross national product (GNP). Countries with costs of protection above 5% of GNP included Anguilla, Cocos Islands, Gambia, Guinea-Bissau, Guyana, Kiribati, the Maldives, the Marshall Islands, Mozambique, Tokelau, Turks and Caicos, and Tuvalu. Fankhauser (1995) has calculated annualized coastal-protection costs for the world on the order of $1 billion per year for a recent estimate of a 50-cm sea-level rise by the year 2100. Inundation and erosion in OECD countries are about half the world total, accounting for between 0.01 and 0.27% of 1985 GDP in OECD countries (Rijsberman, 1991). More refined analyses have been done of several countries' coastal infrastructure-protection needs, including the Netherlands (UNEP and Government of the Netherlands, 1991) and Japan (Kitajima *et al.*, 1993). Optimal protection strategies have been investigated for several locations, including the Netherlands (UNEP and Government of the Netherlands, 1991). See Chapter 9 for additional details concerning coastal impacts and costs.

Settlements in forested regions in many areas are vulnerable to seasonal wildfires. This includes settlements in temperate-zone regions such as Canada (Forestry Canada, 1991), tropical forested regions such as Borneo (*Economist*, 1994), and mediterranean climates like the state of California in the United States or southern Australia (Cheney, 1979; Foster, 1994). If the climate in these areas should become even drier and warmer, the frequency of fire danger would increase (Street, 1989; White, 1992; Ryan, 1993), although it is possible that fuel buildup under drought conditions would decrease, decreasing fire intensities.

Such information needs to be developed for other climate-related impacts. One potential adaptation to a wetter climate or to a warmer climate in an area vulnerable to river flooding from snowmelt would be to expand or reinforce riverine flood-control systems with dikes, check dams, and expanded storage facilities. Alternatively—or in addition to these measures—land-use planning and regulation can be strengthened for hazardous areas. The costs of these actions have not been estimated in relation to climate change, at least in part because the location of future climate-enhanced flood danger is so poorly understood that any estimate would be largely speculation.

Transportation impacts were discussed in the 1990 and 1992 assessments and are discussed in greater detail in Chapters 11 and 21. The findings are locality-specific and have not changed significantly. Although in the colder regions global warming may encourage the poleward expansion of human settlement and open some winter water travel (Sanderson, 1987; Stokoe *et al.*, 1987), thawing of the permafrost may also

disrupt infrastructure and transport (loss of foundations for airports and runways; loss of seasonal ice roads) and adversely affect the stability of existing buildings and conditions for future construction (IBI Group, 1990). If extreme rainfall events become more common, impacts on roads, railways, and other transportation links could become global in reach. Although cost estimates do not exist, they could be very high.

Human muscle power, draft animals, and small watercraft still play a significant role in transportation in many parts of the developing world, especially in the rural areas of those countries located in tropical and subtropical climates. For example, in India, about 10% of tonnage moves by truck, while bullock carts take more than two-thirds (OTA, 1991). Where more frequent or severe heat stress is a possible result of climate change, the work capacity of both humans and draft animals may decline, making transportation less efficient. Where severe weather is more frequent or intense, small craft on rivers, lakes, and other water bodies may be more subject to reduced periods of operation, disrupting farm-to-market distribution systems.

12.3.5. Water Supply

The conclusions for water supply are not dramatically different from the 1990 and 1992 assessments. For example, although some of the details have changed, infiltration of seawater into coastal aquifers is still considered a general potential hazard of sea-level rise, as discussed in Chapter 9.

Changes in water distribution resulting from changed precipitation patterns are important to agriculture, energy, and health. For example, changes in water quality and availability may affect human settlements indirectly through flooding or drought-induced famine and malnutrition. Despite the drilling of many wells, the great Sahelian drought in West Africa during the period 1968 through 1973 (caused by adverse weather compounded by increased human and livestock population pressure on an area of limited long-term biological productivity) resulted in a significant amount of human migration. The 1972–1973 period brought large numbers of rural people from the Niger Republic, Chad, and the far north of Nigeria into the urban areas of Nigeria, including the southern cities of Lagos, Abeokuta, Benin, Warri, Port Harcourt, and Calabar—compounding the urban problems of those cities (Udo *et al.*, 1990). Much of the rapid population growth in the Valley of Mexico has been attributed to a continuous influx of rural residents from drought-ridden agricultural areas (Ezcurra, 1990).

Even under current climate, water availability remains a major and accelerating problem for large human settlements in locations as diverse as California (Vaux, 1991) and Houston, Texas (Scheer, 1986), in the United States; Bombay and Madras in India (Leichenko, 1993); and much of northern urban China (Smil, 1993). Lack of access to clean drinking water is highly correlated with numerous adverse health conditions, including high infant mortality (Parikh, 1992). Water quality can be adversely affected by nonpoint pollution, saltwater intrusion into estuaries,

lowered stream flows, and groundwater mining—all problems associated with climate change, human-population growth, economic development, or all of the above (Jacoby, 1989).

Demand for water is affected by price, income, technology, and other influences. Other things being equal, more water is used as temperatures increase. For example, in Japan, urban water demand has been estimated to increase about 3.3% per degree celsius for days when the maximum temperature is over 17°C (Hanaki, 1993). For additional discussion of the effects of climate change on water supplies, see Chapter 14.

12.3.6. Health

The earlier assessments of global climate change in 1990 and 1992 provided little information on the potential effects of climate change on human health. More recent thought reveals several additional causes for concern (see Chapter 18 for details). This section describes the specific role of human settlements. Climate-related changes in human settlements may affect several elements that are critical to human health. Kalkstein (1993) and Kalkstein and Smoyer (1993) suggest that the major potential pathways are heat stress directly causing premature mortality (particularly in nonacclimated, unprotected populations in hotter developing countries); outbreaks of infectious diseases whose ranges change because of changes in human migration patterns and spread by contact or close proximity between infected and noninfected individuals; and effects of infectious diseases whose agents, vectors, hosts, ecological niches, or predators on vectors are affected by climate, or compounded by changes in land use, eutrophication of waters, and other anthropogenic environmental insults, such as acid rain or pesticides. The infectious diseases include several serious tropical diseases. In addition, if water supplies are disrupted as a result of more frequent droughts and floods, the full range of nontropical waterborne diseases such as cholera, typhoid, diarrheal, and helminth diseases (hookworm, roundworm, etc.) spread by unsafe drinking water may come into play more frequently.

Anthropogenically and climatically reduced biodiversity (e.g, from prolonged droughts) is a particular concern because biodiversity provides the prime buffer of ecosystems against stress and provides for the biological control of pests and pathogens. Tropical and waterborne diseases and diseases directly transmitted person-to-person annually account for about a fifth of the total annual world loss of disability-adjusted life years from all causes, including other health conditions, accidents, and war (World Bank, 1993). The disability-adjusted life year is a statistic that combines the loss of years of life to premature death with an index of the lost quality of life produced by varying degrees of persisting disability (e.g., blindness or paralysis). There are adverse implications for worker productivity, trade, transport, and tourism (Epstein, 1994).

Urban settlements, particularly the often (but not always) overcrowded and poorly serviced slums, shanty towns, and squatter settlements of the developing world, provide a potentially excellent breeding ground for disease organisms and vectors, as well

as poor sanitation and vulnerable populations in close proximity to each other (WHO Commission on Health and the Environment, 1991). These settlements are often located in the least desirable areas, which may be flood-prone lowlands, hazardous waste sites, downwind from industrial sites, or on steep hillsides; therefore, inhabitants will be more vulnerable to, and weakened by, waterborne disease, pollution, and natural disasters, such as floods and landslips. As some agents of infectious diseases become increasingly drug-resistant (e.g., tubercle bacilli and malarial plasmodia) and vectors resistant to pesticides, the importing of these infectious diseases to highly concentrated, vulnerable populations becomes a significant public-health concern.

Tropical Chagas' disease, a leading cause of heart disease throughout the Americas, is becoming increasingly urban. Reports from Honduras and Chile reflect this rural–urban shift, paralleling the movement of populations. Once prevalent in the blood supply, Chagas can be spread directly by blood transfusions. A greater number of heat waves could increase the risk of excess mortality. Increased heat stress in summer is likely to increase heat-related deaths and illnesses (Kalkstein and Smoyer, 1993). Deaths due to cold exposure and blizzards in colder regions like Canada could decrease, although these gains are unlikely to offset the increases in heat-related deaths (see Chapter 18).

Global warming appears likely to worsen air-pollution conditions, especially in many heavily populated and polluted urban areas. Climate change-induced alterations in photochemical reaction rates among chemical pollutants in the atmosphere may increase oxidant levels, adversely affecting humans and complicating the effects of increased urbanization in locations like Mexico City (Griffith and Ford, 1993) or Tehran (Bonine, 1993). The range of certain vector-borne diseases, such as malaria, yellow fever, and dengue, may extend both in latitude and altitude to new areas and settlements currently at the margins of endemic areas. For example, highland cities such as Harare and Nairobi, which are currently malaria-free, are vulnerable (see Chapter 18 for a more complete discussion).

Still another mechanism through which global warming might affect human health is through harmful algal blooms, which promote diseases like paralytic, diarrheal, and amnesic shellfish poisoning, as well as cholera (Epstein *et al.*, 1993). The increase in blooms worldwide is thought to be a direct consequence of human activities on a local or regional scale that could be reinforced by the existence of environmental conditions such as warmer seawater in coastal areas that promotes growth. Excess nutrients from sewage and fertilizers, over-harvesting of fish and shellfish, and loss of coastal wetlands and coral reefs also contribute to the problem.

12.4. Extreme Events

12.4.1. Types of Events

Climatologically, extreme events are associated with "anomalous" weather, sometimes defined in terms of a "return period"

of 10 years, 100 years, or some other value (probabilities equivalent to one event in 10 years, 100 years, etc.). The length of the return period is decided on a case-by-case basis, depending on (1) the climatic phenomenon, such as flood, wind damage, and drought; (2) the climatic region or zone; (3) the season; and (4) the intensity of the impact on human activities, plants, and animals. Extreme amounts/values that cause damage change from year to year as the level of human development and activity in the area changes. Therefore, it is very difficult to define threshold levels of temperature or precipitation that can be used as permanent criteria in any one region or applied everywhere in the world.

One important aspect of extreme events is the apparent randomness and abruptness with which they arrive. Gradual changes in air pollution, acid deposition, desertification, water shortages, salt water intrusion, soil degradation, and deforestation are also serious but tend to arrive slowly enough that local/regional/national authorities can take successful long-term countermeasures.

Extreme events may arrive without any definite cycle or periodicity, so they constitute risks that can be the subject of insurance. For the effects of climate-related extreme events on insurance and the insurance industry, see Chapter 17. Extreme events are often related to disease outbreaks. El Niño/Southern Oscillation events and teleconnected weather patterns across the globe (Glantz *et al.*, 1991) are highly correlated with outbreaks of malaria (Bouma *et al.*, 1994), dengue, and algal blooms (Hallegraeff, 1994), as well as other problems (Glantz *et al.*, 1987). Both droughts and floods are related to outbreaks of vector-borne diseases and agricultural pests. The number of extreme events in terms of economic and insured losses is increasing, at least in part because of the ever-increasing scale of human activity. The amount of insured losses caused by extreme events is increasing at a higher rate than is the amount of economic loss. Insured losses at the beginning of the 1990s are two to three times those of the 1980s (Berz, 1993a, 1993b).

12.4.2. Mechanisms of Effects

To discuss the mechanism of effects of extreme events on human settlements, we refer to the example of typhoon hits in Japan (Fukuma, 1993). Based on the record for the 79 years from 1913 to 1991, 245 typhoons were classified into six grades based on intensity. Changes in the number of deaths are shown in Figure 12-2, with running 20-year averages since 1921. It is clear that the number of deaths is larger for the more severe typhoons and that deaths have been declining in all categories since World War II. This decline is thought to have occurred because increasingly effective countermeasures have been taken during the last 40 years, including more robust infrastructure design standards. These countermeasures appear to be more effective with respect to the mid-class Grade III typhoons than for either the weaker typhoons (where the lower limit of fatalities may have been reached) or the stronger typhoons (where more effective actions still could be taken).

The countermeasures include conservation of mountain slopes, rivers, and coasts; harmonization of institutions and laws related to disaster mitigation; preparation of systems for disaster prevention, including better design; meteorological observation and information systems; promoting people's consciousness of preventing disasters; and development of communication systems for disaster occurrences. Thus, the impact of extreme events on human settlements can be affected by the grade of the extreme event, the level of economic and technological development, and the extent of countermeasures taken. Climate change may affect the intensity or the probability of extreme events. The impacts on human settlements depend in part on the present vulnerability (including coping ability) of the settlements.

12.4.2.1. Floods

Vulnerable regions are some small islands, notably coral atolls; regions hit by tropical cyclones, such as typhoons and
Figure 12-2: Change in numbers of deaths per typhoon hit in Japan during the last 70 years according to Grade I (weak), II (normal), III (strong), IV (stronger), V (violent), and VI (super violent) (Fukuma, 1993).

monsoons; and the lower reaches of big rivers like the Mississippi, Hwang Ho (Yellow River), Yangtze, and Nile. Delta regions in South and Southeast Asia are particularly vulnerable. Local-scale floods show various effects on rice yield, as shown by Yoshino (1993) for tropical Asia. Flooding is a common extreme event that poses challenges for the insurance industry and the public sector (in planning and protecting infrastructure). Although humans possess considerable adaptive management capability to deal with floods, flooding could become a more common problem with climate change, even if average precipitation decreases (see Section 12.3.4; Chapters 14 and 17; and Chapter 6, *Climate Models–Projections of Future Climates*, of the IPCC Working Group I volume).

12.4.2.2. Landslides

Although landslides occur in many regions throughout the world, damaging property and disrupting transportation links, the 1990 and 1992 assessments gave relatively little attention to land stability as a climate-related problem. However, in the poorest hilly cities of the world, many hundreds of thousands of people live in illegal settlements on potentially unstable hillsides especially vulnerable to climate change. Hundreds of people were killed or seriously injured and thousands made homeless by landslides in Rio de Janiero in 1987 and 1992; Medellin, Columbia in 1988; Mexico City in 1990–1992 (Aguilar and Sanchez, 1993); Caracas in 1989 (Hardoy *et al.*, 1992); and Hong Kong in 1925, 1964, 1966, 1972, and 1976 (Styles and Hansen, 1989). A similar degree of susceptibility to landslipping would be found in other areas of deeply weathered rock in tropical and subtropical areas subject to heavy rain.

Many landslides are related to inherently unstable materials that move when subject to extreme rainfalls, such as the Loess Plateau of China (Billard *et al.*, 1992; Derbyshire and Wang, 1994), the quick clays of Quebec, and the deeply weathered crystalline rocks of the tropics and subtropics (Brand, 1989). Others occur in steeplands, such as the Himalayas, the Alps, and the mountains of western Canada and western China, and may be influenced by earthquakes, rapid snowmelt, or extreme precipitation (Brabb, 1991; Haigh, 1994). Relict periglacial landslides occur in much of Northern Europe and North America (Johnson and Vaughan, 1989). Stable under present natural conditions, these landslides are reactivated by urban construction activities and are triggered by heavy rains (Caine, 1980).

Landsliding is regarded as a catastrophic event—one that is large, sudden, and rare on human timescales (Jacobson *et al.*, 1989). Their triggering depends on an earthquake or a rainfall event and is related to antecedent conditions. Alteration in the frequency and magnitude of precipitation related to climate change (caused by changes in tracks of tropical cyclones, for example, or increases in the intensity of rainfall) could alter the probability of landslides and debris flows (Gordon *et al.*, 1992). In some places, currently inactive slides may be reactivated; in others the risks of slipping may be reduced. Greater aridity, on the other hand, could so reduce vegetation or so

increase the risk of fire (which reduces vegetation) that mud flows and debris flows could become more frequent. In some temperate-zone regions, for example, landsliding in inland areas is likely to become more pronounced as a result of higher winter rainfall, increased likelihood of summer droughts, and increased summer storm activity (Jones, 1993).

Landslide susceptibility also is being altered by the movement of more people into urban areas in mountain environments and the expansion of cities from plains into the surrounding hills, both for reasons of prestige among the rich and lack of affordable building space for the poor. Both the wealthy and poor thus become potential victims.

12.4.2.3. Wind

Vulnerable regions include areas susceptible to tropical and non-tropical cyclones, including west-facing mountainous areas for polar cyclones and upper Westerlies. Strong gusts can also be associated with the downbursts of tornadoes. The countries most affected by tornadoes are the United States, Canada, and Russia, where local areas can experience serious tornado and hail damage (Phillips, 1990; Paul, 1994), though they occur in many parts of the world (Grazulis, 1991). Tropical cyclones (hurricanes and typhoons) commonly affect South, Southeast, and East Asia and Oceania, as well as Central America, the Caribbean, and parts of Mexico and the United States. Some authors suggest that storm tracks may change, or that severe tropical cyclones may become more severe with climate change (Okamoto, 1991). However, there is little agreement among climate models on either mid-latitude storms or tropical cyclones (see Chapter 6, *Climate Models–Projection of Future Climates*, of the IPCC Working Group I volume; also see Chapter 17 for further details on cyclone damage).

12.4.2.4. Heat Waves

Heat waves may become more common and severe if the climate warms. Climatologically, in the Northern Hemisphere, the southern part of the temperate zone and northern part of the subtropical zone in summer are the most vulnerable. In the Southern Hemisphere, sub-Saharan Africa and Australia are both vulnerable, especially when heat is combined with drought. Aerologically, vulnerable areas are the eastern parts of prolonged, stationary upper troughs, where warm air flow from the tropics can invade the temperate zone. Heat waves appear to increase overall death rates, even in acclimatized populations. They are a particular concern when combined with heat islands and substandard housing in urban areas (see Chapter 18).

12.4.2.5. Cold Waves

Similarly, cold waves may become less common or severe. Climatologically, in the Northern Hemisphere, the northern part of the subtropical zone and the southern part of the temperate

zone in winter are the most vulnerable. Episodes of extreme cold and blizzards are major climate concerns for the circumpolar countries like Russia and Canada (e.g., Hage, 1985; Phillips, 1993; RSC/CAE, 1994). In the Southern Hemisphere, Antarctic storms sometimes strongly affect weather on New Zealand's South Island. In both hemispheres, severe snow or ice storms can adversely affect most economic sectors. Aerologically, the western parts of the stationary upper trough, where the cold air can more easily flow from higher latitudes, are the most vulnerable areas. In Asia, for example, cold waves can penetrate to 15° to 20°N latitude (Yoshino, 1989; Yoshino and Kawamura, 1989).

12.4.2.6. Droughts

There are meteorological, hydrological, and agricultural droughts. They occur widely, from the tropics to the high latitudes. In the lower latitudes, they are intensified by prolonged dry seasons caused by anomalous monsoon circulation. In the middle latitudes, anomalies in cyclonic activity are effective. The most vulnerable areas are those under the influence of subtropical anticyclones. Droughts could be more severe at higher temperatures because evapotranspiration would be enhanced, reducing soil moisture. Agricultural settlements in regions such as sub-Saharan Africa, Australia, China, southern Europe, and midcontinental North America are projected to be sensitive to drought conditions. See Chapter 13 for details on agricultural effects. Chapter 14 notes that water distribution systems, power plant cooling, and river navigation can be adversely affected and that settlements in the Middle East and North Africa may be particularly vulnerable to drought.

12.4.2.7. Wildfires

So-called "Mediterranean-Climate" regions are at the most risk because of their dry summer climate. The risk of fires is very high in the summer months (Donguedroit, 1991), when severe storms may also spawn lightning strikes. These may become more common if climate changes (Price and Rind, 1993). The regions surrounding the Mediterranean Sea, California in the United States, and southeastern Australia all have suffered from severe fire damage recently. Fires are also frequent in the taiga regions of Siberia, Canada, and Alaska and in Borneo and Indonesia (during El Niño years). These tendencies are related to recent increases in resident population and tourism, inappropriate urban plans and environmental management, shortages of labor in the timber industry, wasteful logging practices and swidden agriculture, lags in upgrading fire prevention systems, and so forth. They could be exacerbated by global warming if it also results in drying or intensification of El Niño conditions and if fuel is available.

12.4.2.8. High Tides, Storm Surges, and Tsunamis

Global warming results in sea-level rise, so the effects of "normal" extreme events such as high tides, storm surges, and

seismic sea waves (tsunamis or "tidal waves") would become more severe. Multiple risks such as earthquake and tsunami or storm surge at high tide are of particular concern.

12.4.2.9. Acute Air-Pollution Episodes

In addition to areas historically famous for air pollution—such as London, Los Angeles, and Mexico City—many developing-world cities are becoming increasingly affected. Air-pollution episodes could become more serious if temperature inversions become more frequent or persistent in these areas.

The effects of extreme events are inherently uncertain and carry with them an element of probability or risk. These risks can and have been calculated for anticipated climate change in some regions, such as coastal Japan (Mimura *et al.*, 1993). More generally, however, many of today's standard engineering and insurance calculations, which depend on historical observation, could be overturned by changes in the intensity or frequency of extreme events that increase the costs, risks, or both costs and risks to lives, infrastructure, and insurance pools.

Extreme events sometimes occur successively or simultaneously. When this happens, as in the case of a series of typhoon hits, the damage is more serious because the area has been made vulnerable by previous damage (e.g., the ground is already waterlogged, or flood-control structures have been weakened). Sometimes a meteorological extreme event occurs immediately following some other form of disaster, more than simply adding to the stress on social and economic conditions. For example, a severe typhoon struck the Philippines just after the eruption of Mt. Pinatubo, causing severe mudflows at the base of the mountain. Such secondary impacts can be relatively serious in comparison with the damage of the original event.

12.5. Adaptation Options

The list of adaptive actions discussed in this section is adapted from United Nations Centre for Human Settlements (Habitat, 1992b). The list includes both actions autonomously taken by humans and deliberate, planned, climate-adjustment actions nurtured by policy. Where data are available, the section also discusses the costs of adaptation. However, not enough focused research has been done on adaptation to permit full comparisons between adaptation and mitigation of climate change or even to fully characterize the costs of adaptation. Although regional and local governments may have limited powers or boundaries that do not correspond to natural physical systems affected by climate change, a holistic approach needs to be taken to planning human settlements. Each settlement must fulfill multiple objectives, of which adaptation to climate will be only one (and in many cases, not even a very important one). Examples of this holistic approach may be found in Douglas (1983) or White (1994). Sector-by-sector adaptations are discussed in Sections 12.5.1 through 12.5.6.

12.5.1. Population Migration

One of the potentially destructive effects from a variety of social and economic perspectives is forced internal or international population movement—both low-key, long-term migrants responding to relative economic opportunity by moving between regions and from rural areas to cities, and "ecological refugees" responding to specific natural disasters. Economic migration can be reduced if economic opportunity and services of civilization can be delivered to the regions of origin and thus prevent the population movement (Calva Tellez, 1992; Rello, 1993). This reduction can be accomplished in part by immigration/emigration policies if regional (especially rural) and national economic development are undertaken at the same time. Controlling the degree of urbanization appears to be doubtful as a solution (Shukla and Parikh, 1992). Decentralizing government administration to secondary cities reduces to some degree the impact of population movements on primary cities because the "pull" effect of government employment is distributed among several locations. Economic dislocation programs, such as disaster assistance, can offset some of the more serious negative consequences of climate change and reduce the number of ecological refugees. Effective land-use regulation can help direct population shifts away from vulnerable locations such as floodplains, steep hillsides, and low-lying coastlines.

12.5.2. Energy

A number of specific actions can be taken to offset the effects of climate change in the energy sector. Increased building-shell efficiency and changes to building design that reduce air-conditioning load show promise (Scott *et al.*, 1994). Though effective, however, some strategies may have other costs (Loveland and Brown, 1990). Air conditioning may offset some of the more deleterious effects of heat waves, although because acclimatization is reduced, this is not necessarily so (McMichael, 1993). Reducing the size of space-heating capacity in response to warmer climate would be a logical adaptive response in more temperate and polar countries and may free up investment funds for other purposes, even within the energy sector. Community design to reduce heat islands (through judicious use of vegetation and light-colored surfaces) (Akbari *et al.*, 1992), reducing motor transportation, and taking advantage of solar resources also should be included in the package of possibilities. Many of these actions, such as urban tree planting and urban mass transit, are typically justified as mitigation options to reduce fossil-fuel use in the urban buildings sector (see Chapter 22) or to reduce the adverse energy-use, congestion, and health consequences of transportation networks that are based on automobiles and motorized two-wheelers (see Chapter 21). Full environmental and health costing of fossil fuels, which can discourage the use of fossil fuels through environmental "adders" (theoretical surcharges on the energy produced with fossil fuels for planning purposes to compare environmental consequences or actual surcharges charged to consumers to discourage their consumption of energy produced with fossil

fuels), is sometimes regarded as a mitigative action. However, these same mitigative responses also have adaptive value in that they reduce the impact of warming on urban discomfort caused by heat-island effects.

Some of these actions have unexpected social costs if not planned appropriately. For example, urban trees can be aesthetically attractive while reducing air-pollution and heat-island effects, altering local meteorological conditions, and providing shelter from wind (NCPI, 1992). However, they also can accelerate desiccation of clay soils (Freeman, 1992)—leading to subsidence—and contribute windthrow to property damage during high-wind events (Stavely, 1991; Shearn, 1994). See Chapter 17 for further details.

Until recently, traditional styles of clothing, buildings, and cultural features such as hours of work varied considerably around the world, mirroring the outdoor environment and each region's unique sociocultural and technical response to it (Shove, 1994). Unique cultural response has been overtaken by standardization in hours of work, clothing, and heating and cooling technology, including standardized definitions of human comfort and "ideal" indoor environments (Fanger, 1970; King, 1990; Baker, 1993). Localized culture- and situation-specific responses, such as reintroducing the "siesta" or varying the strategy between the prestige commercial sector (hotels, banks, and offices) and the residential sector, offer the opportunity to have a less energy-intensive response to global warming. Locally specific strategies will reflect the distribution of wealth and status, slowing if not reversing the trend to globalized lifestyle and standardized indoor environment.

12.5.3. Air Pollution, Waste Management, and Sanitation

Reducing industrial pollution is a desirable activity under current climate because it can not only reduce acute health-threatening conditions like heat waves but also can reduce other pollution-related problems, such as the buildup of heavy metals in the environment, loss of aquatic biodiversity, and loss of forested areas. Reductions in the burning of fossil fuels not only have an impact in solving all of the foregoing problems but have mitigative effects on global warming itself. Reducing automotive traffic in sensitive airsheds has a similar effect, as does substitution of more benign fuel types (e.g., natural gas for coal and the use of unleaded gasoline).

Countermeasures for chemical time bombs include a complete inventory and system of monitoring for urban-area landfills and waste sites; tight control of waste flows from source to final resting place for present waste disposal; and dumping of toxic materials only in safe, permitted sites. Such control is difficult to maintain in poor cities that lack adequate urban infrastructure but is extremely important because so many people depend on shallow groundwater wells. In rural areas, control is more difficult, especially for widely used agricultural chemicals. Safe disposal of containers and residual amounts is extremely important but often neglected, particularly where the chemicals are used by laborers for absentee landlords on large estates.

Although increasing human activity and urbanization are likelier to have more important impacts on sewage management than will climate change, the impact of climate change or the necessity of reduction in GHGs may influence sewage-management policy in the direction of water recycling and reducing energy use. Water demand will increase in many urban areas, whereas severe reduction in available potable-water resources because of climate change is predicted in some areas. By necessity, reuse of treated sewage will increase to cope with relative shortage of urban water resources. Limited reuse of sewage has been applied in areas that are subject to dry climate (South Africa, Israel, California, etc.) or in areas with very high density of urban activity (e.g., Japan). These examples show that reuse of treated sewage for flush toilets, industrial use, agricultural use, or even part of the raw water destined for potable water supply is technologically possible. For some uses, waterborne toxins not addressed by conventional treatment can be a concern.

The reuse of treated sewage requires advanced sewage-treatment technology in addition to the more-conventional secondary treatment. There are many options in the advanced treatment category. Depending on the proposed quality of treated water, its cost and consumption of energy and resources vary. Some of the advanced treatments consume much more energy than the conventional sewage treatment processes. Energy-intensive processes often tend to be adopted in the developed countries so that the quality of treated water obtains acceptance from the public. Savings in energy consumption are important and should be taken into account in such cases. On the other hand, inexpensive and less energy-intensive methods are normally chosen in the developing countries. Such a choice is desirable from the view point of the global environment, but high priority should also be given to avoiding hygienic risk either by using a high grade of treatment or by limiting the uses of the treated sewage.

12.5.4. Infrastructure

As described in the 1992 assessment with respect to the coastal zone in particular, available adaptive responses to flooding fall broadly into three categories: retreat, accommodation, and protection. There are various environmental, economic, social, cultural, legal, institutional, and technological implications for each of these options. Retreat could lead to a loss of property, potentially costly resettlement of populations, and, in some notable cases, refugee problems. Accommodation could result in declining property values and in costs for modifying infrastructure. Protection may require significant investment, can have environmental costs to shorelines, and may be ineffective if the frequency or magnitude of extreme events increases. Generally speaking, building codes and other design and construction standards offer one of the most effective ways to limit the effects of extreme events such as tropical cyclones and flooding. As the climate changes, the standards need to be periodically revisited

and updated. The supporting analysis for the standards needs to be couched in the language of engineers so that design solutions reflect increased climate uncertainty and risk of natural hazards. Also, developing countries may require assistance in obtaining the necessary knowledge and institutional capacity to develop and implement the standards.

In developed countries, the costs of defending infrastructure from river and coastal flooding have been calculated for numerous sites, but mostly for extreme events under current climate conditions. There have been a growing number of region- and city-specific studies that suggest that climate change could prove costly to major urban areas in coastal zones of developed nations. Examples from the United States (Walker *et al*., 1989) and Japan (Mimura *et al*., 1993; see Figure 12-3, which shows typhoon-vulnerable areas of the Tokyo metropolitan area) illustrate the point.

In Japan, protection of coastal infrastructure was estimated to cost $63 billion for raising port facilities (quays, wharfs, jetties, seawalls, etc.), plus $29 billion for coastal facilities (water gates, breakwaters, seawalls, etc.) (Mimura *et al*., 1993). For an extended discussion of strategies and further international estimates of the vulnerabilities and costs of sea-level rise, see Chapter 9, Hoozemans *et al*. (1993), or IPCC CZMS (1992); also see Chapter 17.

Although no comprehensive international estimates have been made of additional pumping-station, water-supply, or drainage requirements for coastal regions, some analyses have been done of the requirements to maintain water balances in some areas. For example, Arai (1990) analyzed the water balance in Tokyo. A handful of estimates have been done on the costs of adapting to changes in lake levels, in the range of a few hundred million dollars for small areas in Lake Michigan (Changdon *et al*., 1989) and Lake Titicaca.

Identification and mapping of landslides provides information on what has happened in the past, but such landslide inventory maps at a scale of 1:100,000 or larger probably cover less than 1% of the land and sea areas of the world. Several urban areas with particular landslide problems have set up detailed schemes for landslide mapping and landslide risk assessment. The work of the Geotechnical Control Office in Hong Kong (Brand, 1989), the San Mateo County Gas Project in California (Brabb, 1993), and the Colorado Geologic Survey (Mears, 1977) are good examples of such schemes. However, many of the poorer countries of the tropics have little information. Even in developed countries like Britain, a detailed inventory of landslides was not completed in the 1980s (D.K.C. Jones, 1991). From such inventories, landslide susceptibility maps can be produced.

Landsliding is usually predictable, and a wide range of techniques is available to help urban planners minimize risk through avoidance, control, and improved resistance (Jones, 1993). Landslide susceptibility maps show areas with different potentials for future landslide movement. Real-time warning systems for landslides are rare, but successful operation of a debris-flow warning system for the San Francisco Bay region indicated that, where sufficient telemetric rain gauges are available, adequate warning may be achieved. Many countries, however, rely on structural measures to mitigate debris flows and rock avalanches. In western China, for example, many long training walls restrict the width of debris flows down valley floors. The safety of such measures could require reevaluation. The effectiveness of a good landslide risk inventory is well illustrated in Hong Kong, where urban land-capability assessment and control of building construction are based on assessments of slope stability (Styles and Hansen, 1989).

Building controls do little for structures that existed before the controls were implemented and those that are built illegally. These situations call for a great increase in understanding and awareness, even in wealthy communities. Many of the poor of the world will continue to exist on hazardous hillsides. Forced evacuation and rigid enforcement of zoning regulations may be only temporary measures unless viable, practical, and economic alternatives are provided for the poor.

Increased storminess or rainfall intensity in regions where settlements are expanding onto hillsides featuring relict periglacial landslides will lead to greater frequency of landsliding. Here, more rigid application of geomorphological knowledge in planning decisions is required. Existing structures that are threatened need to be identified. Particular attention in all regions needs to be paid to mining waste, quarry tailings, and other landfills and spoil heaps, which may become unstable and threaten schools, hospitals, dwellings, business premises, and water quality.

Though the extent of adaptive capacity varies among nations and localities, human beings have developed multiple adaptive responses over the centuries to cope with high fire-danger regimes. Major adaptive responses include both fire prevention and fire control and suppression; use of fireproof and fire-retardant materials such as concrete and steel, rather than wood in buildings; development of extensive firefighting networks in settled areas (including personnel and mechanical firefighting equipment such as fire trucks, fire-hydrant systems, and sprinkler systems in buildings); fire-control systems in rural areas, such as controlled burns to limit fuel, fire breaks, aerial fire retardant delivery, and rural fire departments and "smoke jumpers"; and short-term activity controls during high fire-danger weather, such as prohibitions on open burning, commercial activities such as logging, and recreation activities such as hiking, hunting, or use of off-road vehicles. If frequency or intensity of fire danger warrant, another potential adaptive response involves improved spatial planning of communities and some longer-term land-use controls. These provide better isolation of fires and could limit damage to human settlements. If global climate change makes high fire danger a more common or dangerous occurrence in places such as western North America and southeastern Australia, more frequent and intense application of these principles may reduce vulnerabilities to fire. In locations where fire danger is lessened, relaxation of some controls may be possible and desirable.

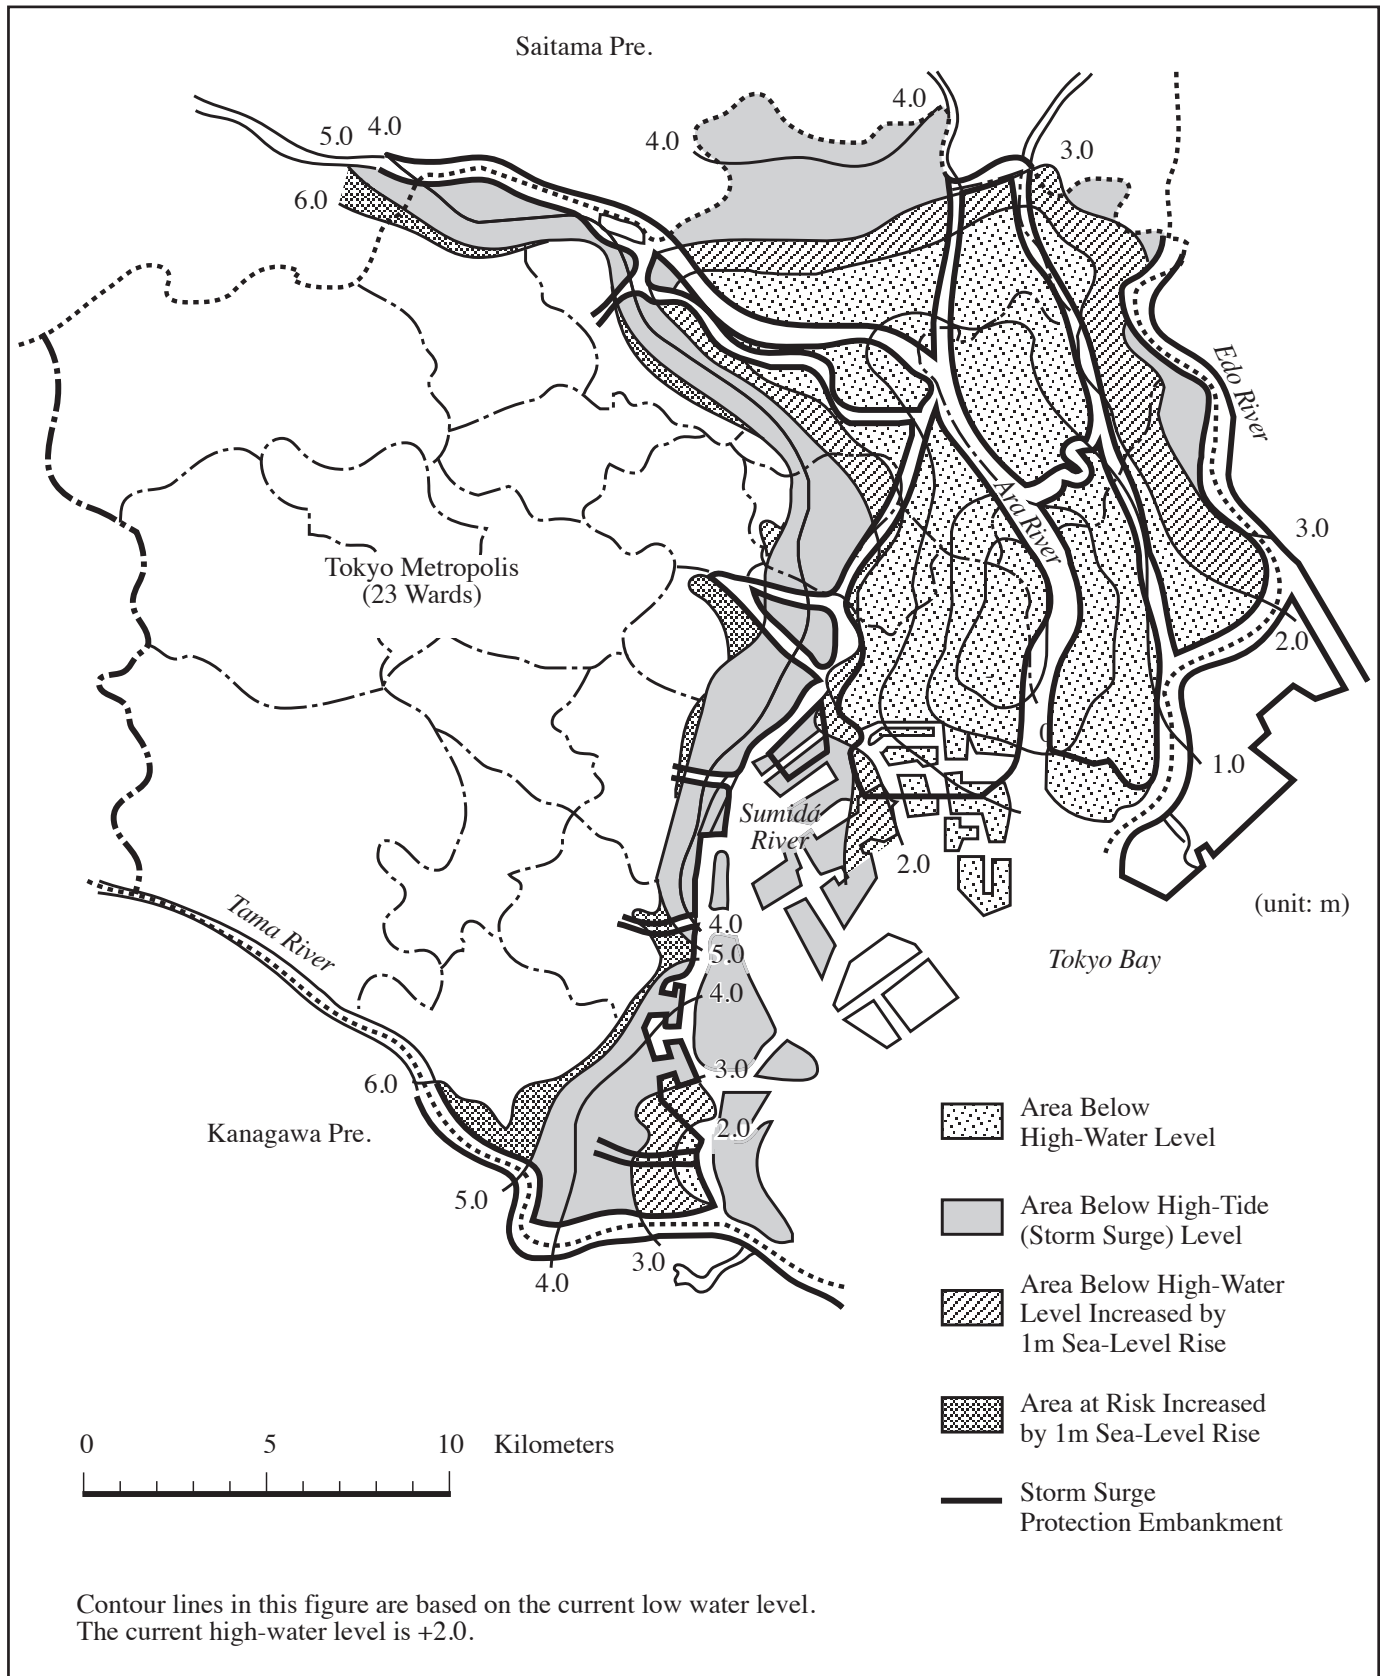
Integrating transportation and land-use planning can reduce the demand for transportation infrastructure. While largely undertaken for mitigative reasons, integrating transportation and land-use planning could reduce the adverse impacts of air pollution under current climate as well as reduce urban heat islands and assure that future heat waves would be less of a


Figure 12-3: Distribution of lowlands and positions of high-tide embankments in Tokyo (Mimura *et al.*, 1993).

health and cooling-energy problem than they otherwise would be. Appropriately timed investments—especially public transit and transportation-management schemes—can improve traffic flow, reduce the need for travel, and emphasize appropriate modal choice (especially foot traffic and bicycles for short trips). These appear particularly promising in reducing local urban air pollution in the developing world (OTA, 1991). In addition, adjusting human settlement patterns may strongly affect transportation in the long run (see Chapter 21).

12.5.5. Water Supply

Potential changes in hydrologic balance because of climate change will have an impact on the availability of water resources and eventually on water balance and water supply. However, more significant and acute imbalance between water demand and the water resource is expected in many regions because of the increase both in population and in per capita water demand. Water-shortage problems exist and are becoming increasingly serious even under present circumstances (Laburn, 1993). Severe imbalances are foreseen, especially in developing countries where water demand is increasing rapidly and the institutional system and water supply facilities are still insufficient. Future management must take into account such socioeconomic-driven increases in water demand and the potential decrease in available water resources. Solutions to such imbalances include minimizing net water use and developing new water resources, including limited wastewater reuse. Prevention of water pollution is necessary to maintain a water quality satisfactory enough for potable water supply. See Chapter 14 for additional details on water-management options. The Nordic Freshwater Initiative proposed two key principles for future sustainable development and water use in developing countries (Jønch-Clausen, 1993). The first principle is management at the lowest appropriate levels. Centralized and top-down approaches to water-resource development and management are often insufficient for efficient local management, although the centralized mechanism is good to ensure national economic and social interests. The second principle is to consider water as an economic good. Numerous opportunities exist for improved management of water infrastructure, pricing policies, and demand-side management of supply (Frederick and Gleick, 1989). The cost includes direct cost, opportunity cost, and environmental cost. Charging for water use induces conservation and protection of water resources and develops the consciousness of water management.

12.5.6. Health

A range of adaptive mechanisms for offsetting the potential human-health effects of global warming lie in improving certain aspects of health services and other public services that settlements provide in any case (World Bank, 1993). Improved sanitation and water treatment both reduce the spread of water-borne diseases and may provide a measure of safeguard against importing exotic enteric waterborne diseases such as cholera.

Effective inoculation programs against tropical diseases are limited to a few arbovirus infections, principally yellow fever and Japanese encephalitis. Vaccination against cholera is about 50% effective for a period of a few months (American Public Health Association,1990). Improved disease-treatment intervention has reduced mortality and morbidity rates from a number of diseases and could prove an effective, if expensive, alternative in some cases. This strategy could take the form of health and relief services' emergency response to specific disease outbreaks, for example. Improved air-pollution control is desirable from a number of perspectives under current climate and could have beneficial effects on reducing the impact of climate warming. Pest suppression/management can in some instances reduce the prevalence of disease vectors or hosts (e.g., the early twentieth century campaign against mosquitos in Panama) and thus offset to some degree the expansion of range of some of these pests.

Finally, disease surveillance could be strengthened and integrated with other environmental monitoring to design early warning systems; develop early, environmentally sound public health interventions; and develop anticipatory societal policies to reduce the risk of outbreaks and subsequent spread of epidemics. For additional details on health considerations, see Chapter 18.

12.6. Needs for Future Research

We are still very much at the infancy of this topic. Information needed to calculate the effects of climate change on human settlements would answer two broad questions, both of which must be answered at the regional and local level: (1) What is the present situation with respect to human population and settlement infrastructure? (2) What are the options for future economic and social development (especially adaptation to climate), and what will determine which option(s) will be adopted?

- **Present Situation**
  - Generally speaking, consistent, useful estimates of infrastructure types and values, especially in flood zones, do not really exist. Databases on regional capital stock are necessary to calculate infrastructure at risk from extreme events. Information is also required on capital turnover rates to determine "natural" replacement rates.
  - Better-founded information is needed to support estimates of the effects of climate on national energy demand, particularly the balance between heating and cooling in temperate-zone countries, which is currently a matter of some controversy. More needs to be done on the inventories and market penetrations of energy-using equipment in the commercial sector in all countries and in the residential sector of developing countries.
- **Future Situation**
  - We need better information on the probability, location, intensity, and consequences of future extreme climate events of all types. Currently, the

information available from climate models on extremes of temperature, precipitation, and windspeed is inadequate to do more than identify this as an issue.

– Cost estimates are needed for nearly every infrastructure and settlement issue. With the exception of the costs of coastal defense and some studies on energy demand, little has been done on the costs associated with the effects of climate change on human settlements. There are only limited databases on the costs of potential urban flooding and landslides, the costs of migration for infrastructure development, and the costs of health intervention programs and air- and water-pollution prevention.

– Data are needed on technology dynamics. Beyond general principles, we know very little about which variables govern the development and adoption of new technologies. Yet this may have a profound impact on the future shape of human settlements.

– We have better data and theories on population fertility, survival, and death, but regional migration is much more difficult to forecast quantitatively.

– Analysis of the future location of economic activity needs a better theory and better data. The general principles underlying locational choice of industry are known. However, it is nearly impossible to extend these principles beyond particular current business decisions to whole industries, especially for many years in the future. Data are needed on the costs of production, potential suppliers and markets, and the costs of transportation, especially in the developing countries.

CONTENTS

EXECUTIVE SUMMARY

Substantial research progress has been made on the impacts of climate change on agriculture since the 1990 IPCC assessment, with new studies for different sites and countries covering many areas of the world. New studies also have been conducted that integrate site, country, and regional impacts to provide information about how global agricultural production and consumption may be affected. On the whole, these studies support the evidence presented in the first IPCC assessment that global agricultural production can be maintained relative to baseline production in the face of climate changes likely to occur over the next century (i.e., in the range of 1 to 4.5°C) but that regional effects will vary widely. Major uncertainties result from the lack of reliable geographic resolution in future climate predictions, difficulties in integrating and scaling-up basic physiologic responses and relationships, and difficulty in estimating farm sector response and adaptation to changing climate as it varies across the world. Thus, while there will be winners and losers stemming from climate impacts on agricultural production, it is not possible to distinguish reliably and precisely those areas that will benefit and those that will lose.

Major conclusions of the assessment cover four areas: (1) The direct and indirect effects of changes in climate and atmospheric constituents on crop yield, soils, agricultural pests, and livestock; (2) estimates of yield and production changes for specific localities, countries, and the world, based on studies that integrate multiple direct and indirect effects; (3) the conditions that determine vulnerability and areas and populations that are relatively more vulnerable to adverse changes; and (4) adaptation potential.

Direct and Indirect Effects

Experimental results, detailed modeling of basic processes, and knowledge of physical and biological processes provide basic understanding of direct and indirect effects of climate on agricultural production:

- The results of a large number of experiments to resolve the effect of elevated CO_2 concentrations on crops have confirmed a beneficial effect. The mean value yield response of C_3 crops (most crops except maize, sugar cane, millet, and sorghum) to doubled CO_2 is +30%. Measured response ranges from -10% to +80%. Only gradually is the basis for these differences being resolved. Factors known to affect the response include the availability of plant nutrients, the crop species, temperature, precipitation, and other environmental factors. Differences in experimental

technique also are responsible for variations in the measured response (High Confidence).
- Changes in soils, e.g., loss of soil organic matter, leaching of soil nutrients, and salinization and erosion, are a likely consequence of climate change for some soils in some climatic zones. Cropping practices such as crop rotation, conservation tillage, and improved nutrient management are, technically, quite effective in combating or reversing deleterious effects (High Confidence).
- Livestock production will be affected by changes in grain prices, changes in the prevalence and distribution of livestock pests, and changes in grazing and pasture productivity. Analyses indicate that intensively managed livestock systems have more potential for adaptation than crop systems. In contrast, adaptation may be more problematic in pastoral systems where production is very sensitive to climate change, technology changes introduce new risks, and the rate of technology adoption is slow (see Chapter 2) (Medium Confidence).
- The risk of losses due to weeds, insects, and diseases is likely to increase (Low Confidence).

Regional and Global Production Effects

To evaluate the direct and indirect effects of climate on yield at the farm, regional, or higher levels requires integrated models that consider system interactions. Issues of scale add uncertainty, and higher-order models have not generally taken into account the climatic effects on soils and pests. Despite these limitations, climate change studies show:

- Crop yields and productivity changes will vary considerably across regions. Thus, the pattern of agricultural production is likely to change in a number of regions (High Confidence).
- Global agricultural production can be maintained relative to base production under climate change as expressed by general circulation models (GCMs) under doubled CO_2 equilibrium climate scenarios (Medium Confidence).
- Based on global agricultural studies using doubled CO_2 equilibrium GCM scenarios, lower-latitude and lower-income countries have been shown to be more negatively affected. Again, crop model simulation results vary widely, e.g., ±20% changes in yield, for specific countries and sites across studies and GCM scenarios (Medium Confidence).

Vulnerability

Vulnerability is used here to mean the *potential* for negative consequences given the range of possible climate changes that might reasonably occur and is not a prediction that negative consequences will occur. Vulnerability can be defined at different scales, including yield, farm or farm sector, regional economic, or hunger vulnerability.

- Vulnerability to climate change depends on physical and biological response but also on socioeconomic characteristics. Low-income populations depending on isolated agricultural systems, particularly dryland systems in semi-arid and arid regions, are particularly vulnerable to hunger and severe hardship. Many of these at-risk populations are found in Sub-Saharan Africa, South and Southeast Asia, as well as some Pacific Island countries and tropical Latin America (High Confidence).

Adaptation

Uncertainty remains with regard to the ability of agricultural systems to adapt to climate change. Historically, farming systems have responded to a growing population and have adapted to changing economic conditions, technology, and resource availabilities. It is uncertain whether the rate of change of climate and required adaptation would add significantly to the disruption likely due to future changes in economic conditions, population, technology, and resource availabilities.

- Adaptation to climate change is likely; the extent depends on the affordability of adaptive measures, access to technology, and biophysical constraints such as water resource availability, soil characteristics, genetic diversity for crop breeding, and topography. Many current agricultural and resource policies are likely to discourage effective adaptation and are a source of current land degradation and resource misuse (High Confidence).
- National studies have shown incremental additional costs of agricultural production under climate change which could create a serious burden for some developing countries (Medium Confidence).

13.1. Introduction

Climate change will affect agriculture through effects on crops (Section 13.2); soils (Section 13.3); insects, weeds, and diseases (Section 13.4); and livestock (Section 13.5). Climatic conditions interact with agriculture through numerous and diverse mechanisms. Mechanisms, effects, and responses include, for example, eutrophication and acidification of soils, the survival and distribution of pest populations, the effects of CO_2 concentration on tissue- and organ-specific photosynthate allocation, crop breeding aims, animal shelter requirements, and the location of production (Brunnert and Dämmgen, 1994). Variation of agricultural and climatic conditions across the world leads to different local and regional impacts (Section 13.6). High levels of uncertainty necessitate assessment of vulnerability to the adverse effects of potential climate change (Section 13.7). The effects of climate change on local, national, and regional economies and food supplies depend on future economic and agricultural conditions and on the international transmission of supply shocks through international trade (Section 13.8). Historically, agriculture has proved to be highly adaptive to changing conditions, but uncertainty remains with regard to adaptation to potential climate change (Section 13.9). Emission-control efforts also will likely affect agriculture (Chapter 23), as will competition for land and water resources from other sectors affected by climate change (Chapter 25).

13.2. Climatic Effects on Crop Plants

The main climate variables important for crop plants, as for other plants, are temperature, solar radiation, water, and atmospheric CO_2 concentration. Important differences in temperature sensitivity and response to CO_2 exist among C_3, C_4, and CAM plants (Chapter A). While the basic physiological response of crop plants are no different than other plants of similar types, crop plants have been selected for particular traits and grow under more highly controlled conditions than plants growing in forests (managed and unmanaged) or other ecosystems. Most crop plants are C_3, the principal C_4 exceptions are maize, millet, sorghum, and sugar cane. Crop traits are selected and bred into different varieties to produce high yields for different climate and resource conditions. Most crop plants are grown as annuals (e.g., grains, potatoes, and most vegetable and fiber crops) with the crop species, variety, and planting time chosen by the farmer at the start of each growing season. Tree fruits, coffee, tea, cocoa, bananas, grapes, many forage and pasture crops, and other small fruits are the principal perennials. Nutrients and water which may be limited under natural conditions are more likely to be (or can be) augmented via fertilization, irrigation, and management of crop residue. Competition with other plants is controlled. The primary focus of crop production is the efficient production of harvestable yield, usually of only one component of the plant (e.g., seed, fruit, root, leaf).

13.2.1. Elevated CO_2 and Crops

Experiments concerning crop performance at elevated CO_2 concentrations in general show a positive but variable increase in productivity for annual crops (Kimball, 1983; Strain and Cure, 1985; Cure and Acock, 1986; Allen *et al.*, 1990; Kimball *et al.*, 1990; Lawlor and Mitchell, 1991; Bazzaz and Fajer, 1992; Gifford and Morison, 1993; Koerner, 1993; Rozema *et al.*, 1993; Mooney and Koch, 1994; Rogers *et al.*, 1994). Annual C_3 plants exhibit an increased production averaging about 30% at doubled (700 ppm) CO_2 concentrations; both biomass and seed production show an increase in almost all experiments under controlled conditions (Cure and Acock, 1986; Rogers and Dahlmann, 1993). Although the mean value response (+30% for C_3 crops) has been confirmed, variations in responsiveness between plant species and ecosystems persist (from -10% to +80%), and only gradually is the basis for these differences being resolved. Fewer experiments have been conducted with perennial crops—woody species in particular—but evidence suggests that the growth response would be less than for annual crops; the measured response for C_4 crops is much smaller than that for C_3 crops.

Variations in the growth enhancement among crops and different varieties of the same crop and over years are high, and interactions with nutrient and water availability are complex (e.g., Goudriaan and De Ruiter, 1983; Chaudhuri *et al.*, 1986; Mitchell *et al.*, 1993). The extent and occurrence of physiological adaptations of the photosynthetic apparatus, particularly of perennial plants, to long-term exposure to high CO_2 concentrations—which is more directly relevant to long-term climate change—are still unresolved (Cure and Acock, 1986; Bazzaz and Fajer, 1992; Wolfe and Erickson, 1993). Plants with nitrogen-fixing symbionts (e.g., peas, beans, alfalfa), under favorable environmental conditions for both symbiont and plant, tend to benefit more from enhanced CO_2 supplies than do other plants (Cure *et al.*, 1988). The content of nonstructural carbohydrates generally increases under high CO_2, while the concentrations of mineral nutrients and proteins are reduced (Mooney and Koch, 1994; Rogers *et al.*, 1994; Koerner and Miglietta, in press). Root/shoot ratios often increase under elevated CO_2 levels favoring root crops and also contribute to soil organic matter build-up (Mauney *et al.*, 1992; Mitchell *et al.*, 1993). Crop plants, like other plants, show increased water use efficiency under elevated CO_2 levels, but water consumption on a ground-area basis vs. a leaf-area basis is much less affected. Water use on a ground-area basis can actually increase if leaf area (canopy) increases. The range of water-use efficiencies among varieties for major crops is wide (e.g., Cure and Acock, 1986; Kimball *et al.*, 1993; Sombroek and Gommes, 1993), providing the opportunity to breed or select for improved efficiency. At higher CO_2 levels, plant growth damage done by air pollutants like nitrogen oxide (NO_x), sulfur dioxide (SO_2), and ozone (O_3) is reduced because of partial stomatal closing and other physiological changes (Van de Geijn *et al.*, 1993).

The wide range in estimated responses to elevated CO_2 is due in large part to the different experimental systems employed

(Gifford and Morison, 1993), each with advantages and disadvantages (Krupa and Kickert, 1989). Year-to-year variations in response also occur because of varying weather conditions that more or less favor CO_2 response of crops. The most widely used experimental system is the open-top chamber. Free-air CO_2 enrichment (FACE) experiments are more expensive but attempt to create conditions close to those likely to be experienced in an open field. Initial results from these experiments confirm the basic positive response of crops to elevated CO_2, but studies have been conducted only for a few crops (Mauney *et al.*, 1992). In addition, even the FACE experimental set-up creates a modified area (Kimball *et al.*, 1993; Vugts, 1993) analogous to a single irrigated field within a dry environment.

13.2.2. *Temperature, Moisture, and Other Variables*

Plant growth and crop yields clearly depend on temperature and temperature extremes, as shown for five major food crops (Table 13-1), and vary for crops with different photosynthetic pathways (Le Houerou *et al.*, 1993). The optimum range for C_3 crops is 15 to 20°C and for C_4 crops 25 to 30°C; for CAM

Table 13-1: Crop physiology: Temperature thresholds (°C) of some major crops of the world (optimum range refers to the entire growing season and narrows under high light and elevated CO_2).

Crop	Optimum Range	Lower Range	Upper Range	References/ Remarks
Wheat (C_3)	17–23	0	30–35	Burke *et al.*, 1988; Behl *et al.*, 1993; optimal enzyme function and representative seasonal foliage temperature
Rice (C_3)	25–30	7–12	35–38	Le Houerou *et al.*, 1993; Yoshida,1981
Maize (C_4)	25–30	8–13	32–37	Le Houerou, 1993; Decker *et al.*, 1986; Pollak and Corbett, 1993; Ellis *et al.*, 1992; Long *et al.*, 1983
Potato (C_3)	15–20	5–10	25	Haverkort, 1990; Prange *et al.*, 1990
Soybean (C_3)	15–20	0	35	Hofstra and Hesketh, 1969; Jeffers and Shibles, 1969

crops a nighttime temperature of 10 to 20°C is optimal. C_4 and CAM crops require a minimum temperature of 10 to 15°C for growth and are relatively sensitive to frost. The minimum temperature for C_3 crops ranges from 5 to 10°C; C_3 crops exhibit variable frost sensitivity. Cumulative temperature above minimum growing temperature is an important determinant of crop phenological development. For annual crops, warmer temperatures speed development, shortening the period of growth and lowering yield if shortened growth period is not fully compensated by more rapid development at the higher temperature (Ellis *et al.*, 1990). The amount of light received during the reproductive stage may determine whether yields fall (Acock and Acock, 1993).

The variation of temperature requirements and temperature extremes for different cultivars of the same species and among species, however, is quite wide for most crops, as shown for major crops such as wheat, rice, maize, and soybean (Table 13-2). Such variation in requirements provides significant scope for adaptation through switching among existing cultivars and crops or introducing genetic variability through conventional plant breeding.

It has been suggested that higher mean temperatures will be accompanied by higher variability and more frequent occurrence of extremes (Katz and Brown, 1992). Such changes could severely affect plant functioning at low and high mean temperatures (Larcher, 1980; Kuiper, 1993).

Climate variability and resultant interannual variability in yield is a fundamental feature of most cropping systems (Gommes, 1993). In temperate areas, low temperatures and/or frost occurrences are the usual limiting factor for growing season length. In tropical and subtropical areas, where temperature variation is less extreme throughout the year than in temperate areas, season-length and seasonal variation depend on regular patterns of precipitation.

Temperature, solar radiation, relative humidity, wind, and precipitation vary not only over the season and year but on a daily basis. The effects of variability can be both positive and negative depending on the crop and the nature of the variability. Cool-season vegetable crops (e.g., spinach, cauliflower, broccoli) perform best when nights are cool; their quality deteriorates under warmer temperatures. Apples, pears, cherries, and many other tree fruits require winter chilling periods for buds to set but can suffer near-total loss of the fruit crop if late frosts damage the blossoms. Alternate thawing and freezing of the ground can cause the loss of perennial forage crops such as alfalfa. Extreme climatic events (e.g., storms with high winds, flooding, heavy rains, hail, hard late or early frosts) can be responsible for severe or total crop loss.

The anticipated increase in temperatures with global warming can lead to spikelet sterility in rice, loss of pollen viability in maize, reversal of vernalization in wheat, and reduced formation of tubers and tuber bulking in potatoes for areas near critical thresholds (Table 13-3). Yield losses can be severe in these

Table 13-2: *Crop phenology for important crops.*

Crop	Base Temp. (°C)	Max. Devel. (°C)	Emergence to Pre-Anthesis (degree days)	Post-Anthesis to Maturity (degree days)	Reference
Wheat	0	20–25	750–1300	450–1050	Van Keulen and Seligman, 1987; Elings, 1992; Hodges and Ritchie, 1991
Rice	8	25–31	700–1300	450–850	Yoshida, 1981; Penning de Vries, 1993; Penning de Vries *et al*., 1989
Maize	7	25–35	900–1300	700–1100	Van Heemst, 1988; Pollak and Corbett, 1993; Kiniry and Bonhomme, 1991; Rötter, 1993
Soybean	0	25–35	highly variable	450–750	Wilkerson *et al*., 1989; Swank *et al*., 1987

Source: Adapted from Acock and Acock, 1993.
Notes: Base Temp. = minimum temperature for growth; Max. Devel. = optimum temperature for crop development; Emergence to Pre-Anthesis = cumulative degree days needed from crop emergence to pre-anthesis (flowering); Post-Anthesis to Maturity = cumulative degree days required (after flowering) to reach maturity.

cases, if temperatures exceed critical limits for periods as short as 1 hour during anthesis (flowering). Burke *et al*. (1988) found that under ample water supply different crop species manage to maintain foliage temperature within their specific optimum range (thermal kinetic window), thereby maximizing biomass accumulation.

Species-specific optimal temperature ranges are relatively narrow compared to diurnal and seasonal foliage temperature fluctuations. If temperature variability on a daily and seasonal basis were to decrease, crop cultivars in environments with mean temperatures close to cultivar-specific optima could profit from prolonged exposure to optimum temperatures. While variability in some climatic dimensions may increase, the temperature increase since the 1940s has been due mainly to increased nighttime temperature (Kukla and Karl, 1993), thus reducing the diurnal variation of temperature and considerably influencing the nighttime respiration. The response of respiration is theoretically derived and experimentally

Table 13-3. *Temperature thresholds: High temperature effects on key development stages of five major arable crops.*

Crop	Effect	Reference
Wheat	Temperature >30°C for more than 8 hours can reverse vernalization	Evans *et al*., 1975
Rice	Temperature >35°C for more than 1 hour at anthesis causes high percentage spikelet sterility	Yoshida, 1981
Maize	Pollen begins to lose viability at temperatures >36°C	Decker *et al*., 1986
Potato	Temperatures >20°C depress tuber initiation and bulking	Prange *et al*., 1990
Soybean	Great ability to recover from temperature stress; critical period in its development unknown	Shibles *et al*., 1975

Source: Acock and Acock, 1993.

well-established, but the concept is challenged for situations where plants or crops are grown continuously and have adapted to the higher temperature (Gifford and Morison, 1993).

Other environmental changes will interact with changes in climate variables and elevated CO_2 to affect crop yields. Among these are exposure to O_3—tropospheric (surface) concentrations of which have doubled over the past 100 years in the Northern Hemisphere (Feister and Warmbt, 1987; Volz and Kley, 1988; Anfossi *et al*., 1991) to a level estimated to reduce yields in the range of 1 to 30% (e.g., Ashmore, 1988; Van der Eerden *et al*., 1988; Bosac *et al*., 1993; Sellden and Pleijel, 1993)—and exposure to ultraviolet-B (UV-B) radiation, which is expected to increase due to stratospheric ozone depletion. UV-B fluxes depend on cloud cover (Van der Leun and Tevini, 1991) and decrease by a factor of 10 with latitude and increase with altitude. Thus, crops grown at high latitudes and high altitudes are most likely to be affected. Plant sensitivities vary widely by species (Rozema *et al*., 1991; Tevini, 1993) and across cultivars of species, such as soybeans (Biggs *et al*., 1981).

Some studies have investigated the combined effect of various stresses including climate, CO_2, O_3, and UV-B on crops (e.g., Goudriaan and De Ruiter, 1983; Chaudhuri *et al*., 1986; Allen, 1990; Mitchell *et al*., 1993; Krupa and Kickert, 1993). Results indicate that rice, barley, sorghum, soybean, oats, beans, and peas are relatively more sensitive to UV-B than other major crops and that wheat, maize, potatoes, cotton, oats, beans, and peas are relatively more sensitive to O_3. For other crops, including cassava, sugar cane, sweet potato, grapes, coconut, rye and peanuts, no clear results are available.

Consistent moisture availability throughout the crop growth period is critical. Overall, the hydrological cycle is expected to intensify with higher evaporation, air humidity, and precipitation. Higher temperatures would, at the same time, increase crop water demand. Global studies have found a tendency for increased evaporative demand to exceed precipitation increase

Box 13-1. Modeling Crop Response to Environmental Change

Climatic and other factors strongly interact to affect crop yields. Models have provided an important means for integrat-
ing many different factors that affect crop yield over the season (Rötter, 1993). Scaling up results from detailed under-
standing of leaf and plant response to climate and other environmental stresses to estimate yield changes for whole farms
and regions, however, can present many difficulties (e.g., Woodward, 1993).

Higher-level, integrated models typically accommodate only first-order effects and reflect more complicated processes
with technical coefficients. Mechanistic crop growth models take into account (mostly) local limitations in resource
availability (e.g., water, nutrients) but not other considerations that depend on social and economic response, such as soil
preparation and field operations, management of pests, and irrigation.

Models require interpretation and calibration when applied to estimating commercial crop production under current or
changed climate conditions (see Easterling *et al*., 1992; Rosenzweig and Iglesias, 1994); in cases of severe stress, relia-
bility and accuracy in predicting low yields or crop failure may be poor. With regard to the CO_2 response, recent compar-
isons of wheat models have shown that even though basic responses were correctly represented, the quantitative outcome
between models varied greatly. Validation of models has been an important goal (Olesen and Grevsen, 1993; Semenov *et
al*., 1993a, 1993b; Wolf, 1993a, 1993b; Delecolle, 1994; Iglesias and Minguez, 1994; Minguez and Iglesias, 1994).

Further integration of models of crop yield, phenology, and water use with geographic-scale agroclimatic models of crop
distribution and economic response has also occurred (e.g., Kaiser *et al*., 1993; Kenny *et al*., 1993; Rötter and van Diepen,
1994). Simplified representations of crop response have been used with climate and soil data that are available on a global
basis (Leemans and Solomon, 1993). More aggregated statistical models have been used to estimate the combined physical
and socioeconomic response of the farm sector (Mendelsohn *et al*., 1994; Darwin *et al*., 1995).

Incorporation of the multiple effects of CO_2 in models has generally been incomplete. Some do not include any CO_2
effects and thus may overestimate negative consequences of CO_2-induced changes in climate. Other models consider
only a crude yield effect. More detailed models consider CO_2 effects on water use efficiency (e.g., Wang *et al*., 1992;
Leuning *et al*., 1993). With few exceptions, most models fail to consider CO_2 interactions with temperature and effects
on reproductive growth (Wang and Gifford, 1995).

in tropical areas (Rosenzweig and Parry, 1994), but this result
varies locally and across climate scenarios. Large changes in
the seasonal pattern of rainfall or changes in the consistency
of rainfall within the crop growing season would likely matter
more for annual crops than changes in annual precipitation
and potential evaporation rates. Some studies suggest
increased intensity of rainfall, which may result in increased
runoff (Whetton *et al*., 1993). Changes in large-scale atmos-
pheric patterns such as the El Niño/Southern Oscillation
(ENSO) and tropical monsoons could cause significant shifts
in rainfall patterns, with consequent effects on agricultural
production. ENSO events currently have widespread and well-
documented impacts on production in Oceania, Latin
America, Africa, South and Southeast Asia, and the United
States (Folland *et al*., 1990, 1991; McKeon *et al*., 1990;
Nicholls and Wong, 1990; McKeon and White, 1992;
Rimmington and Nicholls, 1993), but climate scientists have
not resolved how ENSO events may be affected by long-term
climate change.

A variety of models (see Box 13-1) that integrate understand-
ing of crop yield and climate relationships have been used for
estimating changes in potential crop yield, zonal production
shifts, and regional and global production (see Sections 13.5
and 13.8.2).

13.3. Soil Changes and Agricultural Practices

Climate affects most major soil processes and is a major factor
in soil formation; the potential effects of changing climate and
higher atmospheric CO_2 on soils are highly interactive and
complex (Bouwman, 1990; Buol *et al*., 1990). Many of the
world's soils are potentially vulnerable to soil degradation
(e.g., loss of soil organic matter, leaching of soil nutrients,
salinization, and erosion) as a likely consequence of climate
change (see Chapter 4).

Cropping practices that maintain a more closed ground cover
over longer periods—including crop rotation, planting of cover
crops, and reduced or minimum tillage—combined with inte-
grated nutrient management are quite effective in combating or
reversing current land degradation and would be similarly
effective where climate change had the potential to exacerbate
land degradation (Brinkman and Sombroek, 1993; Rasmussen
and Collins, 1991; Logan, 1991). Brinkman and Sombroek
(1993) found that, in most cases, changes in soils by direct
human action, whether intentional or unintended, are likely to
have a greater impact than climate change. They found that
under a transient scenario of climate change, soil physical,
chemical, and biological processes will be given time to adapt,
thereby counteracting human-induced land degradation.

13.4. Weeds, Insects, and Diseases

Weeds, insects, and pathogen-mediated plant diseases are affected by climate and atmospheric constituents. Resultant changes in the geographic distribution of these crop pests and their vigor in current ranges will likely affect crops. Existing research has investigated climatic determinants of the range of many pests, but the potential changes in crop losses due to climatically driven changes in pests have not been included in most agricultural impact studies (Waggoner, 1983; Stinner *et al.*, 1987; Prestidge and Pottinger, 1990).

13.4.1. Weeds

Weeds will benefit from the "CO_2 fertilization effect" and from improvements in water use efficiency associated with increasing CO_2 concentrations, but the impact on crop production will depend on how enhanced-growth weeds compete with enhanced-growth crops. Of the 86 plant species that contribute 90% of per capita food supplies worldwide, 80 are C_3 plants (Prescott-Allen and Prescott-Allen, 1990), while 14 of the world's 18 worst weeds are C_4 plants (Holm *et al.*, 1977). Experiments generally show C_3 species to benefit from CO_2 enrichment at the expense of C_4 species (Patterson and Flint, 1980, 1990; Carter and Peterson, 1983; Patterson *et al.*, 1984; Wray and Strain, 1987; Bazzaz and Garbutt, 1988).

Regarding temperature, most weeds of warm season crops originate in tropical or warm temperate areas and are responsive to small increases in temperature. For example, the growth of three leguminous weeds increased significantly as day/night temperature increased (Flint *et al.*, 1984). Biomass of C_4 smooth pigweed (*Amaranthus hybridus*) increased by 240% for an approximate 3°C temperature increase; C_4 grasses also showed large increases (Flint and Patterson, 1983; Patterson, 1993).

Accelerated range expansion of weeds into higher latitudes is likely (Rahman and Wardle, 1990; Patterson, 1993) as demonstrated for itchgrass (*Rottboellia cochinchinensis*, Lour.), cogongrass (*Imperata cylindrica*), Texas panicum (*Panicum texanum*), and witchweed (*Striga asiatica*) (Patterson *et al.*, 1979; Patterson, 1995). However, not all exotic weeds will be favored by climatic warming. Patterson *et al.* (1986) found loss of competitiveness under warmer conditions for the southward spread of wild proso millet (*Panicum miliaceum*) in the southwestern United States.

Increasing CO_2 and climate change probably will also affect mechanical, chemical, and natural/biological efforts to control weeds (Patterson, 1993, 1995), which currently cause worldwide crop production losses of about 12% (25% for traditional production systems) (Parker and Fryer, 1975). Environmental factors including temperature, precipitation, wind, soil moisture, and atmospheric humidity influence when herbicides are applied, as well as their uptake and metabolism by crops and target weeds (Hatzios and Penner, 1982; Muzik, 1976). High leaf starch concentrations, which commonly occur in C_3 plants grown under CO_2 enrichment (Wong, 1990), might interfere with herbicide activity. CO_2 enrichment also increases the growth of rhizomes and tubers in C_3 plants (Oechel and Strain, 1985), which could reduce the effectiveness of chemical and mechanical control of deep-rooting, perennial C_3 weeds. On the other hand, increased temperatures and increased metabolic activity tend to increase uptake, translocation, and effectiveness of many herbicides. Natural and biological control of weeds and other pests depends on the synchrony between the growth, development, and reproduction of biocontrol agents and their targets. Such synchrony may be disrupted if climate changes rapidly, particularly if climatic extremes occur more frequently. Global warming could facilitate overwintering of insect populations and favor earlier poleward migrations in the spring, which could increase the effectiveness of biological control of weeds in some cases. Conversely, such enhanced over-winterings would accelerate the spread of viruses by migrating vectors like aphids.

13.4.2. Insect Activity and Distribution

Climate change will affect the distribution and degree of infestation of insect pests through both direct effects on the life cycle of insects and indirectly through climatic effects on hosts, predators, competitors, and insect pathogens. There is some evidence that the risk of crop loss will increase due to poleward expansion of insect ranges. Insect populations faced with modified and unstable habitats created under annual arable agricultural systems generally must diapause (enter a state of dormancy), migrate, otherwise adapt genetically, or die. Insect species characterized by high reproduction rates are generally favored (Southwood and Comins, 1976). Human alteration of conditions that affect host plant survival—irrigation, for example—also affects phytophagous (leaf-eating) insect populations.

Insect life cycle processes affected by climate and weather include lifespan duration, fecundity, diapause, dispersal, mortality, and genetic adaptation. Porter *et al.* (1991) list the following effects of temperature on insects: limiting geographical ranges; over-wintering; population growth rates; number of generations per annum; length of growing season; crop-pest synchronization; interspecific interactions; dispersal and migration; and availability of host plants and refugia. The effects of climate and weather on insect life cycles have been documented for a wide variety of insect pests of agriculture, rangelands, and forests (Dobzhansky, 1965; Fye and McAda, 1972; Tauber *et al.*, 1986; Mattson and Haack, 1987; Kingsolver, 1989; Cammell and Knight, 1991; Harrington and Stork, 1995). Many effects involve changes in the severity of outbreaks following extreme weather events (on the order of hours to weeks). Freezing temperatures are a major factor in mortality, but *Drosophila* sp. insects that survive relatively colder temperatures have been found to be more fecund than cohorts that were not exposed to the low temperatures (Dobzhansky, 1965). Temperatures that exceed critical thresholds frequently have adverse effects on fecundity, as in the cases

of bollworm, *Helicoverpa zea* (Boddie); tobacco budworm, *Heliothis virescens* (F.); beet armyworm, *Spodoptera exigua* (Hübner); cabbage looper, *Trichoplusia ni* (Hübner); saltmarsh caterpillar, *Estigmene acrea* (Drury); and pink bollworm, *Pectinophora gossypiella* (Saunders) (Fye and McAda, 1972).

Abnormally cool, wet conditions are associated with high subsequent infestations of cotton by cotton tipworm, *Crocidosema plebejana* (Zeller) (Hamilton and Gage, 1986). November precipitation and April temperature are the best indicators of mean grasshopper densities in Southern Idaho (Fielding and Brusven, 1990). Drought can affect various physiological processes of plants, which may increase the plants' attractiveness and susceptibility to phytophagous insects (Mattson and Haack, 1987). Intense precipitation has been noted as a deterrent to the occurrence and success of oviposition by insects such as the European corn borer, *Ostrinia nubilalis* (Hübner) (Davidson and Lyon, 1987). Abundant precipitation can affect mortality, for example, through drowning of soil-dwelling insects (Watt and Leather, 1986) but is more likely to affect insects indirectly through climatic effects on insect pathogens, predators, and parasites, as has been shown for *H. zea* pupae especially under persistently saturated soil conditions (Raulston *et al*., 1992).

While the specific ways in which climate change could affect persistent wind patterns such as nocturnal wind jets in the United States and convergence systems such as the Inter-Tropical Convergence Zone (ITCZ) are poorly predicted by GCMs, changes in the strength, timing, and geographical extent of these systems have been hypothesized. Important insect pests of agriculture currently use these systems to disperse widely from decaying habitats to viable habitats (Pedgley, 1982). Corn earworm, *H. zea* moths in the United States (Westbrook *et al*., 1985; Scott and Achtemeier, 1987; Lingren *et al*., 1993), grasshoppers or locusts [*Ailopus simulatrix* (Walker)], old world bollworm [*Heliothis armigera* (Hübner)], and whitefly [*Bemisia tabaci* (Gennadius)] disperse via atmospheric transport. In the case of the ITCZ and locusts, the winds also contribute ephemeral precipitation for host plants as reviewed by Joyce (1983) and Rainey (1989). Changes in these systems would affect the speed and range of dispersal of these pests.

Many of the documented effects of climate on insects are based on unusual weather events affecting the severity of insect outbreaks within their normal range or the (unintended) introduction of exotic species into new environments or extension of (host) crops into new environments (e.g., through irrigation). Human-induced local climate change within urban areas provides evidence of how insects can adapt to changes in their environment. Examples of genetic adaptation include: froggatt (*Dacus tryoni*), lucerne flea (*Sminthurus viridis* L.) and sheep blowfly (*Lucilia cuprina*) (Wied.) in Australia after introduction from Europe or with the expansion of crop areas; the European corn borer, *O. nubilalis* (Hübner) and the European spruce sawfly, *Gilpinia hercyniae* (Hartig) in North America after introduction from Europe; and *Drosophila serrata*

Mallock across latitudes (Birch, 1965). *Drosophila serrata* Mallock also has responded by natural selection to the changed conditions in large cities (Dobzhansky, 1965). Selection to tighten host-insect interaction [such as codling moth, *Cydia pomonella* (L.), in fruit trees] appears to favor the evolution of isolated host races (Poshly and Bush, 1979). Climatic, agronomic, political, and economic factors jointly led to populations of boll weevil, *Anthonomus grandis grandis* Boheman, which adapted differently across cotton areas in the United States (Terranova *et al*., 1990). Although insect populations have been redistributed during periods of major climatic change, a continuous intermixing of beetle species' gene pools in the Rocky Mountains of the United States was determined to have prevented speciation (Elias, 1991).

Understanding of insect physiological development and behavior has led to the development of numerical models that estimate insect growth, movement, and mortality in response to potential changes in climate (Goodenough and McKinion, 1992). Minimum and maximum temperatures, required cumulative degree days, and, where important, the effects of drought or wet conditions (which are the basis for such models), have been established for many common agricultural pests (e.g., Fye and McAda, 1972; Davidson and Lyon, 1987). Simulation models predict potential redistribution of insects under simulated climates.

Specific studies of the likely impacts of climate change were reviewed by Cammel and Knight (1991), Porter *et al*. (1991), Sutherst (1990, 1991), and Sutherst *et al*. (1995). They demonstrate that impacts could be severe in many different environments and involve numerous different species of insect pests. Principal concern is with species that can increase their population size by undergoing an extra generation each year in warmer climates or expand their geographical distributions. For example, Porter *et al*. (1991) found that in Europe *O. nubilalis* would shift 1220 km northward if temperature increased by 3° to 6°C by 2025–2070. For a 3°C temperature increase in Japan, Mochida (1991) predicted expanded ranges for tobacco cut worm (*Spodoptera litura*), southern green stink bug (*Nezera viridula*), rice stink bug (*Lagynotomus eleongatus*), lima-bean pod borer (*Etiella zinckenella*), common green stink bug (*Nezera antennata*), soybean stem gall (*Asphondylia sp*.), rice weevil (*Sitophilus oryzae*), and soybean pod borer (*Legumunuvora glycinivorella*), but a decreased range for rice leaf beetle (*Oulema oryzae*) and rice leaf miner (*Agromyza oryzae*). Vegetation subzones were linked with microclimates to extrapolate spruce weevil hazard zones in British Columbia (Spittlehouse and Sieben, 1994). Models that match the presence of particular species with discrete ranges of temperature and precipitation parameters such as CLIMEX may be especially appropriate for projecting the effects of climate change on insect redistribution (Worner, 1988; Sutherst *et al*., 1995).

Actual insect distributions under climate change will also depend on host distributions (Rainey, 1989), competition with existing species (DeBach, 1965), adaptability to new conditions, and the presence of natural enemies in the area. Because

climate effects on insect life cycles frequently depend on extreme events (e.g., freezing, intense precipitation) and climatic features such as the persistent winds of the Inter-Tropical Convergence system, the reliability of predicted redistribution of insects depends, in part, on the reliability of predictions of these features of climate.

13.4.3. Plant Diseases

The occurrence of plant fungal and bacterial pests depends on temperature, rainfall, humidity, radiation, and dew. Climatic conditions affect the survival, growth, and spread of pathogens, as well as the resistance of hosts. Friedrich (1994) summarizes the observed relationship between climatic conditions and important plant diseases. Among these, mild winters have been associated with more rapid and stronger outbreaks of powdery mildew (*Erysiphe grammis*), brown leaf rust of barley (*Puccinia hordei*), and strip rust of cereals (*Puccinia striiformis*) (Meier, 1985). Mild winters combined with very warm weather conditions provide optimal growth conditions for cercosporea leaf spot disease (*Cercosporea beticola*), powdery mildew (*Erysiphe betae*), and rhizomania disease (*Rizomania*) (Treharne, 1989). Warm, humid conditions lead to earlier and stronger outbreaks of late potato blight (*Phytophthora infestans*) (Löpmeier, 1990; Parry *et al*., 1990). Dry and hot summers generally reduce infestations of most fungal diseases because plant resistance is increased. Summer dryness, particularly in early summer, also decreases rhynchosporium leaf blotch (*Rhynchosporium secalis*) and septoria leaf spot diseases (*Septoria tritici* and *S. nodorum*), but more frequent summer precipitation, particularly heavy storms, would increase incidences of these diseases because rain and rain-borne splash water is the means by which disease spores are spread (Royle *et al*., 1986). Warmer temperatures would likely also shift the occurrence of these diseases into presently cooler regions (Treharne, 1989).

13.5. Animal Agriculture

Climate affects animal agriculture in four ways: through (1) the impact of changes in livestock feedgrain availability and price (e.g., Adams *et al*., 1990; Bowes and Crosson, 1993; Kane *et al*., 1993; Rosenzweig and Parry, 1994); (2) impacts on livestock pastures and forage crops (Wilson, 1982; Martin *et al*., 1991; Easterling *et al*., 1993; McKeon *et al*., 1993); (3) the direct effects of weather and extreme events on animal health, growth, and reproduction (Bianca, 1970; Rath *et al*., 1994); and (4) changes in the distribution of livestock diseases (Stem, 1988; U.S. EPA, 1989).

Generally, the impacts of changes in feedgrain prices or forage production on livestock production and costs are moderated by markets. Impacts of changes in feedgrain supply on the supply of meat, milk, egg, and other livestock products in terms of price increase is substantially less than the initial feedgrain price shock (Reilly *et al*., 1994). Bowes and Crosson (1993)

demonstrated the importance of feed exports or imports into a region in determining downstream impacts on livestock and meatpacking industries. Abel and Levin (1981) found that, for developing country agriculture, livestock are a better hedge against losses than are crops because animals are better able to survive extreme weather events such as drought. The relatively lower sensitivity of livestock to climate change is also documented for the historical case of the U.S. Dust Bowl experience of the 1930s (Waggoner, 1993).

The impact of climate on pastures and unimproved rangelands may include deterioration of pasture quality toward poorer quality, subtropical (C_4) grasses in temperate pastoral zones as a result of warmer temperatures and less frost, or increased invasion of undesirable shrubs—but also potential increases in yield and possible expansion of area if climate change is favorable and/or as a direct result of increasing CO_2 (Martin *et al*., 1993; McKeon *et al*., 1993; Salinger and Porteus, 1993; Campbell *et al*., 1995). (See Chapter 2 for details on possible changes in species composition of rangelands and effects on pastoral agriculture.)

Heat stress has a variety of detrimental effects on livestock (Furquay, 1989), with significant effects on milk production and reproduction in dairy cows (Johnston, 1958; Thatcher, 1974; Khan, 1991; Orr *et al*., 1993). Swine fertility shows seasonal variation due to seasonal climate variability (Claus and Weiler, 1987). Reproductive capabilities of dairy bulls and boars and conception in cows are affected by heat stress (Egbunike and Elmo, 1978; Cavestany *et al*., 1985; Berman, 1991). Livestock management and development of breeds better-suited to tropical climates has been a specific consideration (Bonsma, 1949; Du Preez *et al*., 1990).

Analyses suggest that warming in the tropics and in the subtropics during warm months would likely impact livestock reproduction and production negatively (e.g., reduced animal weight gain, dairy production, and feed conversion efficiency) (Hahn *et al*., 1990; Baker *et al*., 1993; Klinedinst *et al*., 1993; Rath *et al*., 1994). Results are mixed for impacts in temperate and cooler regions: forage-fed livestock generally do better (due to more forage) but more capital-intensive operations, like dairy, are negatively affected (Parry *et al*., 1988; Baker *et al*., 1993; Klinedinst *et al*., 1993). Warming during the cold periods for temperate areas would likely be beneficial to livestock production due to reduced feed requirements, increased survival of young, and lower energy costs.

Impacts may be minor for relatively intense livestock production systems (e.g., confined beef, dairy, poultry, swine) because such systems control exposure to climate and provide opportunity for further controls (e.g., shading, wetting, increasing air circulation, air conditioning, and alterations of barns and livestock shelters). Livestock production systems that do not depend primarily on grazing are less dependent on local feed sources, and changes in feed quality can be corrected through feed supplements. The fact that livestock production is distributed across diverse climatic conditions from

cool temperate to tropical regions provides evidence that these systems are adaptable to different climates.

Many studies of climate and weather impacts on livestock find that the principal impacts are an increased role for management, adoption of new breeds in some cases where climate changes are moderate (for example, Brahman cattle and Brahman crosses are more heat- and insect-resistant than breeds now dominant in Texas and Southern Europe), and introduction of different species in some cases of extreme weather changes (Entwistle, 1974; Hahn, 1988, 1994; Hahn *et al.*, 1990; Baker *et al.*, 1993; Baker, 1994; Klinedinst *et al.*, 1993; Rath *et al.*, 1994).

13.6. Regional Climate Impacts: Studies and Issues

Variation of agriculture systems, climates, resources, and economic characteristics across and within countries may be more important in determining the effects of climate change than differences in climate scenarios themselves. Agricultural policy is an important consideration in most regions. Agricultural policies have had many and changing goals. Climate change is generally not among top policy priorities for agricultural policymakers, but climate change could affect the cost and likelihood of achieving other policy priorities— such as food adequacy and reduction of chronic hunger, improving export competitiveness, assuring regional and national economic and social development, increasing farm income and the viability of rural communities, assuring water availability and quality, reducing or reversing land degradation

and soil loss through erosion, and other conservation and environmental objectives.

13.6.1. Africa and the Middle East

While Africa, particularly sub-Saharan Africa, is highly dependent on agriculture, relatively little quantitative work has been done on the impacts of climate change. Little or no effort has been devoted to studying agricultural effects on countries of the Middle East. The available studies for sub-Saharan Africa suggest that critical thresholds are related to precipitation and the length of the growing season, although warmer temperatures and increased radiation may benefit highland areas. National and local assessments providing a detailed understanding of crop-specific responses and regional impacts are still lacking.

Recent studies (Ominde and Juma, 1991; Ottichilo *et al.*, 1991; Downing, 1992; Schulze *et al.*, 1993; Sivakumar, 1993; Magadza, 1994) indicate that most of Africa will be sensitive to climate change, although some regions may benefit from warmer and wetter conditions (Table 13-4). Downing (1992), in analyses for Kenya, Zimbabwe, and Senegal, evaluated the sensitivity to incremental climatic variations suggested by GCM scenarios for the region. Nationally, he estimated that potential food production in Kenya would increase, particularly if rainfall increases, but that the impacts would vary regionally; sub-humid and semi-arid provinces supporting socioeconomically vulnerable groups would be negatively affected even with increases in national food production potential.

Table 13-4: *Selected crop studies for Africa and the Middle East.*

Study	Scenario	Geographic Scope	Crop(s)	Yield Impact (%)	Other Comments
Eid, 1994	GISS, GFDL, UKMO	Egypt	Wheat Maize	-75 to -18 -65 to +6	w/ CO_2 effect; also temperature and precip. sensitivity; adaptation would require heat-resistant variety development
Schulze *et al.*, 1993	+2°C (1)	South Africa	Biomass Maize	decrease increase	Mapped results, not summarized as average change for entire region
Muchena, 1994	GISS, GFDL, UKMO	Zimbabwe	Maize	-40 to -10	w/ CO_2 effect; also temperature and precip. sensitivity; adaptations (fertilizer and irrigation) unable to fully offset yield loss
Downing, 1992	+2/+4°C, ±20% precip.	Zimbabwe Senegal Kenya	Maize Millet Maize	-17 to -5 -70 to -63 decrease	Food availability estimated to decline in Zimbabwe; carrying capacity fell 11 to 38% in Senegal; overall increase for all crops in Kenya with zonal shifts
Akong'a *et al.*, 1988	Historical droughts, sensitivity	Kenya	Maize, livestock	negative effects of drought	Considered broader socioeconomic impacts, small-holder impacts, and policy implications
Sivakumar, 1993	1945–64 vs. 1965–88	Niger, West Africa	Growing season	reduced 5–20 days	Crop variety development, timely climate information seen as important adaptation strategies

Akong'a *et al.* (1994) and Sivakumar (1993) considered the effects of climatic variability (primarily periodic droughts) on agriculture in some areas of the region, finding that such droughts have significant negative effects on production, crop season length, and higher-order social impacts. The persistence of such periodic droughts and the potential for them to change in frequency and severity in the Sahel and in eastern and southern Africa indicate the need for further research to develop adaptive strategies. The effects of greater frequency and severity include growing aridity in the savannas; deforestation and soil erosion in all farming systems but particularly in the humid, sub-humid, and equatorial regions; and salinization of irrigated lands. The economies of countries of North Africa and the Middle East are generally less dependent on agriculture than are those of sub-Saharan Africa. One study for Egypt (Eid, 1994) indicated the potential for severe impacts on national wheat and maize production.

13.6.2. South and Southeast Asia

South and Southeast Asia include the southern portion of Asia, from Pakistan in the west to Vietnam in the east, as well as Indonesia and the Philippines. Seasonal monsoons are a dominant climate feature that affect agriculture. Matthews *et al.* (1994a, 1994b) have estimated the impacts on rice yields for many countries in the region for equilibrium climate scenarios of three major GCMs that predict temperature and precipitation increases for the region. The results show substantial variation in impact across the region and among the GCMs (Table 13-5).

Table 13-5: Selected crop studies for South and Southeast Asia.

Study	Scenario	Geographic Scope	Crop(s)	Yield Impact (%)	Other Comments
Rosenzweig and Iglesias (eds.), 1994[1]	GCMs	Pakistan	Wheat	-61 to +67	UKMO, GFDL, GISS, and +2°C, +4°C,
		India	Wheat	-50 to +30	and ±20% precip; range is over sites and
		Bangladesh	Rice	-6 to +8	GCM scenarios with direct CO_2 effect;
		Thailand	Rice	-17 to +6	scenarios w/o CO_2 and w/ adaptation also
		Philippines	Rice	-21 to +12	were considered; CO_2 effect important in offsetting losses of climate-only effects; adaptation unable to mitigate all losses
Qureshi and Hobbie, 1994	average of 5 GCMs	Bangladesh	Rice	+10	GCMs included UKMO, GFDLQ,
		India	Wheat	decrease	CSIRO9, CCC, and BMRC; GCM results
		Indonesia	Rice	-3	scaled to represent 2010; includes CO_2
			Soybean	-20	effect
			Maize	-40	
		Pakistan	Wheat	-60 to -10	
		Philippines	Rice	decrease	
		Sri Lanka	Rice	-6	
			Soybean	-3 to +1	
			Coarse Grain	decrease	
			Coconut	decrease	
Parry *et al.*, 1992	GISS	Indonesia	Rice	approx. -4	Low estimates consider adaptation; also
			Soybean	-10 to increase	estimated overall loss of farmer income
			Maize	-65 to -25	ranging from $10 to $130 annually
		Malaysia	Rice	-22 to -12	
			Maize	-20 to -10	Maize yield affected by reduced radiation
			Oil Palm	increase	(increased clouds); variation in yield
			Rubber	-15	increases; range is across seasons
		Thailand sites	Rice	-5 to +8	
Matthews *et al.*, 1994a, 1994b	3 GCMs	India	Rice	-3 to +28	Range across GISS, GFDL, and UKMO
		Bangladesh		-9 to +14	GCM scenarios and crop models; included
		Indonesia		+6 to +23	direct CO_2 effect; varietal adaptation was
		Malaysia		+2 to +27	shown to be capable of ameliorating the
		Myanmar		-14 to +22	detrimental effects of a temperature
		Philippines		-14 to +14	increase in currently high-temperature
		Thailand		-12 to +9	environments

[1] Country studies were by Qureshi and Iglesias, 1994; Rao and Sinha, 1994; Karim *et al.*, 1994; Tongyai, 1994; and Escaño and Buendia, 1994, for Pakistan, India, Bangladesh, Thailand, and the Philippines, respectively.

Spikelet sterility emerged as a major factor determining the differential predictions; where current conditions were near critical thresholds, a difference in mean temperature of less than a degree resulted in a positive yield change rapidly becoming a large decline. However, genetic variability among varieties suggests relative ease in adapting varieties to new climate conditions. Temperature effects alone were generally found to reduce yields, but CO_2 fertilization was a significant positive effect.

Brammer *et al*. (1994) conclude that, among other things, the diversity of cropping systems does not allow a conclusion of magnitude or direction of impact to be made for Bangladesh at this time. Parry *et al*. (1992) showed yield impacts that vary across the countries of Thailand, Indonesia, and Malaysia and across growing season. Coastal inundation was also estimated to be a threat to coastal rice and to fish, prawn, and shrimp ponds. These authors estimated that a 1-meter sea-level rise could cause a landward retreat of 2.5 km in Malaysia; such a rise was estimated to threaten 4200 ha of productive agricultural land, an area equal to slightly less than 1% of Malaysia's paddy rice area. Model results showed that under Goddard

Institute for Space Studies (GISS) doubled CO_2 climates, erosion rates in three Malaysian river basins increased from 14–40%, and soil fertility declined on average by 2–8%.

13.6.3. *East Asia*

Several major studies have been conducted for countries in East Asia, including China (mainland and Taiwan), North and South Korea, and Japan. Possible climatic impacts span a wide range depending on the climate scenario, geographic scope, and study (Table 13-6). For China, results show generally negative yield effects but range from less than 10% (Zhang, 1993) to more than 30% (Jin *et al*., 1994). While finding large changes for all of China, Hulme *et al*. (1992) conclude that to a certain extent, warming would be beneficial, with increasing yield due to diversification of cropping systems. However, they estimated that by 2050, when they expect an average warming for China of 1.2°C, increased evapotranspiration would generally exceed increases in precipitation, thus leading to a greater likelihood of yield loss due to water stress for some rice-growing areas, even as the area suitable for rice increases.

Table 13-6: *Selected crop studies for East Asia.*

Study	Scenario	Geographic Scope	Crops	Yield Impact (%)	Other Comments
Tao, 1992	2 x CO_2 +1°C	China	Wheat Rice Cotton, Fruits, Oil Crops, Potatoes, Corn	-8 -6 -4 to +1	Agricultural productivity loss >5%; included direct CO_2 effect; positive effects in NE and NW; negative in most of the country; no change in SW
Zhang, 1993	+1.5°C	South of China	Rice	-11 to -7	Double-crop; included direct CO_2 effect
Jin *et al*., 1994	GCMs	South of China	Rainfed Rice Irrigated Rice	-78 to -6 -37 to +15	Range across GISS, GFDL, and UKMO scenarios; no consideration of enrichment effects of CO_2
Sugihara, 1991	2 x CO_2 +3°C	Japan	Rice	+10	
Suyama, 1988	+2°C	Japan	Temperate Grass	-10 to +10	Average +5.6% in productivity for grass; included direct CO_2 effect
Yoshino, 1991	+2°C	Japan	Sugar Cane	-8	Rainfall was reduced 25 to 30%, May to October
Seino, 1994	GISS, GFDL, UKMO	Japan	Rice Maize Wheat	-11 to +12 -31 to +51 -41 to +8	Impacts vary by GCM scenarios and area; included direct CO_2 effect; generally positive in N and negative in S
Horie, 1993	GCMs	Hiroshima and Akita, Japan	Rice	-45 to +30	Estimated 14% increase for all of Japan; range based on different crop models, GCMS, and across sites; included direct CO_2 effect; Akita more favorable than Hiroshima
Matthews *et al*., 1994a, 1994b	GCMs	South Korea Mainland China Taiwan Japan	Rice	-22 to +14 -18 to -4 +2 to +28 -28 to +10	Range across GISS, GFDL, and UKMO scenarios and crop models; included direct CO_2 effect; varietal adaptation capable of ameliorating the effects of a temperature increase in currently hot environments

For China, warming would likely cause a general northward movement of agroclimatic regions, with certain exceptions in the south where the moisture deficit may increase even more than in the north. The general possibility of increased summer dryness in the continental mid-latitudes suggests the following six areas as most likely to be negatively affected by climate change (Lin Erda, 1994): the area around the Great Wall lying southeast of the transition belt between crop agriculture and animal husbandry; the Huang-Hai Plains where dryland crops like wheat, cotton, corn, and fruit trees are grown; the area north of Huai River including Eastern Shandong that lies along the south edge of the south temperate zone; the central and southern areas of Yunnan Plateau; middle and lower reaches of Yangtze River; and the Loess Plateau. In general, these areas would be at heightened risk of drought and would suffer potential increases in soil erosion. The Yunnan Plateau, with generally abundant rainfall, is subject to alternating droughts and waterlogging; production is sensitive to changes that would increase the variability of climate.

Indices of vulnerability based on physical productivity and socioeconomic capability to adapt show that among China's thirty provinces, Shanxi, Inner Mongolia, Gansu, Hebei, Qinghai, and Ningxia are particularly vulnerable and less able to adapt to climate change. These seven provinces produced 12% of China's total agricultural output value in 1990 (*Statistical Yearbook of Agriculture of China*, 1991). Thus, the areas along the Great Wall and Huang-Hai Plains are areas that are both socioeconomically and agronomically vulnerable to climate change and also are areas where climate projections suggest possible adverse changes in climate.

Climate change will occur against a steadily increasing demand for food in China over the next 55 years (Lu and Liu, 1991a, 1991b). The increased annual cost of government investment only (excluding farmers' additional costs) in agriculture due to climate change through 2050 was estimated at 3.48 billion U.S. dollars (17% of the cost of government investment in agriculture in 1990).

Studies for Japan (Table 13-6) indicate that the positive effects of CO_2 on rice yields would generally more than offset negative climatic effects in the central and northern areas, leading to yield gains; in the southwest, particularly in Kyushu, the rice yield effects were, on balance, estimated to be negative for several climate scenarios (Seino, 1993a, 1993b). Horie (1987) found generally negative effects on rice yield in Hokkaido under the GISS climate scenario when rice variety was not changed but found increased yields if longer maturing varieties were adopted. Horie (1991), under the Oregon State University (OSU) climate scenario, found that rice yields would fall in most areas of the country but that changes in rice variety and other management changes could recover most losses except in the southwest, where the projected increase in temperature of 4.0–4.5°C exceeded the temperature tolerances of japonica rice varieties. Additional considerations for Japanese agriculture are possible changes in flowering and maturation of fruit trees, with potential northward shifts in cultivated areas and changed distribution of insect pests (Seino, 1993a).

13.6.4. Oceania and Pacific Island Countries

Oceania includes Australia, New Zealand, Papua New Guinea, and numerous small islands and coral atolls of the Pacific Island Countries (PICs).

Findings for Australia include: (1) poleward shifts in production, (2) varying impacts on wheat including changes in grain quality, (3) likely inadequate chilling for stone fruit and pome fruit and lower fruit quality, (4) increased likelihood of heat stress in livestock, particularly dairy and sheep, (5) increased infestation of tropical and subtropical livestock parasites but possible decreases for other species, (6) livestock benefits due to warmer and shorter winters, (7) increased damage due to floods and soil erosion, (8) increased drought potential with wheat and barley more sensitive than oats, (9) changes in the severity of outbreaks of downy mildew on grapevines and rust in wheat, and (10) beneficial effects of elevated CO_2 levels for many agricultural crops (Hobbs *et al.*, 1988; Nulsen, 1989; Pittock, 1989; Wardlaw *et al.*, 1989; Blumenthal *et al.*, 1991; Wang *et al.*, 1992; CSIRO, 1993; Hennessy and Clayton-Greene, 1995; Wang and Gifford, 1995).

Studies of New Zealand agriculture considered the main effects of climate change on New Zealand's important pastoral agriculture to be: (1) a poleward spread of subtropical pastures, (2) a resultant decrease in the area of temperate pasture, (3) higher yields, (4) altered seasonality of production, (5) spread of growth to higher elevations, and (6) decreased growth in the eastern areas of the North Island due to drier and warmer conditions (Ministry for the Environment, 1990; Salinger and Hicks, 1990; Martin *et al.*, 1991). Models to predict effects on forage production systems are currently being developed and validated. Initial modeling simulations of the effects of doubled-CO_2 climates on pasture yield including the beneficial effects of CO_2 varied from +10 to +77% (Korte *et al.*, 1991; Butler *et al.*, 1991; Martin *et al.*, 1991). The higher figures, however, likely overestimated the beneficial effects of CO_2 (Campbell, 1994). More recent work (Campbell *et al.*, 1995; Newton *et al.*, in press) indicates gains of up to 15%.

Studies have found variable impacts on horticultural crops in New Zealand, with a general poleward shift, including an expansion of the area for subtropical crops but a contraction of area suitable for temperate crops such as apples and kiwi fruit that require winter chilling (Salinger *et al.*, 1990). Studies for maize suggest expansion of the suitable growing area into the Canterbury Plains of the South Island (Kenny *et al.*, 1994; Tate *et al.*, 1994; Warrick and Kenny, 1994).

For small island states, fewer studies have been conducted. Singh *et al.* (1990) conclude that, in general, crop yields would be lower because of reduced solar radiation (from increased cloudiness), higher temperature (leading to shorter growth duration and increased sterility), and water availability (both drought and inundation). Sea water intrusion also could affect some coastal areas. Some of the negative effects, particularly

Table 13-7: *Selected studies for Australia and New Zealand.*

Study	Scenario	Geographic Scope	Crops	Yield Impact (%)	Other Comments
Campbell, 1994; Campbell *et al*., 1995; Newton *et al*., in press	Various	New Zealand	Pasture	increase overall, but decrease in some regions	GCM scenarios and climate sensitivity result in yield increases w/ and w/o CO_2 fertilization; increases of up to 15% w/ CO_2 fertilization; earlier studies found larger increases, but likely overestimated the CO_2 effect; additional findings include altered seasonality of pasture with effects on livestock management
Salinger *et al*., 1990	*	New Zealand	Temperate Crops and Pasture	increase	Crop shifts of 200m in altitude and 200km poleward; earlier crop maturation; longer frost-free season
McKeon *et al*., 1988	+2°C, -20% winter precipitation, +30% rest	SW Queensland, Australia	Semi-Arid Perennial Grass, Wheat	+31 (-1, +35) +23 (-6, +35)	Temperature only (precipitation only in parentheses); no CO_2 effect; for grasslands, increased risk from undesirable shrubs and grasses, animal nutrition and health, and soil erosion; new areas may be available
Vickery *et al*., 1993	+2°C, +10 to +20% precip. Nov. to March	Northern NSW, Australia	Cool Temperate Grazing	not assessed	Expansion of high NPP (3.2 to 4.8 t/ha) area from 59 to 64% of the region; soil and landscape as possible limiting factors not considered
Erskine *et al*., 1991	GISS, GFDL, UKMO	S. Australia	Wheat	-6 to +13	Included CO_2 to 555 ppm; results w/o CO_2 were -15 to -16%; no varietal adaptation or other management change
Wang *et al*., 1992	+3°C	Horsham, Victoria, Australia	Wheat	-34 to +65	Included CO_2 to 700 ppm; range across cultivars; losses occurred for early-maturing varieties and stemmed mainly from shortened vegetative growing period
Russel, 1988	+2 to +4°C	Queensland, Australia	Sugar Cane	+9 to +13	Southward expansion possible; also considered similar temperature declines; yields -40 to -17%

*Used climate scenarios as given in Salinger and Hicks (1990), which are mean changes derived from the results of several GCMs.

of C_3 crops, would be offset by the beneficial effects of elevated CO_2. No quantitative estimates of sensitivities or thresholds directly related to agriculture have been reported in major impact studies (e.g., Hughes and McGregor, 1990; Pernetta and Hughes, 1990; Hay and Kaluwin, 1992).

Singh (1994) considers the vulnerability of small island nations to some large changes in climatic conditions that, while not currently predicted by climate models, indicate sensitivities. Increasing aridity (reductions in rainfall and prolonged dry seasons) affecting small islands and the leeward side of bigger islands was estimated to result in general crop failure, migration of human populations, wind erosion, and negative impacts on wildlife. A somewhat less severe drying (prolonging the dry season by 45 days or more) would decrease yields of maize (30 to 50%), sugar cane (10 to 35%), and taro (35 to 75%). Singh (1994) also found that significantly increased rainfall (+50%) during the wet season on the windward side of large islands, while increasing yields of taro

(5 to 15%), would reduce yields of rice (10 to 20%) and severely reduce maize yields (30 to 100%). Maize failures from increased precipitation stem from inundation, and rice yield losses stem from increased cloudiness (reduced solar irradiation).

13.6.5. Areas of the Former USSR

Climate impact studies conducted over the past 15 years include those of Zhukovsky and Belechenko (1988), Zhukovsky *et al*. (1992), and Sirotenko *et al*. (1984). These studies did not include the direct effect of increasing atmospheric CO_2. Recent estimates have included coverage of most of the region and have included the CO_2 effect (Menzhulin and Koval, 1994) and other environmental change (Sirotenko and Abashina, 1994; Sirotenko *et al*., 1991). These new studies also have been the first conducted for this region based on climate scenarios drawn from GCM runs (Table 13-8).

Table 13-8: *Selected crop studies for Russia and the former Soviet republics.*

Study	Scenario	Geographic Scope	Crop(s)	Yield Impact (%)	Other Comments
Menzhulin and Koval, 1994	GISS, GFDL, UKMO	Russia and Former Soviet Republics	Winter and Spring Wheat	-19 to +41	Included CO_2 effect; GISS strongly positive, UKMO negative; temperature sensitivity alone of 2 and 4°C resulted in yield losses of 20 to 30%; impacts also varied widely across the 19 sites studied
Sirotenko and Abashina, 1994; Sirotenko *et al.*, 1991[1]	EMI	Russia	Crop Yield, Grassland Productivity	+10 to+35 -2 to +26	Large positive effect in Southern Volga and Northern Caucasus areas; slightly negative crop yield in S. Krasnoyarsky and Far East; range is w/ and w/o +20% CO_2, +30% tropospheric ozone, and -20% soil humus
	CCC, GFDL		Crop Yield, Grassland Productivity	-14 to +13 -27 to -2	

[1]These studies used a reconstructed Eemian Interglacial (EMI) climate and the Canadian Climate Centre (CCC) and Geophysical Fluid Dynamics Laboratory (GFDL) GCMs. The temperature and precipitation predictions of the GCMs were scaled by the factors 0.51 (CCC) and 0.45 (GFDL) to generate climates that could be observed by the year 2030.

Sirotenko and Abashina (1994) and Sirotenko *et al.* (1991) scaled the equilibrium temperature and precipitation derived from GCMs to generate scenarios applicable to the year 2030 and used the Eemian interglacial period (EMI) climate. In the EMI scenario, warming was greatest in January and precipitation increased substantially in both January and July, whereas the GCM scenarios suggested drier and warmer summer conditions. Changes in potential crop yield and potential productivity of grasses are based on a geoinformation system CLIMATE-SOIL-YIELD and a dynamic-growth crop simulation model (Sirotenko, 1981; Abashina and Sirotenko, 1986; Sirotenko, 1991) (Table 13-8). The results indicate that the climate response of crops and grasses can differ even in sign.

The estimated response of agriculture varied significantly across the region as well as across climate scenarios. Sirotenko and Abashina (1994) and Sirotenko *et al.* (1991) estimate the impacts to be favorable on agriculture of the northern areas of European Russia and Siberia and to cause a general northward shift of crop zones. Actual changes in production would reflect both areal expansion and the yield changes on existing crop areas as reported in Table 13-8. The more arid climate of the Canadian Climate Centre (CCC) and Geophysical Fluid Dynamics Laboratory (GFDL) GCMs was projected to have severe effects on grain production in the steppes of Povolzhye, Northern Caucasus, and the southern portion of Western Siberia, where grain production was estimated to fall by 20–25%. Menzhulin and Koval (1994) simulated yield increases exceeding 50% in the northwestern, central, and eastern regions of Kazakhastan under the GISS scenario, primarily because of increased moisture in these currently arid areas, but these areas did not benefit substantially under the GFDL scenario. Overall, the UK Meteorological Office (UKMO) scenario produced the largest yield declines.

Sirotenko and Abashina (1994) and Sirotenko *et al.* (1991) found that potential increases in ozone and loss of soil organic matter reduced potential yields substantially; when combined with the climate/CO_2 scenarios, grass yields declined by about one-quarter and crop yields by 10% in both CCC and GFDL GCM scenarios. Kovda and Pachepsky (1989) report the potential for significant additional soil loss and degradation resulting from climate change.

Historically, climate variability has been a significant contributor to yield variability in areas of the former USSR. For example, the increase in aridity during the 1930s was estimated to have decreased yields by 25–39% (Menzhulin, 1992). If drier conditions prevail under climate change, similar yield effects may occur.

13.6.6. Latin America

Climate impact studies for Latin America that include the direct effect of CO_2 generally show negative impacts for wheat, barley, and maize but positive impacts for soybeans (Table 13-9). A study of Norte Chico, Chile, suggested decreased yields for wheat and grapes but increases for maize and potatoes (Downing, 1992). The Norte Chico results are difficult to generalize because the climate for Chile exhibits steep temperature gradients from east to west due to the change in altitude, as well as wide variation from north to south.

The largest area with clear vulnerability to climate variability in the region is the Brazilian northeast. Like most agricultural areas of Latin America, this region has a rainy season when crops are grown and a dry season with little or no rain. In the case of the Brazilian northeast, the rainy season is relatively short (3–4 months) and the occurrence of years with no rainy season is frequent. These years are characterized by the occurrence of famine and large-scale migrations to metropolitan areas. Climatic variations that would result in shorter rainy seasons and/or increased

Table 13-9: *Selected crop studies for Latin America.*

Study	Scenario	Geographic Scope	Crop(s)	Yield Impact (%)	Other Comments
Baethgen, 1992, 1994	GISS, GFDL, UKMO[1]	Uruguay	Barley Wheat	-40 to -30 -30	w/ and w/o CO_2; with adaptation, losses were 15 to 35%; results indicate increased variability
Baethgen and Magrin, 1994	UKMO	Argentina Uruguay	Wheat	-10 to -5	w/ CO_2; high response to CO_2, high response to precipitation
Siquera *et al.*, 1994; Siquera, 1992	GISS, GFDL, UKMO[1]	Brazil	Wheat Maize Soybean	-50 to -15 -25 to -2 -10 to +40	w/ CO_2, w/o adaptation; adaptation scenarios did not fully compensate for yield losses; regional variation in response
Liverman *et al.*, 1991, 1994	GISS, GFDL, UKMO[1]	Mexico	Maize	-61 to -6	w/ CO_2; adaptation only partly mitigated losses
Downing, 1992	+3°C, -25% precip.	Norte Chico, Chile	Wheat Maize Potatoes Grapes	decrease increase increase decrease	The area is especially difficult to assess because of the large range of climates within a small area
Sala and Paruelo, 1992, 1994	GISS, GFDL, UKMO[1]	Argentina	Maize	-36 to -17	w/ and w/o CO_2; better adapted varieties could mitigate most losses

[1]These studies also considered yield sensitivity to +2 and +4°C and -20 and +20% change in precipitation.

frequency of rainless years would have extremely negative consequences for the region.

13.6.7. Western Europe

Simulated yields of grains and other crops have been generally found to increase with warming in the north, particularly when adaptation is considered, but decrease substantially in the Mediterranean area even with adaptation (Table 13-10). Northern yield increases depend on the beneficial effects of CO_2 on crop growth and climate scenarios showing sufficient increases in precipitation to counter higher rates of evapotranspiration. Yield declines in the Mediterranean region are due to increased drought resulting from the combination of increased temperature and precipitation decreases (or insufficient increases to counter higher evapotranspiration).

For many vegetable crops, warmer temperatures will generally be beneficial, with the options and possibilities for vegetable production generally expanding in northern and western areas. For cool-season vegetable crops such as cauliflower, larger temperature increases may reduce the number of plantings possible during cooler portions of the year or decrease production, particularly in southern Europe (Kenny *et al.*, 1993; Olesen and Grevsen, 1993). Decreased yield quality is also possible, with the effect most pronounced in southern Europe.

Warmer winters will reduce winter chilling and probably adversely affect apple production in temperate maritime areas, and could lead to loss of adequate winter chilling for crops such as peaches, nectarines, and kiwi fruit in southern Europe.

Significant shifts in areas suitable for different types of grapes also could occur (Kenny and Harrison, 1992).

Among other effects, warming implies reduction in greenhouse costs for horticultural production. However, increased infestations of pests such as the Colorado beetle on potatoes and rhizomania on sugar beet may result from higher temperatures.

Studies have investigated changes in crop potential evapotranspiration (PET) (Le Houerou, 1994; Rowntree, 1990), finding that under higher temperatures the crop growing season would be extended for grain crops, assuming an increase in the number of frost-free days. For southern Europe, the extension of the growing season would likely be insufficient to avoid high summer temperatures by planting earlier. Thus, reduced grain filling period and lower yields are likely. Other studies have explored how the climatically limited range for crops, including maize, wheat, cauliflower, and grapes, would change under various GCMs and other climate scenarios (Carter *et al.*, 1991a, 1991b; Parry *et al.*, 1992; Kenny *et al.*, 1993; Kenny and Harrison, 1993; Wolf, 1993a, 1993b). In general, these studies found a northward shift of crop-growing zones with potential for grain maize to be grown as far north as the UK and central Finland. Increased demand for irrigation and/or increased areas likely to suffer from water deficits, particularly in southern Europe, also were found.

13.6.8. USA and Canada

Studies listed in Tables 13-11 (USA) and 13-12 (Canada) show a wide range of impacts. Much of the wide variation reflects

differences among sites. Effects are more likely negative or more severely negative for southern areas and for climate scenarios such as the UKMO GCM scenario in which the temperature increases are large (+5.2°C) or the GFDL scenario in which summer aridity increased.

Rosenzweig (1985) simulated increased areas for wheat production, especially in Canada, under the GISS climate change scenario, while major wheat regions in the United States remain the same (Rosenzweig, 1985). Crosson (1989) found that warmer temperatures may shift much of the wheat-maize-soybean producing capacity northward, reducing U.S. production and increasing production in Canada. Shifting climate zones may result in lower production of corn or wheat and different and more diverse crops because the productivity in the new areas is likely to be limited due to the shallow, infertile soils (CAST, 1992).

Across studies in Table 13-11 for the USA that combined biophysical and economic impacts, market adjustments lessen the impacts of negative yield changes. Different assumptions about changes in U.S. population, income, trade barriers, and institutions were found, in some cases, to determine whether the net economic impact of climate change on the USA was negative or positive. Kaiser *et al.* (1993) found that possible increases in agricultural commodity prices could more than offset farm income loss. Mendelsohn *et al.* (1994) used an econometric approach to directly estimate the impact of climate change on agricultural revenue and asset values. This approach more fully considers potential adaptation to different climates as directly observed across climates that vary as a result of geography. They found that for the United States, warming would generally be beneficial even without the direct effect of CO_2. This approach calculates an equilibrium response after complete adjustment and does not consider price changes.

A number of studies have considered the vulnerability of prairie agriculture to climate change in Canada (Cohen *et al.*, 1992). Factors cited as contributing to vulnerability include the

Table 13-10: *Selected crop studies for Western Europe.*

Study	Scenario	Geographic Scope	Crop(s)	Yield Impact (%)	Other Comments
Oleson *et al.*, 1993	*	Northern Europe	Cauliflower	increase	Quality affected by temperature; longer season
Goudriaan and Unsworth, 1990	+3°C	Northern Europe	Maize (fodder)	increase	Shift to grain production possible
Squire and Unsworth, 1988	+3°C	Northern Europe	Wheat	increase	
Kettunen *et al.*, 1990	GCMs	Finland	Potential Yield	+10 to +20	Range is across GISS and UKMO GCMs
Rötter and van Diepen, 1994	+2°C (winter), +1.5°C (summer)	Rhine Area	Cereals, Sugar Beet, Potato, Grass	+10 to +30	Also +10% winter precipitation; includes direct effect of CO_2; range is across crop, agroclimatic zone, and soil type; decreased evapotranspiration (1 to 12%), except for grass
UK Dept. of Environment, 1992	GCMs +1, +2°C	UK	Grain Horticulture	increase or level increase	Increased pest damage; lower risk of crop failure
Wheeler *et al.*, 1993	*	UK	Lettuce	level	Quality affected; more crops per season possible
Semonov *et al.*, 1993	*	UK France	Wheat	increase or decrease	Yield varies by region; UKMO scenario negative; includes adaptation and CO_2
Delecolle *et al.*, 1994	GCMs** +2, +4°C	France	Wheat Maize	increase or level	Northward shift; w/ adaptation, w/ CO_2; GISS, GFDL, and UKMO GCMs
Iglesias and Minguez, 1993	GCMs**	Spain	Maize	-30 to -8	w/ adaptation, w/ CO_2; irrigation efficiency loss; see also Minguez and Iglesias, 1994
Santer, 1985	+4°C	Italy/Greece	Biomass	-5 to +36	Scenarios also included -10% precipitation
Bindi *et al.*, 1993	+2, +4°C and *	Italy	Winter Wheat	not estimated	Crop growth duration decreases; adaptation (using slower developing varieties) possible

*   Climate scenarios included GISS, GFDL, and UKMO and time-dependent scenarios, using GCM methodology, based on emission scenarios proposed by the IPCC in 1990. Composite scenarios for temperature and precipitation were based on seven GCMs and scaled by the global-mean temperature changes associated with the IPCC 1990 emission scenarios for the years 2010, 2030, and 2050 (Barrow, 1993).

** These studies also considered yield sensitivity to +2 and +4°C and -20 and +20% change in precipitation.

prairie's importance as an agricultural producer, located in a marginal climate, constrained by both temperature and precipitation; soil limitations that limit shifting of cropping northward; known sensitivity to climate as evidenced by past drought experiences; and vulnerability to midcontinental drying indicated by GCMs. The effects of the 1988 drought are an indication of the region's sensitivity to climate variability. The effects included dust storms and wind erosion, production declines of 29% (grains) to 94% (hay), falling grain inventories, higher prices, poor pastures for livestock with some movement of cattle to moister areas, higher feed costs for livestock, and farm income reductions of 50% to 78% compared to 1987 figures.

13.7. Regional Summary: Relative Vulnerability

There has been a substantial number of new agricultural impact studies since the 1990 IPCC and the 1992 update, as reviewed

in Section 13.6. For countries in sub-Saharan Africa, the Middle East and North Africa, Eastern Europe, and Latin America, however, there are still relatively few studies. For most regions, studies have focused on one or two principal grains. These studies strongly demonstrate the variability in estimated yield impacts among countries, scenarios, methods of analysis, and crops, making it difficult to generalize results across areas or for different climate scenarios. Thus, the ability to extend, interpolate, or extrapolate from the specific climate scenarios used in these studies to "more" or "less" climate change is limited.

Given these uncertainties in both magnitude and direction of impact, a key issue is *vulnerability* to possible climate change. Vulnerability is used here to mean the *potential* for negative consequences that are difficult to ameliorate through adaptive measures given the range of possible climate changes that might reasonably occur. Defining an area or population as vulnerable,

Table 13-11: *Selected U.S. agricultural impact studies.*

Study	Scenario	Geographic Scope	Crops	Yield Impact (%)	Other Comments
Adams *et al.*, 1988, 1990, 1994	GCMs[1]	U.S.	All	increase and decrease	Results vary across GISS, GFDL, and UKMO climates and regions; generally positive for 2°C and negative for 4°C; net economic effects depend on exports and CO_2 effects; increased irrigation; adaptation mitigates losses
Cooter, 1990 Easterling *et al.*, 1993	GISS 1930s analog	South Missouri, Iowa, Nebraska, Kansas	Maize Maize Sorghum Wheat Soybean Alfalfa	decrease -23 to -6 -20 to +26 -11 to +17 -26 to +2 -5 to +22	Potential risk of aquifer contamination More severe effect w/o CO_2 or adaptation; less severe or increase w/ CO_2 and adaptation
Kaiser *et al.*, 1993, 1994	Mild, severe	Central and southeast states, Minnesota, Nebraska	Maize Wheat Sorghum Soybean	increase and decrease	Climate scenarios included +2.5°C/+10% precipitation and +4.2°C/+20% precipitation; economic adaptation included; northern states less affected; results vary by crop/scenario
Mendelsohn *et al.*, 1994	+2.5°C, +8% precip.	U.S. county level	All	not estimated	Positive effect on crop revenue after long-run adjustment when considering revenue shares as weights that give greater importance to vegetables, fruits, etc.
Mearns *et al.*, 1992a, 1992b Muchow and Sinclair, 1991	GISS	Kansas Illinois	Wheat Grains	increased variability and crop failure increase or slight decrease	Precipitation more important than temperature in scenarios, except for GISS Most sensitive to precipitation changes
Rosenzweig *et al.*, 1994	GISS, GFDL, UKMO*	Southeast U.S., Great Lakes U.S. sites	Soybean Maize Wheat	-96 to +58 -55 to +62 -100 to +180	w/ CO_2 effect; UKMO scenario, southern sites more severely affected; average for total USA assessed for wheat (-20 to -2%), maize (-30 to -15%), and soybeans (-40 to +15%); Peart *et al.* (1989), Ritchie *et al.* (1989), and Rosenzweig (1990) are similar studies

[1]These studies also considered yield sensitivity to +2 and +4°C and -20 and +20% change in precipitation.

therefore, is not a prediction of negative consequences of climate change; it is an indication that, across the range of possible climate changes, there are some climatic outcomes that would lead to relatively more serious consequences for the region than for other regions.

Vulnerability depends on the unit of observation and the geographic scale considered. *Yields* are relatively more vulnerable if a small change in climate results in a large change in yield. Evidence suggests that yields of crops grown at the margin of their climatic range or in climates where temperature or precipitation could easily exceed threshold values during critical crop growth periods are more vulnerable (e.g., rice sterility: Matthews *et al.*, 1994a, 1994b).

Farmer or farm sector vulnerability is measured in terms of impact on profitability or viability of the farming system. Farmers with limited financial resources and farming systems with few adaptive technological opportunities available to limit or reverse adverse climate change may suffer significant disruption and financial loss for relatively small changes in crop yields and productivity. For example, semi-arid, cool temperate, and cold agricultural areas may be more vulnerable to climate change and climate variability (Parry *et al.*, 1988).

Regional economic vulnerability reflects the sensitivity of the regional or national economy to farm sector impacts. A regional economy that offers only limited employment alternatives for workers dislocated by the changing profitability of farming is relatively more vulnerable than those that are economically

diverse. For example, the Great Plains is one of the U.S. regions most dependent on agriculture, and thus might be the most economically vulnerable to climate change (Rosenberg, 1993).

Hunger vulnerability is an "aggregate measure of the factors that influence exposure to hunger and predisposition to its consequences" involving "interactions of climate change, resource constraints, population growth, and economic development" (Downing, 1992; Bohle *et al.*, 1994). Downing (1992) concluded that the semi-extensive farming zone, on the margin of more intensive land uses, appears to be particularly sensitive to small changes in climate. Socioeconomic groups in such areas, already vulnerable in terms of self-sufficiency and food security, could be further marginalized.

These different concepts of vulnerability include different scales of impact—from crop to individual farmer to food markets to the general economy. Given these various definitions and scales of impact, there are people vulnerable to climate change in most regions. Key characteristics of each of the regions help to suggest those more likely to have vulnerable populations (Table 13-13).

By most measures, many of the populations in sub-Saharan Africa appear most vulnerable. The region is already hot, and large areas are arid or semi-arid; average per capita income is among the lowest in the world and has been declining since 1980; more than 60% of the population depends directly on agriculture; and agriculture is generally more than 30% of gross domestic product (GDP). Relatively little of the cropland

Table 13-12: *Selected Canadian agricultural impact studies.*

Study	Scenario	Geographic Scope	Crop(s)	Yield Impact (%)	Other Comments
Williams *et al.*, 1988[1]	GISS84	Saskatchewan	Spring Wheat	-28 to -18	Large interannual fluctuations underlie mean impacts (e.g., -78% yield impact in extreme year); temperature increase of 3°C offset by +40% precipitation
Mooney, 1990[1]; Mooney *et al.*, 1991[1]	GISS	Manitoba, Alberta, Saskatchewan	Spring Wheat, Multiple Crops	-36 (Manitoba) negative and positive	Similar for other crops; corn and potatoes increased; precipitation derived from analogous region data; greater crop variety, production area increase
van Kooten[1]	CCC	SW Saskatchewan	Spring Wheat	-15 to +2	Positive effects when CCC precipitation used; negative used current norm for precipitation
Arthur and Abizadeh, 1989[1]	GISS, GFDL	Alberta, Manitoba, Saskatchewan	Wheat, Oats, Barley, Flax, Canola, Hay	small decrease to +28	10 out of 12 scenarios resulted in gain in net crop revenue; adapt by planting earlier
Brklacich *et al.*, 1994; Brklacich and Smit, 1992	GISS, GFDL, UKMO[2]	Alberta, Manitoba, Saskatchewan, Ontario	Wheat	-40 to +234	Results varied widely by site and scenario; adaptation and CO_2 were strongly positive effects; Ontario study showed increased net returns, but also variability; N gains and S loses

[1]As reported in Cohen *et al.*, 1992.
[2]These studies also considered yield sensitivity to +2 and +4°C and -20 and +20% change in precipitation.

is irrigated, and much of the agricultural land is used for grazing. Severe famine and starvation have been more prevalent in sub-Saharan Africa than in other regions over recent decades. Political and civil instability have greatly worsened problems. The potential for continued instability is an additional factor that increases vulnerability.

Populations in South Asia are vulnerable because of heavy dependence on agriculture and high population density. Agriculture accounts for more than 30% of GDP in most countries in the region. Each hectare of cropland supports 5.4 people. Tropical storms are an important feature of the climate around which current systems operate. These storms can be destructive but also are the main source of moisture. Changes in their frequency or severity would have significant impacts.

The area is already intensely cropped, with 44% of the land area used as cropland. An estimated 31% of cropland is already irrigated, which may reduce vulnerability somewhat, providing water resources remain adequate. An additional factor that may reduce vulnerability in the future is the relative strength of the economy over the past decade. Countries in this area also have been relatively successful in avoiding the more severe effects of food shortages through programs that ensure access to food during potential famine situations. Chronic hunger remains a problem, however, for the poorer segments of the population, particularly in semi-arid and arid parts of the region.

Within East Asia, populations in the more arid areas of China appear most vulnerable to the possibility of mid-latitude continental drying. In general, the region supports a large population

[1]Agricultural land includes grazing and cropland, reported as a percent of total land area. Cropland is reported as a percent of
 agricultural land. Irrigated area is reported as a percent of cropland.
[2]GNP is in 1991 U.S.$; annual growth (%/annum) is for the period 1980–1991.

Source: Computed from data from FAO Statistics Division (1992); GNP per capita, GNP growth rates, and agriculture as a share of the economy are from World Bank, *World Development Indicators 1993*, and temperature and climate classes from Rötter *et al*., 1995. Note: East Asia GNP excludes Japan. Also, regional GNP data generally include only those countries for which data are given in Table 1 in *World Development Indicators*. Countries with more than 4 million population for which GNP data are not available include Vietnam, Democratic Republic of Korea, Afghanistan, Cuba, Iraq, Myanmar, Cambodia, Zaire, Somalia, Libya, and Angola; land areas are in hectares, production is in metric tonnes.

per hectare of cropland (12.6). The rapid economic growth achieved over the past decade, the fact that the region's climate is somewhat cooler, and the diverse sources of food production reduce vulnerability of populations in this region. Japan's GNP provides it with significant capability to limit climatic losses from agriculture compared with other countries in the region.

Southeast Asia combines tropical temperatures with generally ample moisture, but the region is subject to tropical storms. The region supports a large population with a relatively high population density per hectare of cultivated land. For several countries in this region, agriculture contributes more than 30% of GDP. GNP per capita is somewhat higher than that of either South or East Asia, and growth has been substantial over the past decade. However, Table 13-13 excludes several countries in the region due to lack of data. These countries, including Vietnam, Cambodia, and Myanmar, have relatively large populations, and their economic performance has been poorer than others in the region. Populations in these countries may be particularly vulnerable to changes in tropical storms.

The Middle East and North Africa are already very hot and generally arid. The current climate greatly limits the portion of land currently suitable for agriculture. A large share of current cropland is irrigated. Among developing country areas, a relatively smaller share of the population (32%) depends directly on agriculture. Agriculture is quite diverse; fruits, vegetables, and other specialty crops are important. The region is heterogeneous, including relatively wealthy oil-exporting countries, Israel, and several poorer countries—making the regional average economic performance somewhat misleading. Per capita GNP has fallen substantially over the past decade, with declining oil prices and political disruptions partly responsible.

Latin America and countries that now make up the area that was formerly the USSR are similar in terms of per capita GNP. While data are unavailable with regard to economic performance for the area of the former USSR, evidence strongly suggests that the region suffered a decline in per capita GNP over the past decade, as has Latin America. The two regions are also similar in that average population density and population per hectare of cropland are moderate to low. Estimates of potential additional cropland for the world suggest that these two areas could be the source of substantial additional cropland (Crosson, 1995). Thus, expansion of land area or relocation to adapt to climate change is a possible response, partly mitigating vulnerability. The prevalence of childhood malnutrition, infant mortality, and low median age at death are somewhat higher in Latin America than in the area of the former USSR (World Bank, 1993). While both regions are primarily humid, substantial agricultural areas are arid or semi-arid and drought-prone. The notable difference between the two regions is that Latin America is generally already tropical or subtropical, and even though GCMs predict less warming in the tropics, further warming may be deleterious. In contrast, agriculture in large areas of the former USSR is limited by cool temperatures and so may benefit from warming. Arid areas of tropical Latin America, such as northwest Brazil, are particularly vulnerable to changes in ENSO events if they result in less reliable precipitation.

Europe, the USA and Canada, and Oceania have high GNP per capita, the agricultural population is a small share of the total population, and agriculture is in general a small share of the economy. As a result, vulnerability to climate-change-induced hunger or severe economic distress for the overall economy is relatively low. These areas are important for world food production. Mid-continental areas of the U.S. and Canada, the Mediterranean area of Europe, and large areas of Australia are prone to drought, which would be exacerbated if climate change reduced moisture availability or increased the demand for water as occurs in several GCM scenarios. Economic dislocation is likely to be limited to the agricultural sector or to subregions highly dependent on agriculture.

Small island nations, especially where incomes are low, are subject to particular vulnerabilities. Potential loss of coastal land to sea level rise, salt water intrusion into water supplies, damage from tropical storms, and temperature and precipitation change will combine to affect the agriculture of island nations. Sea water inundation and salt water intrusion are not unique to small island nations. However, these problems take on greater importance where coastal area is a high proportion of the total area of the country, alternative sources of fresh water are limited, and the area available for retreat from sea-level rise is limited. Local sources of food are especially important for these countries because transportation costs can be substantial for remote locations with small populations, particularly for highly perishable products. Most attention has been focused on Pacific Island Countries in Oceania, but other island countries such as the Maldives are presented with similar conditions.

13.8. Global Agricultural Issues and Assessments

13.8.1. The Current and Future Agricultural System

Climate change will be only one of many factors that will affect world agriculture. The broader impacts of climate change on world markets, on hunger, and on resource degradation will depend on how agriculture meets the demands of a growing population and threats of further resource degradation. World agriculture has proven in the past to be responsive to the increasing demand for food. Evidence of this is the trend of falling real prices for food commodities (Mitchell and Ingco, 1995, estimated a 78% decline between 1950 and 1992) and the steady growth of worldwide food production over the past 3 decades. Average annual increases were 2.7% per annum during the 1960s, 2.8% during the 1970s, and 2.1% during the 1980s.

Despite global abundance, many countries suffer from disrupted agricultural production and distribution systems, such that famine and chronic hunger are a reality or a distinct threat. While the number of people suffering from chronic hunger has declined (from an estimated 844 million in 1979 to 786 million in 1990; Bongaarts, 1994), the causes of famine are complex,

including a lack of the rights and means to obtain food (employment, adequate income, and a public system for responding to famine) (e.g., Sen, 1981, 1993); political systems disrupted by war and unrest; ineffective or misdirected policies; as well as, or in addition to, drought and other extreme climatic events (McGregor, 1994). The nearly 800 million people still estimated to suffer from chronic hunger and malnutrition represent 20% of the population of developing countries, with the percentage as high as 37% in sub-Saharan countries (FAO, 1995). In many situations of chronic hunger, the population is rural and their livelihood depends primarily on agriculture. However, Kates and Chen (1994a, 1994b), though noting the potential risks of climate change beyond those represented in median cases, provide an array of actions that could be undertaken to achieve a food-secure world.

Agricultural and resource policies have important effects on agricultural production, and national governments have intervened in agriculture in many ways and for various reasons (Hayami and Ruttan, 1985). Many developed countries have subsidized agriculture and thereby encouraged production, while intentionally idling land to control surplus stocks of agricultural commodities. Many developing countries have controlled food prices to benefit lower-income food consumers but have thereby discouraged domestic production. Reduction of trade-distorting government interventions in agriculture was part of the recently concluded round of the General Agreement on Tariffs and Trade (GATT). National policies also greatly affect land use and water use, management, and pricing.

Three major studies of the future world food situation suggest that in the absence of climate change, food supply will continue to expand faster than demand over the next 20 to 30 years, with world prices projected to fall (Alexandratos, 1995; Mitchell and Ingco, 1995; Rosegrant and Agcaoili, 1995). Others are less optimistic, citing limits on further land expansion and irrigation, resource degradation, and reduced confidence that the historical rates of increase in yield will continue (Bongaarts, 1994; McCalla, 1994; Norse, 1994).

Factors that will jointly determine whether agricultural supply increases can keep pace with demand include (1) how fast demand will grow, (2) the future availability of land and its quality, (3) the future availability of water, and (4) whether improvements in technology will continue to result in rapid yield growth. Finally, economic growth and development are closely tied to demand growth and, in many developing countries, are also dependent on agricultural development.

13.8.1.1. Demand Growth

Between 1950 and 1990, world population grew at a 2.25% compound annual rate. Through 2025, population is projected to grow at a compound annual rate of between 1.13% and 1.55% (high and low UN variants). The decade of the 1990s is projected to have the largest absolute population addition, with declining additions in subsequent decades (Bongaarts, 1995).

Thus, food supply growth could slow by 40–50% from recent decades while maintaining per capita food production levels. Income growth likely will cause demand to grow more rapidly than population and will change the composition of demand, most likely away from food grains and toward meat, fruits, and vegetables. The shift to meat is likely to increase the demand for grain for livestock feed. Increased demand generated by increased income growth would allow more and higher-quality food to be consumed per capita (Mitchell and Ingco, 1995), but this depends on how food consumption is distributed. Beyond 2025, population growth is generally projected to be low as world population is projected to stabilize by around 2075.

13.8.1.2. Land Quantity and Quality

Some estimates suggest that there is much potentially available land (Buringh and Dudal, 1987), but the cost of bringing it under production may be high, with attendant adverse environmental impacts limiting expansion (Crosson, 1995). Intensification of production on existing cropland may worsen land degradation and put additional pressure on water and soil resources. Firm data on the extent and severity of land degradation and its impact on production potential for most of the world are not available (El-Swaify *et al*., 1982; Dregne, 1988; Nelson, 1988; Lal and Okigbo, 1990), but a recent overview (Oldeman et al., 1990), though still qualitative in economic terms, confirms significant degradation and loss of arable land, especially in Africa (see Chapter 4). Studies disagree on the extent to which intensification affects land degradation (Crosson and Stout, 1983; Brown and Thomas, 1990; Tiffen *et al*., 1993). Competition for agricultural resources for other uses may also affect the supply and price of land for agriculture. Carbon sequestration, biomass energy production, forest product production, the potential development of new non-food agricultural products, and removal of agricultural land from production for other environmental objectives will affect the amount of land available for food production (see Chapters 23, 24, and 25).

13.8.1.3. Water Supply and Irrigation

Irrigation has contributed significantly to increased production in the past. Currently, 17% of global cropland is irrigated, but this 17% of land accounts for more than one-third of total world food production. An estimated additional 137 million hectares have the potential to be irrigated, compared with the 253 million hectares currently irrigated (World Bank, 1990), but the cost of doing so may be prohibitive. Current water systems in many developing countries achieve low efficiencies of water distribution, and average crop yields are well below potential (Yudelman, 1993; Crosson, 1995; Rosegrant and Agcaoili, 1995). There are environmental and health-related effects of irrigation such as soil salinization and the spread of water-borne diseases that may limit further expansion (Brown and Thomas, 1990; Dregne and Chou, 1990; Jensen *et al*., 1990; Crosson, 1995). Major factors contributing to these irrigation problems in both developing and developed countries

are unpriced and heavily subsidized water resources; inadequate planning, construction, and maintenance of water systems; unassigned water rights or rules that limit the transfer of rights; and conflicts between development and distribution goals (Frederick, 1986; Asian Development Bank, 1991; Moore, 1991; Umali, 1993; Yudelman, 1993; Appendine and Liverman, 1994). Solutions to these problems are available in most cases, and a recent study found that investments in irrigation have been at least as profitable as investments in other agricultural enterprises (World Bank, 1994). Changes in potential irrigation water supply due to climate change have not generally been integrated into agricultural impact studies, with few exceptions (e.g., Rosenberg, 1993). For climatic impacts on water supply, see Chapter 10.

13.8.1.4. Future Yield Growth

Assumed continuation of yield increases due to improving technology and further adoption of existing technologies is uncertain. Gaps between actual and potential yield are cited as evidence of unexploited production potential, but potential yields are rarely, if ever, attained in practice (Tinker, 1985; Plucknett, 1995). Realization of improved varieties depends on continuation of agricultural research and crop breeding systems and the exchange of germplasm (Duvick, 1995).

13.8.1.5. Future Economic Development

The impact of climate change on human populations in terms of famine, chronic hunger, health, and nutrition will depend on how and whether currently poor areas develop over the next 20 to 50 years. The future path of development of currently vulnerable countries remains uncertain. Policy failures, wars, and political and civil unrest are identified causes, but correcting these problems has proved difficult (e.g., van Dijk, 1992; Anand and Ravallion, 1993). Lagging agricultural development has been identified as a consequence of significant policy distortions in many developing countries, conflicting with the industrial sector and limiting the ability of the broader economy to grow (Hayami and Ruttan, 1985; Adelman and Vogel, 1992; Cavallo *et al.*, 1992; FAO, 1995).

13.8.2. Global Climate Impact Studies

Accurate consideration of national and local food supply and economic effects depends on an appraisal of changes in global food supply and prices. International markets can moderate or reinforce local and national changes. In 1988, for example, drought presented a more severe threat because it occurred coincidentally in several of the major grain-growing regions of the world.

While uncertainties continue to exist about the direction of change in global agricultural production resulting from climate change, changes in the aggregate level of production have been found to be small to moderate (Kane *et al.*, 1992; Fischer *et al.*, 1994; Reilly *et al.*, 1994; Rosenzweig and Parry, 1994). Studies show that a disparity in agricultural impact between developed and developing countries can be reinforced by markets (Tables 13-14, 13-15).

Rosenzweig *et al.* (1994) found that in lower-latitude developing countries, cereal grain crop yields and production declined under climate change scenarios ranging from 2.5 to 5.2°C. The study further found that the population at risk of hunger (defined as a measure of food energy availability, which depends on income and food price levels, relative to nutritional requirements) could increase despite adaptation. The study involved agricultural scientists in 18 countries using comparable crop growth models for wheat, rice, maize, and soybean (IBSNAT, 1989) and consistent climate change scenarios (Rosenzweig and Iglesias, 1994). Estimated yield changes were the basis for supply changes in the Basic Linked System (BLS), a world food trade model (Fischer *et al.*, 1988).

Reilly and Hohman (1993) and Reilly *et al.* (1994) used the same national crop yield changes as Rosenzweig *et al.* (1994) in a different trade model and found that agricultural exporters may gain even though their supplies fall as a result of higher world prices. They found that developing countries did worse in economic

Table 13-14: *Change in cereals production under three different GCM equilibrium scenarios (percent from base estimated in 2060).*

Columns may not sum to total due to independent rounding. Adaptation is level 1, as in Table 13-14.

terms as a group, but that some developing countries benefitted. The pattern of winners and losers varied among climate scenarios. Moreover, they found that food-importing countries were found, in some cases, to suffer economic loss because of higher world prices even if the country's crop production potential improved.

Table 13-14 also illustrates how trade and adaptation capability can interact. Developing countries' production levels fell more under adaptation level 1 (small changes in planting dates, changes in cultivars, and additional irrigation water for areas already irrigated) than with no adaptation because their estimated capability to adapt was less than in developed countries. Thus, cereal production in developing countries fell further as trade shifted toward developed-country exports at the expense of developing country production. At adaptation level 2 (substantial changes in planting dates, changes in crop, and extension of irrigation systems), this situation was reversed.

Another global modeling effort considered potential yield and distribution of crops based on a crop suitability index (Cramer and Solomon, 1993; Leemans and Solomon, 1993). Although considering only one climate scenario and omitting the effect of CO_2 fertilization, they found that high-latitude regions uniformly benefited from longer growing periods and increased productivity. Other regions either did not benefit significantly or lost productivity.

More recent work considering global agriculture under climate change found far greater potential for global agriculture to adapt to changing climate than earlier studies (Darwin *et al.*, 1995; reported in Reilly, 1995). This study estimated that climate change alone as represented by equivalent doubled-CO_2 climate scenarios of UKMO, GISS, GFDL, and OSU, without consideration of the direct effects of CO_2, would result in global production losses of less than 1% if no additional land area were devoted to agriculture. If new land area could be brought under cultivation, grain production was estimated to increase on the order of 1%.

13.9. Adaptation

Historically, farming systems have adapted to changing economic conditions, technology, and resource availabilities and have kept pace with a growing population (Rosenberg, 1982; CAST, 1992). Evidence exists that agricultural innovation responds to economic incentives such as factor prices and can relocate geographically (Hyami and Ruttan, 1985; CAST, 1992). A number of studies indicate that adaptation and adjustment will be important to limit losses or to take advantage of improving climatic conditions (e.g., National Academy of Sciences, 1991; Rosenberg, 1992; Rosenberg and Crosson, 1991; CAST, 1992; Mendelsohn *et al.*, 1994).

Despite the successful historical record, questions arise with regard to whether the rate of change of climate and required adaptation would add significantly to the disruption likely due to future changes in economic conditions, technology and resource availabilities (Gommes, 1993; Harvey, 1993; Kane and Reilly, 1993; Smit, 1993; Norse, 1994; Pittock, 1994; Reilly, 1994). If climate change is gradual, it may be a small factor that goes unnoticed by most farmers as they adjust to other more profound changes in agriculture stemming from new technology, increasing demand for food, and other environmental concerns such as pesticide use, water quality, and land preservation. However, some researchers see climate change as a significant addition to future stresses, where adapting to yet another stress such as climate change may be beyond the capability of the system. Part of the divergence in views may be due to different interpretations of adaptation, which include the prevention of loss, tolerating loss, or relocating to avoid loss (Smit, 1993). Moreover, while the technological potential to adapt may exist, the socioeconomic capability to adapt likely differs for different types of agricultural systems (Reilly and Hohmann, 1993).

13.9.1. The Technological Potential to Adapt

Nearly all agricultural impact studies conducted over the past 5 years have considered some technological options for adapting to climate change. Among those that offer promise are:

- **Seasonal Changes and Sowing Dates**—For frost-limited growing areas (i.e., temperate and cold areas), warming could extend the season, allowing planting of longer maturity annual varieties that achieve higher yields (e.g., Le Houerou, 1994; Rowntree, 1990). For short-season crops such as wheat, rice, barley, oats, and many vegetable crops, extension of the growing season may allow more crops per year, fall planting, or, where warming leads to regular summer highs above critical thresholds, a split season with a short summer fallow. For subtropical and tropical areas where growing season is limited by precipitation or where the cropping already occurs throughout the year, the ability to extend the growing season may be more limited and depends on how precipitation patterns change. A study for Thailand found yield losses in the warmer season partially offset by gains in the cooler season (Parry *et al*., 1992).

- **Different Crop Variety or Species**—For most major crops, varieties exist with a wide range of maturities and climatic tolerances. For example, Matthews *et al*. (1994) identified wide genetic variability among rice varieties as a reasonably easy response to spikelet sterility in rice that occurred in simulations for South and Southeast Asia. Studies in Australia showed that responses to climate change are strongly cultivar-dependent (Wang *et al*., 1992). Longer-season cultivars were shown to provide a steadier yield under more variable conditions (Connor and Wang, 1993). In general, such changes may lead to higher yields or may only partly offset losses in yields or profitability. Crop diversification in Canada (Cohen *et al*., 1992) and in China (Hulme *et al*., 1992) has been identified as an adaptive response.

- **New Crop Varieties**—The genetic base is broad for most crops but limited for some (e.g., kiwi fruit). A study by Easterling *et al*. (1993) explored how hypothetical new varieties would respond to climate change (also reported in McKenney *et al*., 1992). Heat, drought, and pest resistance; salt tolerance; and general improvements in crop yield and quality would be beneficial (Smit, 1993). Genetic engineering and gene mapping offer the potential for introducing a wider range of traits. Difficulty in assuring that traits are efficaciously expressed in the full plant, consumer concerns, profitability, and regulatory hurdles have slowed the introduction of genetically engineered varieties compared with early estimates (Reilly, 1989; Caswell *et al*., 1994).

- **Water Supply and Irrigation Systems**—Across studies, irrigated agriculture in general is less negatively affected than dryland agriculture, but adding irrigation is costly and subject to the availability of water supplies. Climate change will affect future water supplies (see Chapter 10). There is wide scope for enhancing irrigation efficiency through adoption of drip irrigation systems and other water-conserving technologies (FAO, 1989, 1990), but successful adoption will require substantial changes in how irrigation systems are managed and how water resources are priced. Because inadequate water systems are responsible for current problems of land degradation, and because competition for water is likely to increase, there likely will be a need for changes in the management and pricing of water regardless of whether and how climate changes (Vaux, 1990, 1991; World Bank, 1994). Tillage method and incorporation of crop residues are other means of increasing the useful water supply for cropping.

- **Other Inputs and Management Adjustments**—Added nitrogen and other fertilizers would likely be necessary to take full advantage of the CO_2 effect. Where high levels of nitrogen are applied, nitrogen not used by the crop may be leached into the groundwater, run off into surface water, or be released from the soil as nitrous oxide. Additional nitrogen in ground and surface water has been linked to health effects in humans and affects aquatic ecosystems. Studies also have considered a wider range of adjustments in tillage, grain drying, and other field operations (Kaiser *et al*., 1993; Smit, 1993).

- **Tillage**—Minimum and reduced tillage technologies, in combination with planting of cover crops and green manure crops, offer substantial possibilities to reverse existing soil organic matter, soil erosion, and nutrient loss, and to combat potential further losses due to climate change (Rasmussen and Collins, 1991; Logan, 1991; Edwards *et al*., 1992; Langdale *et al*., 1992; Peterson *et al*., 1993; Brinkman and Sombroek, 1993; see also Chapter 23). Reduced and minimum tillage techniques have spread widely in some countries but are more limited in other regions. There is considerable current interest in transferring these techniques to other regions (Cameron and Oram, 1994).

- **Improved Short-Term Climate Prediction**—Linking agricultural management to seasonal climate predictions (currently largely based on ENSO), where such predictions can be made with reliability, can allow management to adapt incrementally to climate change. Management/climate predictor links are an important and growing part of agricultural extension in both developed and developing countries (McKeon *et al*., 1990, 1993; Nichols and Wong, 1990).

13.9.2. The Socioeconomic Capability to Adapt

While identifying many specific technological adaptation options, Smit (1993) concluded that necessary research on their cost and ease of adoption had not yet been conducted.

One measure of the potential for adaptation is to consider the historical record on past speeds of adoption of new technologies (Table 13-16). Adoption of new or different technologies depends on many factors: economic incentives, varying resource and climatic conditions, the existence of other technologies (e.g., transportation systems and markets), the availability of information, and the remaining economic life of equipment and structures (e.g., dams and water supply systems).

Specific technologies only can provide a successful adaptive response if they are adopted in appropriate situations. A variety of issues has been considered, including land-use planning, watershed management, disaster vulnerability assessment, port and rail adequacy, trade policy, and the various programs countries use to encourage or control production, limit food prices, and manage resource inputs to agriculture (CAST, 1992; OTA, 1993; Smit, 1993; Reilly *et al.*, 1994; Singh, 1994). For example, studies suggest that current agricultural institutions and policies in the United States may discourage farm management adaptation strategies, such as altering crop mix, by supporting prices of crops not well-suited to a changing climate, providing disaster payments when crops fail, or prohibiting imports through import quotas (Lewandrowski and Brazee, 1993).

Existing gaps between best yields and the average farm yields remain unexplained, but many are due in part to socioeconomic considerations (Oram and Hojjati, 1995; Bumb, 1995); this adds considerable uncertainty to estimates of the potential for adaptation, particularly in developing countries. For example,

Baethgen (1994) found that a better selection of wheat variety combined with an improved fertilizer regime could double yields achieved at a site in Uruguay to 6 T/ha under the current climate with current management practices. Under the UKMO climate scenario, yields fell to 5 T/ha—still well above 2.5–3.0 T/ha currently achieved by farmers in the area. On the other hand, Singh (1994) concludes that the normal need to plan for storms and extreme weather events in Pacific island nations creates significant resiliency. Whether technologies meet the self-described needs of peasant farmers is critical in their adaptation (Cáceres, 1993). Other studies document how individuals cope with environmental disasters, identifying how strongly political, economic, and ethnic factors interact to facilitate or prevent coping in cases ranging from the Dust Bowl disaster in the United States to floods in Bangladesh to famines in the Sudan, Ethiopia, and Mozambique (McGregor, 1994). These considerations indicate the need for local capability to develop and evaluate potential adaptations that fit changing conditions (COSEPUP, 1992). Important strategies for improving the ability of agriculture to respond to diverse demands and pressures, drawn from past efforts to transfer technology and provide assistance for agricultural development, include:

- Improved training and general education of populations dependent on agriculture, particularly in countries where education of rural workers is currently limited. Agronomic experts can provide guidance on possible strategies and technologies that may be effective. Farmers must evaluate and compare these options to find those appropriate to their needs and the circumstances of their farms.
- Identification of the present vulnerabilities of agricultural systems, causes of resource degradation, and existing systems that are resilient and sustainable. Strategies that are effective in dealing with current climate variability and resource degradation also are likely to increase resilience and adaptability to future climate change.
- Agricultural research centers and experiment stations can examine the "robustness" of present farming systems (i.e., their resilience to extremes of heat, cold, frost, water shortage, pest damage, and other factors) and test the robustness of new farming strategies as they are developed to meet changes in climate, technology, prices, costs, and other factors.
- Interactive communication that brings research results to farmers—and farmers' problems, perspectives, and successes to researchers—is an essential part of the agricultural research system.
- Agricultural research provides a foundation for adaptation. Genetic variability for most major crops is wide relative to projected climate change. Preservation and effective use of this genetic material would provide the basis for new variety development. Continually changing climate is likely to increase the value of networks of experiment stations that can share genetic material and research results.

Table 13-16: *Speed of adoption for major adaptation measures.*

Adaptation	Adjustment Time (years)	Reference
Variety Adoption	3–14	Dalrymple, 1986; Griliches, 1957; Plucknett *et al.*, 1987; CIMMYT, 1991; Wang *et al.*, 1992
Dams and Irrigation	50–100	James and Lee, 1971; Howe, 1971
Variety Development	8–15	Plucknett *et al.*, 1987; Knudson, 1988
Tillage Systems	10–12	Hill *et al.*, 1994; Dickey *et al.*, 1987; Schertz, 1988
New Crop Adoption: Soybeans	15–30	FAO, Agrostat (various years)
Opening New Lands	3–10	Medvedev, 1987; Plusquellec, 1990
Irrigation Equipment	20–25	Turner and Anderson, 1980
Transportation System	3–5	World Bank, 1994
Fertilizer Adoption	10	Pieri, 1992; Thompson and Wan, 1992

- Food programs and other social security programs would provide insurance against local supply changes. International famine and hunger programs need to be considered with respect to their adequacy.
- Transportation, distribution, and market integration provide the infrastructure to supply food during crop shortfalls that might be induced in some regions because of climate variability or worsening of agricultural conditions.
- Existing policies may limit efficient response to climate change. Changes in policies such as crop subsidy schemes, land tenure systems, water pricing and allocation, and international trade barriers could increase the adaptive capability of agriculture.

Many of these strategies will be beneficial regardless of how or whether climate changes. Goals and objectives among countries and farmers vary considerably. Current climate conditions and likely future climates also vary. Building the capability to detect change and evaluate possible responses is fundamental to successful adaptation.

13.10. Research Needs

The continuing uncertainty in projections suggests three critical, high-priority research needs:

- Development and broad application of integrated agricultural modeling efforts and modeling approaches particularly applicable at the regional scale, including increased attention to validation, testing, and comparison of alternative approaches. Climate effects on soils and plant pests, consideration of other environmental changes, and adaptation options and economic responses should be an integrated part of the models rather than treated on an *ad hoc* basis or as a separate modeling exercise. Inclusion of these multiple, joint effects may significantly change our "mean" estimate of impact, and more careful attention to scale and validation should help to reduce the range of estimates for specific regions and countries across different methodologies.
- Development of the capability to readily simulate agricultural impacts of multiple transient climate scenarios. Study of the sensitivities of agriculture to climate change and the impacts of doubled-CO_2 equilibrium scenarios has not led to the development of methods that readily can be applied to transient climate scenarios. To deal credibly with the cost of adjustment, about which there is significant uncertainty, the process of socioeconomic adjustment must be modeled to treat key dynamic issues such as how the expectations of farmers change, whether farmers can easily detect climate change against a background of high natural variability, and how current investments in equipment, education, and training may lead to a system that only slowly adjusts, or adjusts only with high cost and

significant disruption. The ability to readily simulate effects under multiple climate scenarios is necessary to quantify the range of uncertainty.
- Evaluation of the effects of variability rather than changes in the "mean" climate, and the implication of changes in variability on crop yields and markets. Extreme events have severe effects on crops, livestock, soil processes, and pests. The more serious human consequences of climate change also are likely to involve extreme events such as drought, flooding, or storms, where agricultural production is severely affected.

State-of-the-art research has begun addressing these areas, and a number of promising approaches have begun to appear in the literature or are expected soon. Most are, as yet, "demonstration" research projects, choosing limited geographic areas where data are more available and considering convenient examples for climate scenarios. Caution in drawing broader policy implications from such studies is warranted because there is little or no basis to make inferences to broader populations, to other locations, or to specific climate scenarios.

CONTENTS

EXECUTIVE SUMMARY

Water availability is an essential component of welfare and productivity. Much of the world's agriculture, hydroelectric power production, municipal and industrial water needs, water pollution control, and inland navigation is dependent on the natural endowment of surface and groundwater resources. Changes in the natural system availability would result in impacts that generally are greatest in regions that are already under stress, including currently arid and semi-arid areas, as well as areas where there is considerable competition among users. The purpose of water resources management is to ameliorate the effects of extremes in climate variability and provide a reliable source of water for multiple societal purposes. This evaluation of climate-change impacts focuses on the expected range of changes in the hydrological resources base and the sensitivity of the water supply and water demand components of the water management systems to climate change. It also makes an assessment of the viability of adaptive water management measures in responding to these impacts.

There are reasons for water resources managers, especially in developing nations, to be concerned by the results of climate-change scenarios, which show that the freshwater resources in many regions of the world are likely to be significantly affected. In particular, current arid and semi-arid areas of the world could experience large decreases in runoff—hence posing a great challenge to water resources management. Global-change-induced perturbations may follow widespread periodic and chronic shortfalls in those same areas caused by population growth, urbanization, agricultural expansion, and industrial development that are expected to manifest themselves before the year 2020 (High Confidence).

Uncertainties require considerable investment in research in order to improve prediction and adaptive responses. Some uncertainties in assessing the effects of climate change on water resources are:

- Uncertainties in general circulation models (GCMs) and lack of regional specification of locations where consequences will occur
- Insufficient knowledge on future climate variability, which is a basic element of water management
- Uncertainties in estimating changes in basin water budgets due to changes in vegetation and in atmospheric and other conditions likely to exist 50 to 100 years from now
- Uncertainties in future demands by each water sector
- Uncertainties in the socioeconomic and environmental impacts of response measures.

Hence, predicting where water resources problems due to climate change will occur can only be realized on a subcontinental scale at this time. However, water management decisions are made on the localized, watershed scale. Therefore, despite increases in the number of impact assessments and improvements in the new class of transient GCMs, there is little that can be added to the conclusions of the first two IPCC reports on the subject, other than to note the regions and countries most likely to be vulnerable through a combination of increased demands and reductions in available supplies. However, one important addition is the limited but growing analyses of water systems in the developing world. These limited studies seem to suggest that developing countries are highly vulnerable to climate change because many are located in arid and semi-arid regions and most existing water resources systems in these countries are characterized as isolated reservoir systems. Also, there is more evidence that flooding is likely to become a larger problem in many temperate regions, requiring adaptations not only to droughts and chronic water shortages but also to floods and associated damages and raising concerns about dam and levee failures (Medium Confidence).

Water management is a continuously adaptive enterprise, responding to changes in demands, hydrological information, technologies, the structure of the economy, and society's perspectives on the economy and the environment. This adaptation employs four broad interrelated approaches: new investments for capacity expansion; operation of existing systems for optimal use (instream and offstream); maintenance and rehabilitation of systems; and modifications in processes and demands (e.g., conservation, pricing, and institutions). These water management practices, which are intended to serve the present range of climate variability (which in itself is considerable), may also serve to ameliorate the range of perturbations such as droughts that are expected to accompany climate change. However, adaptations come at some social, economic, and environmental costs.

Most of the standard water resources performance criteria—such as reliability, safe yield, probable maximum flood, resilience, and robustness—are applicable in dealing with the impacts of climate change on water resources systems. This is not to suggest that we can become complacent in our response to climate change. The emphasis of water resources management in the next decades will be on responses to increased demands, largely for municipal water supply in rapidly urbanizing areas, energy production, and agricultural water supply. Water management strategies will focus on

demand management, regulatory controls, legal and institutional changes, and economic instruments. The principal conclusions are as follows:

- Most of the regional water resources systems in the 21st century, particularly in developing countries, will become increasingly stressed due to higher demand to meet the needs of a growing population and economy, as well as to protect ecosystems (High Confidence).
- Arid and semi-arid watersheds and river basins are inherently the most sensitive to changes in temperature and precipitation (High Confidence).
- Water demand for irrigated agriculture is very sensitive to climate change, especially in arid and semi-arid regions (High Confidence).
- The current generation of transient GCMs, though much improved, does not offer the degree of watershed-specific information or anticipated variability in future climate required to allow robust estimates to be made regarding changes in water availability (High Confidence).
- Water demand management and institutional adaptation are the primary components for increasing the flexibility of water resources systems to meet increasing uncertainties due to climate change (High Confidence).

- Increased streamflow regulation and water management regimes may be necessary to enable water systems to meet their goals (High Confidence).
- Isolated single-reservoir systems are less adaptable to climate change than integrated multiple-reservoir systems (High Confidence).
- Technological innovations and cost-effective technologies have already played a major role in water management; likely future technological changes can serve to mitigate many of the consequences of climate change (Medium Confidence).
- Changes in the mean and variability of water supply will require a systematic reexamination of engineering design criteria, operating rules, contingency plans, and water allocation policies (Medium Confidence).
- Temporal streamflow characteristics appear to be more variable under future climate scenarios, and amplification of extremes appears likely (Low Confidence).

14.1. Introduction

14.1.1. Objectives

Water resources are an important aspect of the world's social, economic, and ecological systems. Agriculture, hydroelectric power production, municipal and industrial water demands, water pollution control, and inland navigation are all dependent on the natural endowment of surface and groundwater resources. Civilizations have flourished and fallen as a consequence of regional climatic changes, and many "hydraulic civilizations" were formed around the need to control river flow. This endowment is not evenly distributed spatially or temporally. With the imbalance of water supply and demand, many nations are in water-scarce situations and face water crises at a local level. From 1940 to 1987, global water withdrawals increased 210%, while the world's population increased by 117% (Gleick, 1993; Shiklomanov, 1993). A global water resources assessment for the year 2025 (Strzepek *et al*., 1995) suggests that for the United Nations median population forecast of 8.5 billion (a 55% increase over 1990) and a globally balanced economic growth path, global water use may increase by 70%.

The potential for the world to face a water-stressed condition in 2025 under population and economic growth makes assessment of possible water resource impacts associated with climate change an essential component of the IPCC assessment. Changes in hydrological processes are discussed in Chapter 10. This chapter examines the impact on water supply and use and evaluates possible water management response strategies. Water resources management is the interaction of technology, economics, and institutions for the purpose of balancing water supply with water demand and coping with hazards associated with hydrological extremes. The goal of this chapter is to provide an understanding of the sensitivity of the components of water resources systems to potential climate change. Because the water management process occurs at local and regional levels, this chapter cannot provide an assessment of global or continental impacts of climate change; however, it will glean from available literature the sensitivities of various water systems to increases and decreases in river runoff and examine changes in water demands due to changes in regional climate. Because changes in water use will affect many sectors of society and the economy, other chapters in this volume are referenced, such as those addressing wetlands, coastal zones and small islands, energy supply, transportation, human settlements, agriculture and forestry, fisheries, health problems, and financial services.

The main message of this chapter is that climate change will impact the water resources systems of the world but that we will be able to adapt—though at some cost economically, socially, and ecologically. Some analysts (Rogers, 1993a, 1993b; Klemes, 1993; Stakhiv, 1994) feel that current systems will respond well and costs will be minimal; others feel that adaptation will be difficult and in some cases extremely costly. The reason for this disparity is that the sensitivities, impacts, and costs are nonuniformly distributed across the globe. Most analyses have been conducted for regions in the developed world. The limited case studies implemented on river basins in developing countries show that sensitivities, impacts, and costs may be high. Also, much more research is needed on the response of water demands to climate change, especially non-withdrawal uses such as recreation, fisheries, wetlands, ecosystems, and waterfowl protection.

14.1.2. An Overview of Assessment Issues and Concepts

The two previous IPCC assessments outlined the extensive difficulties in conducting meaningful analyses of climate-change impacts on hydrology and water resources (Shiklomanov *et al*., 1990; Stakhiv *et al*., 1992). Since then, many studies have been conducted in different basins—almost exclusively in developed countries—but the general conclusions of the earlier IPCC assessments have not changed. The uncertainties of climate-change impact analysis, especially at the catchment scale, remain large.

It is necessary to distinguish between the physical effects of climate change—which are reviewed in Chapter 10—and the impacts, which reflect a societal value placed on a change in some physical quantity. The impact depends largely on the characteristics of the water-use system: In some cases, a large climate-change effect may have a small impact; in others, a small change may have a large impact.

There are many different types of water supply systems in operation in the world. The simplest "system" extracts water from a local stream or village borehole; this is characteristic for most of the developing world and rural areas in many developed countries. Such supply systems, with no storage, are potentially very sensitive to climate change. The next system level consists of a single managed source—which may be a river, reservoir, or aquifer—coupled with a distribution network to provide water to users and possibly also to treat wastes and return effluents to the river. The sensitivity of such a system to climate change will depend on its characteristics—for example, on the storage-to-runoff ratio and on the seasonal distribution of water supply and demand. The most sophisticated systems are integrated networks, comprising several sources and possibly involving the transfer of water over large distances. Such systems usually are found only in developed countries; their sensitivity to climate change will depend on system structure and the degree of utilization.

Most water managers, whether they are with agencies dealing with multiple-reservoir systems or with small utilities dependent on groundwater, are concerned with three issues: new investments for capacity expansion; the operation and maintenance of existing systems; and modifications in water demand (Rogers, 1993b). Most developed countries have completed major capital-intensive developments of water resources infrastructure. Water managers in those countries operate under conditions of stable population and increased pressure for the incorporation of environmental protection objectives into the operation of existing water resources systems. The main issue

they face is reallocation of existing water among competing uses. This requires continuous adaptation driven by new hydrologic information, ecological constraints, water-quality standards, and shifts in demands and preferences. Water-supply entities also may wish to explicitly or implicitly reconsider the level of service delivered. Institutional adaptation—consisting of changes in organizations, laws, regulations, and tax codes—may be the most effective means for aligning water demands with available supplies (Frederick, 1993; Rogers and Lydon, 1994; World Bank, 1994). This situation is a reality for managed water systems but less so for unmanaged systems (e.g., wetlands) dependent entirely on river flow, groundwater level, or precipitation. Water managers in developing countries are facing population growth-driven increases in water demands, and these demands are met primarily by increasing the water supply via capital-intensive investments to develop infrastructure. With planning and construction times of 20 to 30 years or more for major water projects, the question asked by many water resources managers in developing countries (Riebsame *et al*., 1995) is how climate change might impact the design of new water resource infrastructure.

14.2.   Impact of Climate on Water Supply

14.2.1.   Introduction

Climate change is likely to have an impact on both the supply of and demands for water. This section focuses on the supply of water, looking at the river catchment scale, the global and regional context, and water quality; Section 14.3 considers impacts on demands. Most climate-change impact studies have taken the form of sensitivity analyses by feeding climate-change scenarios into hydrological models. The outputs of these studies tend to be expressed in terms of changes in the reliable yield of the systems, changes in the volume of water that can be supplied, or changes in the risk of system failure. Virtually all of the studies have simulated what would happen in the absence of adaptation to change. In practice, however, water management authorities will adapt using existing or new management options—as shown to be feasible in the Great Lakes region by Chao *et al*. (1994) and Hobbs *et al*. (1995)—although such adaptation may incur added costs and involve tradeoffs that result in reductions in service for some water users. Only a few studies (Riebsame *et al*., 1995; Strzepek *et al*., 1995) have considered factors other than climate change that might affect water resources over the next few decades, such as population growth, economic development, and urbanization.

There are several possible effects of global warming on the amount of water available within a catchment or water supply area; these are summarized in Table 14-1. The relative importance of each characteristic varies considerably among catchments, depending not only on the hydrological change but also on the characteristics of the supply system. For example, a conjunctive-use system involving several reservoirs, river regulation, and groundwater boreholes will be affected differently

Table 14-1: *Summary of effects of global warming on water supply.*

Effect of Global Warming	Impact on Water Supply Reliability
Change in river runoff	Yield in direct water abstraction Yield in reservoir systems
Change in groundwater recharge	Yield of groundwater supply systems
Change in water quality	Yield of abstraction systems
Rise in sea level	Saline intrusion into coastal aquifers Movement of salt-front up estuaries, affecting freshwater abstraction points
Change in evaporation	Yield of reservoir systems

than a supply system based on direct abstractions from an unregulated river.

Obviously, changes in river runoff will affect the yields of both direct river abstractions and reservoir-based supply systems, and changes in groundwater recharge will affect groundwater yield. Changes in water quality will affect the amount of suitable water available to a supply system. A rise in sea level has two potential effects. First, there is a risk of saline intrusion into coastal aquifers, contaminating the water supply. This is a major potential threat—particularly to small, low-lying islands, whose main source of water frequently is a shallow lens of freshwater lying just a few meters above sea level (see Chapter 9). Second, a rise in sea level would mean that saltwater could penetrate further upstream into an estuary, perhaps threatening low-lying freshwater intake works. The effects of these changes in the amount of water available on water uses—and hence on system risk and reliability—will be influenced by changes in demands.

Section 14.2.2 reviews some published studies on changes in resource availability at the catchment scale (which focus mostly on surface water resources), and Section 14.2.3 broadens the perspective to a regional scale. Section 14.2.4 reviews how changes in water quality affect the availability of water resources. The effects of changes in hydrological regimes and water quality are examined in Chapter 10.

14.2.2.   The River Catchment Scale

This section looks at the availability of water supplies under changed climatic conditions. For hundreds of years, people have adapted their habits and economic activities to relatively variable climatic and hydrological conditions—implicitly assuming that the average climatic state and the range of variability are stable.

This assumption may no longer be valid in some regions of the world because of possible alterations in stochastic properties of hydrological time series. Differences in the output of GCMs coupled with the variety of hydrological transfer models make it difficult to offer a reliable region-specific assessment of future water availability. It is doubtful whether the current technique of conducting "worst-case" analyses—wherein the most extreme scenario of a given GCM is used to develop hydrological responses—is useful for a critical appraisal of regional sensitivities to climate change. If anything, this type of analysis skews the evaluation and deflects the search for pragmatic responses. Progress in hydrological sensitivity analyses in developed nations is accompanied by large information gaps for developing countries that are most often affected by aridity and desertification. Although numerous new water resources impact studies have been conducted, few are from Africa, Asia, South America, or developing countries in general.

Studies that have considered possible changes in water supply in specific areas fall into three groups. The first group of studies infers changes in potential supply directly from modeled changes in annual and monthly water balance. Problems in maintaining summer supplies from direct river abstractions may be inferred, for example, if summer river flows are projected to decline (Arnell and Reynard, 1993). The second group of research has considered the sensitivity of hypothetical supply systems—usually single reservoirs—to changes in inputs. The third group of studies has largely been conducted since IPCC's 1992 Supplementary Report and consists of investigations into specific water-supply systems. Some have looked at individual reservoirs or groundwater resource systems; others have examined entire integrated water-supply systems, including real system operating rules. Table 14-2 lists these studies; several are summarized below.

These studies have simulated river flows using conceptual hydrological models but have used a variety of different scenarios. Mimikou *et al*. (1991), Wolock *et al*. (1993), Nash and Gleick (1993), and Kirshen and Fennessey (1995) all examine the effects of arbitrary changes in precipitation and temperature inputs to investigate the sensitivity of their modeled water resources systems to changes in inputs. A 20% reduction in rainfall in the Acheloos basin in Greece, for example, would increase the risk of system failure (inability to provide target supplies) from less than 1% to 38% (Mimikou *et al*., 1991); similarly, with a 20% reduction in rainfall, the New York City reservoir system in the upper Delaware valley would be in a "state of crisis" between 27% and 42% of the time, depending on temperature increases (Wolock *et al*., 1993). Nash and Gleick (1993) and Kirshen and Fennessey (1995) additionally use scenarios based on equilibrium GCM experiments, as do Gellens (1995), Kaczmarek and Kindler (1995), Riebsame *et al*. (1995), Salewicz (1995), Strzepek *et al*. (1995), and, in a generalized way, Hewett *et al*. (1993). All of these studies indicate that water resources systems could be very vulnerable to change in climatic inputs and that a small change in inputs could lead to large changes in system performance, but that there is considerable variability between scenarios. Riebsame *et al*. (1995)

found isolated single-reservoir systems in arid and semi-arid regions to be extremely sensitive and less able to adapt (greater than 50% decreases in reservoir yields), with economic and ecological crisis conditions developing in some basins under climate change and seasonal flooding problems in others.

The remaining set of studies (Hobbs *et al*., 1995; Lettenmaier *et al*., 1995a, 1995b, 1995c, 1995d, 1995e; Steiner *et al*., 1995; Waterstone and Duckstein, 1995; Shiklomanov *et al*., 1995), largely undertaken in the United States, have used scenarios based on the three most recent transient GCM simulations (GFDL-tr, UKMO-tr, and MPI-tr) to investigate possible impacts on integrated, multipurpose water resources systems. All of these studies note the difficulties in forecasting meaningful impacts under the wide range of uncertainties inherent in the analysis; in many cases, the GCM simulations did not reproduce current catchment climate very well. However, a general conclusion from the studies is that even with the large variability in future climate represented by the three transient GCM experiments, most of the systems investigated possess the robustness and resilience to withstand those changes, and adequate institutional capacity exists to adapt to changes in growth, demands, and climate. This conclusion is in contrast to that of many other studies—some summarized above—that have found large changes in system reliability under climate change. There are two main reasons for this difference: First,

Table 14-2: *Investigations into effects of global warming on specific water resources systems.*

the transient scenarios tend to produce smaller changes in climate than the scenarios based on earlier GCMs; second, the transient-GCM studies examine highly integrated systems, which are inherently more robust than the isolated single-reservoir systems investigated in most other studies.

In some countries, water is predominantly taken from rivers, lakes, and reservoirs; in others, it largely comes from aquifers: Only 15% of Norwegian water is taken from aquifers, for example, whereas 94% of Portuguese supplies comes from groundwater. There have been very few studies of changes in groundwater recharge and implications for aquifer yield. Hewett *et al*. (1993) simulate an increase in recharge, and hence an increase in reliable yield, in part of the chalk limestone aquifer in southern England, but different scenarios in the same region suggest a decline in yield. The effect of a sea-level rise on saline intrusion into coastal aquifers has been investigated in a number of small islands and has been found to be potentially significant (see Chapter 9). Studies in Britain, however, have found that although there are many coastal aquifers potentially at risk, a rise in sea level would have little effect on intrusion and yields (Clark *et al*., 1992). Saline intrusion along estuaries generally has been found to pose limited threats to freshwater intakes because the change in the position of the salt front is small relative to the intertidal range (Wolock *et al*., 1993; Dearnaley and Waller, 1993).

This section has introduced some of the studies into water resource availability that have been undertaken in the last five years. There are several points to draw in conclusion. First, there are considerable uncertainties in estimating impacts, due partly to uncertainties in climate-change scenarios and partly to difficulties in estimating the effects of adaptations—both autonomous and climate-induced—over the next few decades. Second, there is evidence that isolated, single-source systems are more sensitive to change than integrated, multipurpose systems, which are considerably more robust. Much of the world's water, however, is managed through single-source, single-purpose systems. Third, there is a suggestion that, in countries with well-managed, integrated water resources, the additional pressures introduced by climate change could be met, with some costs, by techniques already in place to cope with changing demands and management objectives. There is little information, however, about the economic and societal costs of this adaptation. Waterstone *et al*. (1995), for example, conclude that institutional adaptation—changes in water laws, organizations, prices, fees, water marketing, and reservoir operating criteria—could serve to ameliorate the combined effects of increasing population and warming in the semi-arid Rio Grande basin in the southwestern United States, and Hobbs *et al*. (1995) believe that conventional management practices for coping with fluctuating lake levels would be capable of mitigating the effects of climate change on the Great Lakes. Fourth, and perhaps most important, some studies (Riebsame *et al*., 1995; Strzepek *et al*., 1995) show that water resources in developing countries often are small-scale, isolated, and under considerable stress and may have a difficult time adapting to climate change effectively. Although the latter studies cover a

range of hydroclimatic zones, there is still a major gap in our understanding of the impacts of climate change on the less-developed world—a situation that urgently needs to be rectified. The U.S. Country Studies Program currently is cooperatively studying the vulnerability and adaptability of water resources systems in more than 30 developing countries, with results expected in 1996.

14.2.3. *The Global and Regional Context*

The growing interest in possible consequences of anthropogenic climate change on regional water resources has given rise to a wealth of studies on the sensitivity of water balance to climatic variables. Much less information is available on the economic and societal consequences of projected global warming. The heaviest current pressures on water resources are the increasing population in some parts of the world and increasing concentrations in urban areas. The illusion of abundance of water on the Earth has clouded the reality that in many countries renewable freshwater is an increasingly scarce commodity (Postel, 1992; World Bank, 1992, 1994; Engelman and LeRoy, 1993). Climate change is likely to have the greatest impact in countries with a high ratio of relative use to available renewable supply. Regions with abundant water supplies are unlikely to be significantly affected, except for the possibility of increased flooding. Paradoxically, countries that currently have little water—for example, those that rely on desalination—may be relatively unaffected.

One study (Strzepek *et al*., 1995) suggests that, although global water conditions may worsen by 2025 due to population pressure, climate change could have a net positive impact on global water resources. This result, presented in Figure 14-1, is based on runoff characteristics obtained for one particular climate scenario (Miller and Russel, 1992) and should be interpreted with caution. Another macroscale study (Kaczmarek *et al*., 1995)—based on three transient climate scenarios—leads to a similar conclusion for the Asian continent, while suggesting that in Europe changed climatic conditions will be associated with some decrease of per capita water availability.

Following the concept of Falkenmark and Widstrand (1992) of a water stress index based on an approximate minimum level of water required per capita, Engelman and LeRoy (1993) use 1,000 m^3 per person per year as a benchmark for water scarcity around the world. They found that in 1990 about 20 countries, with a total population of 335 million, experienced serious chronic water problems and that by 2025, 31 countries with 900 million inhabitants could fall into this category because of expected population growth. Table 14-3 summarizes the combined impact of population growth and climate change on water availability in selected countries, based on the IPCC (1992a) socioeconomic scenarios and the results of three transient GCM runs. The second column lists per capita water availability for the present (1990); the third column shows water availability for current climatic conditions, reflecting population growth alone to the year 2050. The last column shows the range of
Figure 14-1: Global freshwater vulnerability (Strzepek *et al*., 1995).

combined effects of population growth and climate change for the three transient scenarios. The sensitivities of national water supplies to changes in temperature and precipitation were estimated by a method proposed by Kaczmarek (1990). It should be added that the future water availability data do not take into account possible changes in water resources systems development (e.g., increased storage, desalination).

The results show that in all countries with high population-growth rates, future per capita water availability will decrease independent of the assumed climate scenario. Large discrepancies may be noted among results obtained for some countries by means of various atmospheric models. This example clearly demonstrates how difficult it would be to initiate water resources adaptation actions based on currently available methods of climate predictions. It can be expected that in many regions of the world, nonclimatic factors will dictate what measures must be undertaken to secure sustainable water supply (Frederick, 1994; Rogers and Lydon, 1994). Predicted climate changes, however, could redistribute water supplies, adding a new, highly uncertain component to the challenge of managing water resources.

Although it is appealing to devise thresholds or benchmarks for water scarcity, such as the one proposed by Falkenmark and Widstrand (1992)—in which economic water scarcity is defined as the condition in which renewable freshwater availability falls below 1,000 m³ per person per year—it is important to realize that such a threshold is useful only as a rough benchmark for

comparison of relative conditions, perhaps to serve as a cautionary flag. Other comparable thresholds have been suggested at 1,700 m³ per person per year to reflect a condition of water stress, whereas the World Bank (Falkenburg *et al*., 1990) suggests a 500 m³ per person per year threshold. On the other hand, Rogers (1992) considers such thresholds not useful in developing water management strategies, noting that both Malta and Israel—with annual per capita water availabilities of 85 m³ and 460 m³, respectively—are doing quite well in managing, recycling, and reclaiming their very limited water supplies.

Water availability, food production, population and economic growth, and climate change are linked in a complex way. Conflicts among interests are inherent in regional water management, particularly in regions with scarce water resources. Four objectives important for sustainable water planning may be identified: economic efficiency, environmental quality, equity considerations, and reliability. Transformation in the structure and characteristics of water supply and demand due to climatic and nonclimatic factors may add new aspects to existing social and political problems. Socioeconomic factors greatly influence the ability to solve these problems in the absence of necessary institutions, capital, and technology.

Access to freshwater may be complicated by conflicts arising over rights to water in shared river basins (e.g., Mekong and Nile—Riebsame *et al*., 1995) and in aquifers that cross international borders (Engelman and LeRoy, 1993). A great number

Table 14-3: Water availability (m³/yr) in 2050 for the present climatic conditions and for three transient climate scenarios (GFDL, UKMO, MPI).

Country	Present Climate (1990)	Present Climate (2050)	Scenario Range (2050)
China	2,500	1,630	1,550–1,780
Cyprus	1,280	820	620–850
France	4,110	3,620	2,510–2,970
Haiti	1,700	650	280–840
India	1,930	1,050	1,060–1,420
Japan	3,210	3,060	2,940–3,470
Kenya	640	170	210–250
Madagascar	3,330	710	480–730
Mexico	4,270	2,100	1,740–2,010
Peru	1,860	880	690–1,020
Poland	1,470	1,250	980–1,860
Saudi Arabia	310	80	30–140
South Africa	1,320	540	150–500
Spain	3,310	3,090	1,820–2,200
Sri Lanka	2,500	1,520	1,440–4,900
Thailand	3,380	2,220	590–3,070
Togo	3,400	900	550–880
Turkey	3,070	1,240	700–1,910
Ukraine	4,050	3,480	2,830–3,990
United Kingdom	2,650	2,430	2,190–2,520
Vietnam	6,880	2,970	2,680–3,140

of water resources systems are shared by two or more nations. In several cases, there have already been international conflicts. As a result of population pressure, and in cases of negative impacts of climate change, tensions are likely to increase. In order to avoid future conflicts over water use among riparian countries, joint legal agreements should be established. One possibility is to form international water agencies or commissions, with terms of reference including inventory, assessment, monitoring, and apportionment of water resources and due account for possible changes caused by climatic trends. Joint planning is essential for basin-scale water resources development and management in order to cope with negative consequences of climate change. International water agencies should arbitrate on regional water issues and be supported by national legal frameworks to back the regional arbitration accordingly. To be able to fulfill this task, international water agencies in developing countries require well-trained people with knowledge of global-scale processes and, in some cases, external funding for research and development.

14.2.4. Implications of Changes in Water Quality

Water management is concerned not merely with the supply of water but with the supply of water of appropriate quality as well. The definition of "appropriate" varies among uses.

Potable water has to be of the highest quality, whereas industry and, to a lesser extent, agriculture can use lower-quality water. Irrigation increasingly employs recycled "dirty" water, raising concern about salinity and public acceptance of wastewater use. Many water management problems around the world today, in fact, relate to the quality of surface water and groundwater. Climate change might exacerbate some of these problems by complicating an already expensive, evolving management process. Water-quality problems usually stem from some form of pollution, ranging from the discharge of untreated sewage into watercourses to the discharge of treated sewage effluent, the leaching of agricultural chemicals, and chemical and thermal pollution from industry. There is a considerable range of experience in dealing with water quality. In some countries, the focus is on preventing poor water quality; in others, effort is directed toward rehabilitation, treatment, sanitation, and public health. In many countries, water quality is hardly addressed at all.

The potential effects of climate change on aquatic ecosystems are reviewed in Chapter 10. Of particular concern for water users are dissolved oxygen content, nitrate and organic pollution concentrations, sediment load, and salinity. The main conclusion is that rivers that presently have poor water quality are likely to be those most affected by changes in temperature, lower flow rates, and increased input of pollutants; climate change is therefore likely to exacerbate water-quality problems in places where such problems already are potentially severe.

Water management agencies in many countries are spending significant sums on maintaining and improving surface and groundwater quality. Although approaches vary, improvement plans tend to include target water-quality and effluent standards, infrastructure for treating effluent returns and polluted water, policies to prevent pollution, and policing. These actions also can be used to maintain and improve water quality under climate change, obviously at some additional cost. For example, it may be necessary to reduce the quantity of treated effluent that can be discharged to a stream with reduced flows, with consequent implications for the discharging organization.

14.3. Impact of Climate on Water Demands

Section 14.2 considered changes in the ability of water resources systems to supply water; this section looks at the demand side. It is useful to distinguish between offstream demands—specifically domestic, industrial, and agricultural demands—and instream demands, such as power generation, navigation, recreation, and ecosystems protection. Increases in water demand are driven by population and economic growth. Demand management has two dimensions: the first long-term, the second in response to short-term shortages. In the long term, one can reduce offstream water demands substantially through technological, economic, legal and administrative, and educational measures. In the short term, demand during temporary supply shortages can be managed through demand reduction measures (such as rationing) and public education.

14.3.1. Agricultural Water Demands

At present, more than 65% of global water withdrawals is for agricultural use; much of this is evaporated and consequently lost to catchment runoff. Irrigation increased significantly until the 1970s, when the rate of expansion fell sharply; since 1980, the annual rate of expansion has been less than 1%—less than the rate of population increase (Postel, 1992). Rapid expansion in the future is unlikely as the cost of developing new schemes increases and investments in irrigation decline. Agricultural irrigation practices are inefficient in many areas of the world. Changes in irrigation technology (such as the use of drop irrigation) often can compensate for anticipated increases in food demands. The effects of climate change on agricultural policy and irrigation requirements are discussed in Chapter 13. It is important to emphasize that the effects of climate change on agricultural demands for water, particularly for irrigation, will depend significantly on changes in agricultural potential, prices of agricultural produce, and water costs.

Both rainfed and irrigated crops will require more water in a warmer world, and this water may not be available through increased precipitation. Allen *et al*. (1991) simulate changes in irrigation demand in the Great Plains region of the United States, showing that the demand for water to irrigate alfalfa would increase, due largely to increases in the length of the crop growing season and crop-water requirements during summer. Another U.S. study—based on a Thornthwaite water-balance model (McCabe and Wolock, 1992)—indicates that, for a broad range of increases in temperature and precipitation, annual irrigation demand increases, even with a 20% increase in precipitation. In a study in Lesotho, Arnell and Piper (1995) simulate an increase in irrigation demands of 7% with a 10% decline in runoff and an increase of more than 20% with a 2°C increase in temperature. They also examine the performance of a hypothetical reservoir supplying irrigation water and find major changes in the reliability of supply. Studies in the UK lead to the conclusion that an increase in temperature of 1.1°C by 2050 may result in an increase in spray irrigation demands of 28%, over and above a projected 75% increase to meet growing demands (Herrington, 1995). Similar calculations in Poland result in a 12% increase in irrigation demands with a 1°C temperature increase and a 1.8% change in water requirements with a 1% precipitation change during the vegetation season. Irrigation demand seems to be more sensitive to changes in temperature than to changes in precipitation. Model results indicate that increased stomatal resistance to transpiration counteracts the effects of temperature increases on irrigation demand.

14.3.2. Municipal Demands

Municipal demands are essentially for domestic and commercial uses. In many developed countries, some components of demand are decreasing due to greater appliance efficiency, but others are increasing as new appliances, such as waste disposal units and automatic washing machines, become more widespread. Herrington (1995) estimates changes in the components

of domestic demand in southern England, with and without climatic change and assuming no change in water pricing policies. An increase in per capita demand of 21% is projected between 1991 and 2021 without climate change, with an additional 5% increase due to global warming—largely due to an increase in garden water use. Other studies have found a similar percentage change in domestic and municipal demand due to global warming (Cohen, 1987; Kaczmarek and Kindler, 1989; Kirshen and Fennessey, 1993; Hanaki, 1993; Steiner *et al*., 1995). Little is known about the impact of climate change on domestic water use in developing countries, but nonclimatic factors—population growth, economic development, water-use efficiency, and water pricing—probably will dominate in shaping trends of future water use in most African and Asian regions.

14.3.3. Industrial Water Use and Thermal and Hydropower Generation

In most developed countries, the demand for water for industrial purposes is declining as traditional major water users such as the steel industry decline in significance and as water is used more efficiently. It should be added, however, that in many cases these water-consuming industrial users are relocating to the developing world, complicating the water resource situation in those regions. Strzepek and Bowling (1995) have found that under a moderate growth assumption, global industrial water use in 2025 may increase by 1.7 to 2.3 times 1990 levels, and most of this growth will occur in the developing world. Climate change is expected to have little direct impact on industrial water use.

A change in water quantity may affect the degree to which demands for cooling water can be satisfied, and a rise in water temperature will reduce the efficiency of cooling systems (Dobrowolski *et al*., 1995). It also might be more difficult to meet regulatory constraints defining acceptable downstream water temperatures, particularly during extreme warm periods. Several French nuclear power stations were forced to close down or operate well below design capacity during the drought of 1991. A reduction in water availability might lead to an increase in the use of closed-cycle cooling systems as simulated in the Tennessee Valley Authority system (Miller *et al*., 1993). Changes in water availability and temperature may not cause significant impacts on long-term or annual total production potential—only a 2% decline in annual net system generation was found in the Tennessee Valley—but they could cause short-term operational problems during critical periods.

A change in hydrological regimes has an obvious potential impact on hydropower production but also may affect thermal power generation and general industrial demands for cooling water. Mimikou *et al*. (1991) show a very large change in the risk of being unable to generate design power from hydropower reservoirs in central Greece. In Norway, Saelthun *et al*. (1990) find increased generation potential due largely to a shift in the timing of inflows, mainly as a result of reduced snowfall; the current "waste" of power in the spring is much reduced.

Riebsame *et al.* (1995) examine hydropower generation in four developing-country basins. In the Zambezi basin, the possible reduction of hydropower at Lake Kariba could be replaced by the construction of a new plant at Batoka Gorge, but for a significant cost. Hanemann and McCann (1993) examine the economic cost of changes in hydropower potential in northern California. Under a scenario based on the GFDL equilibrium GCM, annual hydropower production would decrease by 3.8%; production would be 48% higher in January but as much as 20% lower during the peak-load summer months. Water would have to be released during the spring to leave room for flood control. As a result of the reduced hydropower generation, production of power by natural gas would have to increase by 11% to meet the same demands, leading to a $145 million (1993 prices) increase in annual system costs (12.5%). In some cases, the expected shift in the runoff hydrograph, combined with changes in the distribution of irrigation water demands, may lead to reduced energy generation.

14.3.4. Navigation

Changes in flow regimes and lake levels can be expected to affect navigation potential, but there have been very few studies on this topic. The sensitivity of river navigation to extreme conditions was well illustrated on the Mississippi River during the drought of 1988, when river traffic was severely restricted (with consequent effects on the agricultural sector due to difficulties in transporting the grain harvest). High river flows also restrict navigation by increasing energy costs and flooding riverside facilities. Navigation on the river Rhein, for example, is constrained by periods of both high and low flows, and considerable sums are spent on dredging and maintaining channels; a change in sediment load could have major implications for these activities. An increase in temperature, however, would increase the duration of the navigation season on rivers affected by seasonal ice cover. Studies in the Great Lakes (Chao *et al.*, 1994) suggest that a longer shipping season due to a reduction in ice cover would just compensate for lost draft due to lower levels; shipping companies would be able to adjust their operating season in the Great Lakes because many of the raw materials transported are stockpiled.

14.3.5. Recreation and Other Instream Water Uses

There have been very large investments in water-based recreation in many countries, and many large facilities are operated to maximize recreation potential. The effects of global warming on recreation are difficult to determine. Changes in the volume of water stored in a reservoir might affect the use of the reservoir for recreation (Frederick, 1993), and a change in water quality might also affect the recreational use of the water. There are established procedures for estimating the economic benefits of access to recreation, but the sensitivity of recreational use to hydrological characteristics—reservoir storage volume, water quality, and so forth—is not well known; the effects of possible changes therefore are difficult to quantify.

One exception is the Great Lakes, where there are clear relationships between beach area, length of recreation season, and recreational benefits: Both beach area and recreation season length would increase under climate warming, resulting in an estimated doubling of recreational benefits, according to Chao *et al.* (1994).

One-tenth of the world's commercial fish yield is obtained from inland waters (Covich, 1993), and recreational fishing also has high economic value. The effects of changes in water temperature, water quality, and river flow regimes on fish populations are outlined in Chapter 10; this section focuses on implications of changes for sport fishing and aquaculture. Hanemann and Dumas (1993) simulate the effects of one global warming scenario on Chinook salmon runs in the Sacramento River, California, and find a reduction in the salmon population largely due to reductions in spawning habitats. Loomis and Ise (1993) estimate the change in the economic value of recreational fishing in the Sacramento River based on an empirical relationship between the number of fish caught and the number of fishing trips made. The reductions in fish population result in an annual loss of recreational benefit of $35 million (1993 values)—a 23% decrease (assuming no change in anglers' willingness to travel to the river).

Stefan *et al.* (1993) conclude that, for the state of Minnesota, the impact of climate change on fishery resources may be significant. Overall fish production may increase, but cold-water fisheries will be replaced in part by warm-water fisheries. This coincides with findings in Poland and Hungary related to the impact of thermal pollution. The comprehensive study of fish yields performed by Minns and Moore (1992) in several hundred watersheds in eastern Canada shows considerable redistribution of fishery capability.

The final instream use to be considered in this section is ecosystem protection. Instream ecosystems demand a certain minimum quantity of water (which may vary throughout the year), and water managers in many countries increasingly are balancing these demands with those of more traditional water users. Several techniques are being developed to estimate instream demands (Stalnaker, 1993); these techniques can be used in principle to estimate the effects on these demands of changes in water availability. However, this has not yet been done, largely because the instream demand models are very uncertain. In principle, it might be possible to maintain certain aquatic ecosystems by managing river flow regimes to minimize changes, but this is perhaps not desirable in an ecological sense because it would create a system that would not be sustainable without human intervention. The general issue of managing the impacts of climate change on natural ecosystems is discussed in Chapter 10 and elsewhere.

14.3.6. Competition Between Demands

Water demand in general increases in all sectors with an increase in temperature; this is a well-accepted consequence of

climate change. At the same time, regional and local precipitation changes, which will have important impacts on water demands, are much less clear. Studies of individual sectors and systems show great potential for adapting to water conditions in a changed climate. However, as we move into the 21st century, population and economic pressures may create water-stressed conditions in many parts of the world. Many of the responses being proposed to adapt to climate change require reduction of demands and reallocation of water among water-use sectors.

Present water management is concerned with reconciling competing demands for limited water resources. Currently, these conflicts are solved through legislation, prices, customs, or a system of priority water rights. Change in the amount of water available and water demands is likely to lead in many cases to increased competition for resources. Conflicts may arise between users, regions, and countries, and the resolution of such conflicts will depend on political and institutional arrangements in force. The challenge will be to create integrated demand/supply management systems, as discussed below.

14.4. Management Implications and Adaptation Options

14.4.1. Considerations for Response Strategies

In general, most countries and civilizations have faced water shortages due to natural climate variability, anthropogenic changes and desertification, or overexploitation and pollution of the resource base. Management of water resources inherently entails mitigating the effects of hydrological extremes and providing a greater degree of reliability in the delivery of water-related services. Because different uses have different priorities and risk tolerances, the balance points among them after climate change could be quite different from the present (e.g., hydropower and instream uses may be lost disproportionately compared to water supply). No enterprise is risk-free: Society decides on the level of risk-bearing through the acceptance of certain levels of risk and reliability, as expressed by cost-effective standards and criteria. The marginal cost of reducing each additional increment of risk typically rises rapidly as reliability approaches 100%. Hence, water managers usually deal with 90%, 95%, and 99% levels of reliability as useful performance measures of the available quality and quantity of water.

The same is true in mitigating other natural hazards, especially in traditional approaches to drought mitigation, flood control, and damage mitigation. Given some of the preliminary results of GCM experiments regarding potential changes in rainfall intensity and frequency (Gordon *et al*., 1992; Whetton *et al*., 1993), it appears that flood-related consequences of climate change may be as serious and widely distributed as the adverse impacts of droughts. This should raise concerns about dam safety and levee design criteria and spur reconsideration of flood plain management policies. The devastating floods of 1993 in the upper Mississippi River basin have resulted in a U.S. Interagency Floodplain Management Review Committee

report (1994) on just such policy issues, exemplifying the need for constant adaptation in the field of water resources management. Comparable adaptations are anticipated in the wake of the most recent European floods of January 1995.

To alleviate human-induced droughts occurring at a regional scale as a consequence of inappropriate land-use practices, wise criteria for land use should be developed to minimize storm-induced runoff and, consequently, minimize erosion and nutrient loss and maximize interception and infiltration. Such strategies would maintain or enhance the recycling of moisture, which at a (sub)continental scale is necessary to sustain rainfall in the region. Most watershed management practices for erosion control and water harvesting do contribute, albeit unintentionally, to the reestablishment of moisture feedback to the atmosphere and, consequently, to the recycling of moisture and rainfall. In view of the vulnerability of regions presently affected by anthropogenic droughts and the dire consequences of resulting desertification, this field of research merits full attention.

The first IPCC reports (1990a, 1990b) contain a discussion of the philosophy of adaptation and a list of adaptation options suited to the range of water management problems that are expected under climate change. Based on a review of the most recent literature, no additional water management actions or strategies unique to climate change have been proposed as additions to the list, other than to note that many nations have pledged to implement action plans for sustainable water resources management as part of their obligation toward Agenda 21. In that respect, the principles laid out in that document would serve as a useful guide for developing a strategy that would enable nations, river basin authorities, and water utilities to prepare for and partially accommodate the uncertain hydrologic effects that might accompany global warming. The World Bank (1993) lays out a framework for water resources management that is expected to serve the needs of developing nations well into the next century and to meet the objectives of Agenda 21.

There are many possibilities for individual adaptation measures or actions. An overview of water supply and demand management options is presented by Frederick (1994) as part of an attempt to develop approaches for dealing with increasing water scarcity. A long-term strategy requires the formulation of a series of plausible development scenarios based on different combinations of population growth assumptions along with economic, social, and environmental objectives (Carter *et al*., 1994). After these scenarios are established, taking into account the possibility of climate change, a set of alternative long-term strategies for water management must be formulated that consists of different combinations of water management measures, policy instruments, or institutional changes, and is designed to best meet the objectives of a particular growth and development scenario and its consequent CO_2 emissions rate. The range of response strategies must be compared and appraised, each with different levels of service reliability, costs, and environmental and socioeconomic impacts. Some will be better suited to dealing with climate change uncertainty (i.e., more robust and resilient), and others

will focus on environmental sustainability. Some are likely to emphasize reliability of supply. The reality is that, after the application of engineering design criteria to various alternatives, the selection of an "optimal" path is a decision based on social preferences and political realities. Engineering design criteria, however, also evolve over time and are updated as new meteorological and hydrological records are extended and the performance of water management systems is tested under varying conditions.

All major institutions that deal with water resources planning and management agree that future water management strategies should include various cost-effective combinations of the following management measures:

- Direct measures to control water use and land use (regulatory, technological)
- Indirect measures that affect behavior (incentives, taxes)
- Institutional changes for improved management of resources
- Improvement in the operation of water management systems
- Direct measures that increase the availability of supply (reservoirs, pipelines)
- Measures that improve technology and the efficiency of water use.

Different strategies apply to different circumstances. Watersheds that have little or no control over natural flows and are largely dependent on precipitation must implement a different set of water management strategies than river basins with a high degree of control in the form of reservoirs, canals, levees, and so forth. Similarly, rapidly urbanizing areas will require different responses than agricultural regions. There is no standard prescribed approach. However, a rational management strategy undertaken to deal with the reasonably foreseeable needs of a region in the absence of climate change, according to the principles espoused in Agenda 21, also will serve to offset many of the possible adverse consequences of climate change.

14.4.2. *Implications for Planning and Design*

The nature of contemporary water resources management is such that countless numbers of principal factors, economic criteria, and design standards are incorporated simply because of the complexity of integrated water management (e.g., hydropower, ecosystem support, water supply) and objectives (e.g., reliability, costs, safety). Some factors that are routinely assessed inherently represent design thresholds such as the minimum instream flow required for maintaining an aquatic ecosystem or the "probable maximum flood" that is used for most dam-safety risk analyses. The accepted level of water supply reliability of a system is a threshold as well, determined essentially by public preference, economics, and engineering analysis. Planning, by its nature, has inherent risks and develops alternative plans that are packages of complementary actions, project regulations, and management measures that reduce risks

in different water-use sectors (with a variety of socioeconomic and environmental impacts and a range of benefits and costs).

Engineering design is largely concerned with performance and reliability. Once a particular plan is selected, engineers ensure that each of the separate components functions as planned and that, collectively, the water management system performs reliably. This was true in Roman times (Frontinus, 98 AD) as well as in contemporary times. Water resources systems are designed to perform reliably over most but not all of the range of anticipated hydrological variability. That reliability criterion is determined through a combination of risk, costs, benefits, environmental impacts, and societal preference. Hence, if climate change alters the frequency, duration, and intensity of droughts and floods, new reliability criteria will evolve over time to adjust for the perceived changes in both availability and use—as will the corresponding types of adaptive behavior.

It also is useful to think of hydrological or watershed response sensitivity to change measured in terms of physical effects. A complementary notion is the susceptibility of various water-use sectors (e.g., hydropower, irrigation, recreation) to incremental changes of outputs (e.g., kilowatt-hours, revenues, visitors). Finally, the vulnerability to failure of a water management system itself—consisting of pipes, pumping stations, reservoirs, and delivery rates—also must be appraised in terms of reliability targets measured as changes in quality, quantity, and probability. To that end, water resources planners, hydrologists, and design engineers have developed a set of practices that explicitly address a range of hydrological, economic, and engineering risk and uncertainty factors and implicitly encompass some notion of sensitivities and thresholds. Fiering (1982) and Hashimoto *et al.* (1982a, 1982b) developed the concepts of robustness (sensitivity of design parameters and economic costs to variability); reliability (a measure of how often a system is likely to fail); resiliency (how quickly a system recovers from failure); vulnerability (the severity of the consequences of failure); and brittleness (the capacity of "optimal" solutions to accommodate an uncertain future). Many if not most of these concepts are analyzed as part of contemporary hydrological and water resources management decisions (Kundzewicz and Somlyody, 1993; Kaczmarek *et al.*, 1995). Riebsame *et al.* (1995) analyze the sensitivities and adaptabilities of five international river basins in the context of the criteria discussed above. The results are presented in Table 14-4.

Table 14-4: *Overall basin sensitivity and adaptability (Riebsame et al., 1995).*

Basin	Hydrological Sensitivity	Structural Robustness	Structural Resiliency	Adaptive Capacity
Uruguay	moderate	high	high	high
Mekong	low	low	high	low
Indus	moderate	high	moderate	high
Zambezi	high	low	low	low
Nile	high	high	low	low

There is a growing tendency to devise management systems that complement supply development with demand management. Nonstructural management measures are increasingly relied on to provide needed robustness without decreasing the overall reliability of a system. Hence, flood-control levees in the United States are now designed to provide varying levels of protection, whereas in the past there was a fixed level of flood protection based on a calculation of the "standard project flood." Today, a levee can be designed to offer protection against a flood with a 2% chance of occurrence (a 50-year return period) in conjunction with a well-organized flood warning and evacuation plan. For example, all 360 U.S. Corps of Engineers reservoirs have both drought contingency plans and flood warning and dam-safety evacuation plans. However, it is important to remember that the combination of numerous design factors, operating rules, reservoir storage allocation decisions, flood forecasting and evacuation planning, and drought contingency planning provides a considerable degree of robustness, resiliency, and flexibility to contend with uncertainty and surprises. Coupled with demand management and institutional and regulatory changes that are needed to cope with anticipated changes in population and demands, water management systems of this scale, if properly managed, offer a well-balanced strategy for dealing with risk and uncertainty, including many of the impacts of climate change. The purpose is to reduce, if not minimize, the adverse social, economic, and environmental consequences of changes in water resources regardless of the agent of change (Stakhiv, 1994), although the costs of adaptation to climate change could be substantial. Most important is the reality that water resources management is an inherently continuous adaptive endeavor at many different levels and spatial scales.

This is not to suggest that we can become complacent in our response to climate change. The challenges and barriers to implementing the water management principles of Agenda 21 are difficult enough to overcome. The water situation in the Middle East and North Africa is precarious and projected to deteriorate as a consequence of population growth and unplanned development. In sub-Saharan Africa (World Bank, 1994), the water situation is expected to worsen due to desert encroachment and drying up of water sources as a result of increased deforestation. Droughts, desertification, and water shortages are a permanent feature of daily life in those countries. The list of nations with water supply problems will expand with the accelerated pace of urbanization. By the year 2030, urban populations will be twice the size of rural populations. By 2000, there will be 21 cities in the world with more than 10 million inhabitants, 17 of which will be in developing countries. It is expected that the population without safe drinking water will increase from 1 billion people in 1990 to 2.4 billion by 2030, assuming a "business-as-usual" scenario. Similarly, population without adequate sanitation will grow from 1.7 billion to 3.2 billion by the year 2030 (World Bank, 1992). Addressing these issues would make it easier to cope with the impacts of climate change when and if they become significant (IPCC, 1992; Goklany, 1992).

On the other hand, the picture may not be as bleak as it appears, in the sense that it is easier and more efficient to organize a water supply, treatment, and delivery system for urban areas with concentrated populations. Also, demands can be more easily managed to promote water-use efficiency. Although municipal and industrial water use will grow, per capita use is likely to decrease and the quality of drinking water will increase with centralized treatment. Many future urban water demands are likely to compete with the irrigated agricultural sector—which uses about 88% of all water withdrawn in Africa, 86% of all water withdrawn in Asia, and 87% of all water withdrawn in the arid Middle East and North Africa (World Bank, 1994). New sources of supply will have to be developed, but existing water use will have to be more effectively managed and efficiently used.

The reality is that increasing water demands will intensify competition for scarce water and further concentrate water use in urban centers. During the next 30 years, these real and complex needs will preoccupy water managers. Water management planning will address these needs, which precede the climate-change signal and thereby serve as a *de facto* adaptation mechanism. Climate change, in its many manifestations, is likely to be a perturbation on what are already difficult and complicated water management problems. Existing drainage systems, water-control structures, and conveyance and distribution systems typically are designed on the basis of design floods or droughts of different return periods and/or annual exceedance probabilities, which are derived from past failures and associated perceived degrees of tolerable risk and economic costs. Because there is a significant turnover in water management infrastructure, with considerable maintenance and major rehabilitation occurring in most countries about every 30 years, it can be expected that the operating capacity of such structures can be made to conform to evolving changes in climate. Analytical tools are available to provide the necessary degree of confidence in the design and operation of such systems in a reliable manner.

14.4.3. *Impact on Flood Risk and Management*

Although the potential impact of global warming on the occurrence of flood disasters has been alluded to frequently in popular accounts of global warming, there have been very few studies addressing the issue explicitly. This is largely because it is difficult to define credible scenarios for changes in flood-producing climatic events (Beran and Arnell, 1995). Chapter 10 outlines the potential effects of global warming on riverine floods, and Chapter 9 reviews the effects of a rise in sea level and changes in storms on coastal flooding. This section considers the implications of changes in flood occurrence for flood risk and management. There are four major implications: a change in flood loss, a change in flood risk and the standard of service currently provided by flood management and protection schemes, a change in the cost of protecting against floods, and impacts on public and private financial institutions.

The effect of a change in the frequency of floods on flood losses has to be set against many other factors, including population

growth, economic development, and expansion onto flood plains. These factors have large impacts, making it difficult to detect climate-related change on flood loss statistics.

It might be easier, however, to detect a change in the standard of service provided by existing flood management schemes. Flood protection works and flood plain land-use plans usually are based on either a risk analysis to determine the most cost-effective level of protection (balancing costs against benefits) or on some legislative or institutional guideline for standard of service. Urban-flood-protection works, for example, typically provide protection against floods with a return period of up to 100 years. A change in flood frequency characteristics can have a very significant effect on flood risk and hence standards of service: A small change in flood magnitudes can have a very large effect on the risk of a particular critical value being exceeded. Beran and Arnell (1995) have shown that, assuming statistical properties similar to those of British rivers, a 10% increase in the mean—with no change in the year-to-year variability of floods—would result in a current 10-year flood occurring on average once every 7 years.

Increased flood frequencies probably would lead to increased expenditures on flood management. Most directly, the costs of providing or improving structural flood defenses would increase; indirect costs to society also may be incurred if larger areas of potentially productive floodplain land are excluded from development by flood plain zoning policies. However, there have been no quantitative studies of the costs of maintaining flood protection in the face of global warming.

Finally, an increase in flood losses may place significant strains on public finances, if damages are covered by public funds, or on the insurance industry. The amount of aid provided varies from country to country, as does the amount of coverage provided by the insurance industry. At the global scale, the international insurance and reinsurance industry may be seriously threatened by the occurrence of a few large, closely spaced storm events.

The Mississippi floods of 1993 and the European floods of 1994/1995 triggered major reviews of flood management policies. It is unlikely that flood management in the 21st century will be similar to flood management in the 20th century; there will probably be an increasing emphasis on adopting nonstructural measures and coping with uncertainty in risk assessments. The future effects of global warming on flood risk and flood management therefore must be seen against this changing institutional and technical background.

14.5. Research Needs

Uncertainties and analytical difficulties confront attempts to quantitatively analyze the direct effects of global warming on water resources demands. Considerable research investment is required in order to improve prediction and adaptive responses

in the face of these uncertainties and methodological problems, including:

- Uncertainties in GCMs and lack of regional specification of locations where consequences will occur
- The absence of information on future climate variability
- Uncertainties in estimating changes in basin water budgets due to changes in vegetation and atmospheric and other conditions likely to exist in the future
- Uncertainties in the future demands of each water sector
- Uncertainties in the socioeconomic and environmental impacts of response measures
- Water management criteria under a potential nonstationary climate
- Linkage of water and agricultural sectors through detailed study of the impact of climate change on irrigation
- The impact of land-use and land-cover changes on water management
- The role and impact on groundwater management and conjunctive use.

It is doubtful whether some of these uncertainties can be completely eliminated, and, as with anything in the future, unforeseen elements will arise.

CONTENTS

EXECUTIVE SUMMARY

The fundamental question on which this chapter focuses involves forest resource availability and resource consumption: Will the resources from future forests be adequate to meet future needs? Although all forest amenities are of interest, this chapter concentrates primarily upon those for which data are most available, reliable, and measurable: wood and wood products. All of the conclusions depend upon uncertain climate model simulations (resource availability), uncertainty in adaptive changes in forest product use, and uncertain regional human population growth scenarios (resource consumption). Assuming all of these variables change as projected by their respective scenarios, the following forest resource responses are likely (note that none of the conclusions summarized below were considered in the 1990–1992 IPCC Assessments):

- Tropical land use will be much more important than change in climate and atmospheric chemistry in affecting forest product availability there, at least until the middle of the next century (High Confidence). Growing stock in the tropics is projected to decline by about half from anthropogenic deforestation, while consumption is predicted to expand because of a threefold increase of population. The projected standing stock decline appears even after calculation of concomitant changes in climate and atmospheric chemistry, which could increase both productivity and the areas where tropical forests can potentially grow.

- Under these circumstances, tropical forests of densely populated countries in Africa and Asia would be most vulnerable to loss (High Confidence). These areas contain rapidly expanding human populations and concomitant increasing needs for forest products, especially but not entirely for fuelwood. Fuelwood consumption is expected to increase throughout the 55-year study period (High Confidence).

- Temperate-zone wood requirements are likely to continue being met for at least the next century (Medium Confidence). This conclusion is based on assumed climate and land use changes that leave temperate forest covering about as much land by the year 2050 as today. Also, current harvests from plantations and wildland forests are expected to increase only marginally. Additionally, annual growth increments are assumed to remain constant through 2050. Finally, an increasing proportion of requirements for wood is expected to be met by imports from outside the temperate zone.

- Future wood availability in boreal regions is uncertain at best, based on current data, scenarios, and models (High Confidence). Future production is expected to be controlled by increases in climate-induced irregular and large-scale mortality events, which cannot be simulated or predicted with current models. These could generate considerable surplus wood from salvage fellings, but would severely decrease standing stocks over the long term. In addition, current and future harvests in boreal forests are expected to be largely determined by needs outside the zone. The models underlying future projections contain no consideration of these forest economic or trade processes or their implications, a particularly critical omission in boreal regions. Therefore, the available information does not support realistic analysis of future boreal forest product demand.

- Total global wood consumption will exceed the availability expected by the year 2050 (Medium Confidence). Analysis of increasing human populations, with the assumption of constant per capita wood use, suggests that the annual need for timber will exceed the current 2% annual growth increment before the year 2050. Although we assume that the annual increment will remain constant, it could increase slightly from warming and enhanced atmospheric CO_2 concentrations, or it could decrease greatly from growth declines and mortality brought on by climate change.

- Future temperate and possibly tropical zone requirements for boreal forest products may result in serious shortfalls of boreal industrial roundwood during the 21st century based on the analysis of temperate and tropical zone forest standing stocks and requirements (High Confidence).

- The livelihood of indigenous tropical peoples will be adversely affected if climate and land-use change induce forest losses (High Confidence). These peoples depend on a large diversity of forest products that are expected to undergo declines in biodiversity and forest regeneration due to climate change and may be subject to forest degradation apart from land conversion.

- Options for adapting to and ameliorating potential global timber supply shortages in the future include the following actions: In the tropics, the greatest progress may be achieved by reducing social pressures driving land conversion (e.g., by increasing crop and livestock productivity on current agricultural lands) and by development of large tree plantations (High Confidence). In temperate areas, use of modern forestry practices to reduce harvest impacts on ecosystems, combined with substitution of nontimber products for forest products, could reduce climate impacts

significantly (Medium Confidence). In boreal regions, the most useful focus may be on adapting to potential climate-induced large-scale disturbances, such as by rapid reforestation of disturbed areas with warmth-adapted seed provenances (Medium Confidence).

- Research needed to conduct a more accurate assessment of climate change impacts on future forest product availability includes (1) obtaining new data needed to demonstrate and quantify direct effects of atmospheric CO_2 on ecosystem productivity and tree growth (High Confidence), and (2) uniform reporting and assembly of national forest inventory data sets (High Confidence). New mathematical models will be needed especially to (a) simulate transient (lagged) responses of forests to rapid climate change, (b) integrate relationships among climate changes, ecological responses, and economic forces and responses, and (c) simulate regional climate changes and their effects (High Confidence).

15.1. Introduction

This chapter examines the changes induced in human-valued properties and products of forests (primarily wood and wood products) by potential shifts in vigor, productivity, and geographic distribution of tree species populations and of forest ecosystems. These shifts are expected to arise from global changes in climate and atmospheric chemistry. In addition, this chapter examines the roles of other forces—particularly of land use, which may modify or mask effects of changing climate and atmospheric chemistry. The changing commodities and amenities derived from forests are a tertiary response to the initial forcing caused by increased atmospheric concentrations of greenhouse gases. As such, the commodities cannot be estimated reliably until accurate forecasts are made of the intermediate processes and outcomes (climate, atmospheric chemistry, and resulting forest density and growth patterns). On the other hand, we can and do assess the socioeconomic responses to quantitative estimates of changing climate, land use, and forest ecosystem responses that are expected to arise from current practices and processes and from potential future ones.

This chapter focuses on the fundamental question of forest resource availability and resource needs: Given that the availability of growing stocks and related amenities from today's forests are adequate to meet today's needs under today's climate, will the availability from future forests be adequate to meet future needs under predicted future climates? The analysis avoids the more complex issues of economic responses to changes in potential growing stocks (as expected in decreasing prices because of enhanced harvests from use of new technologies, increasing prices from decreasing supplies, and changing prices from product substitution resulting from increasing prices). It concentrates instead on estimating the quantity of growing stock to which economics must be applied and the size of the population needing forest products.

Chapter 1 of this volume evaluates forest geographical, ecological, and productivity responses to changing climate and atmospheric chemistry. Chapter 24 of this volume examines the need for and effects of actions taken to mitigate increasing atmospheric CO_2 concentrations. These include forests subjected to unplanned and nonsustainable forest management practices. A third related chapter in the Scientific Assessment (Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, of the IPCC Working Group I volume) defines expected changes in global carbon cycling from shifts in forest geography and productivity under future changes in climate and atmospheric chemistry.

This chapter encompasses wood and wood products and amenities from all forests, whether or not they can be used by humans. Although all forest amenities are of interest, the chapter concentrates primarily upon those for which data are most available and reliable: wood products [roundwood (i.e., that portion of wood and bark removed from forests), industrial roundwood (i.e., that portion of roundwood to be processed

further), and fuelwood and charcoal (i.e., that portion of roundwood to be consumed for cooking, heating, and so on)].

The term "availability" of roundwood is used throughout this report, rather than the economically significant term "supply." Roundwood availability (as distinguished from supply or production) depends on the amount of growing stock and on annual growth increments. These are determined by climate, soils, management, and forested area. Only a fraction of growing stocks is normally considered as commercial forest, and only a fraction of commercial forest is available for harvest (supply). Even if harvested wood equalled growing stock—say, by application of advanced technologies—wood products can only be harvested up to the amount of available growing stock. Hence, growing stock is a more conservative estimator of the fundamental limit to harvests than is some smaller quantity, such as sustainable harvest level (see Section 15.5.2).

In the current assessment, we assume that even intensive management will not increase potential harvests beyond the maximum potential natural growing stock. Although the assumption is probably safe, the role of management in increasing future forest biomass (= growing stocks) is examined in detail by Brown *et al*. in Chapter 24. They conclude that during the next 55 years, about 20 Gt (Table 24-4) could be added by forestation to the approximately 1000 Gt (Table 24-1) already present in above- and belowground biomass stocks of forests. This potential 2% contribution by management may not be realized within the realities of limited forest management budgets.

In contrast to variables controlling growing stocks, harvests from forests will depend on the technology available to harvest and market roundwood, and demand for the resulting wood products (and hence, price of the products), as well as the amount of growing stock itself. Demand for wood products ("need" and "consumption" are noneconomic terms used in this report in place of "demand") and related amenities will change with shifts in size and geographic distribution of population, with technological and financial prosperity of end users, with price of the products, with availability of alternative products, and so on. Assessment of these variables is beyond the scope of the current chapter, although they could be profitably examined in the next IPCC assessment report. Here, we assume that per capita consumption remains constant and that population size increases as in the IS92A population projection (IPCC, 1992). In developed countries (e.g., Australia), per capita consumption actually declined during the last decade (FAO, 1992) and could do so in other countries in the future.

15.1.1. 1990 IPCC Forestry Assessment Results

The 1990 IPCC assessment of forestry (IPCC, 1990a) was confined to managed forests—difficult entities to assess because forest areas or volumes are rarely measured as "managed" or "unmanaged," and when they are so divided, the definitions of "managed" vary widely. As a consequence, the 1990 assessment contained few quantitative conclusions. However, it did

define uncertainties and issues of importance. In particular, it suggested that forest plantations are probably much more vulnerable to environmental change than are mixed-species and mixed-age stands. The latter contain species and developmental stages that may be less vulnerable to chronic climate change at any given point in time or space, whereas the former are easier for forest pests to invade.

The assessment recommended that impact analysis focus upon transitional climate and forest responses that may be with us for several decades, rather than on a single future long-term "equilibrium" climate. Finally, it recommended that "in the face of great uncertainties about rates and magnitudes of climatic changes, forest responses to potential climate change, and socioeconomic repercussions of climate-induced forest changes, it is prudent to prepare for severe undesirable impacts to ensure that viable and flexible options are implemented to maintain sustainable forest ecosystems." The results of our report are consonant with these two fundamental recommendations. However, unlike earlier efforts, our assessment was developed to go a step further in documenting the level of predictability in future forest production and consumption as constrained by projected changes in climate and land use.

15.1.2. 1995 IPCC Forestry Assessment Strategy

The current chapter approaches the assessment first by quantifying present and future roundwood availability and potential consumption as accurately as possible with available data and models (Section 15.2). Then the validity of these estimates is assessed, first for the globe as a whole (Section 15.2), then within tropical, temperate, and boreal forest regions (Sections 15.3, 15.4, and 15.5). Both validity assessments are based upon less quantifiable but relevant estimators of timber availability and consumption that are not included in the models. These analyses generate definitions of certainties, uncertainties, and unknowns regarding future availability of and needs for timber. Adaptation measures to reduce effects of specific changes are then discussed (Section 15.6). Last, monitoring and modeling products needed to resolve identified uncertainties and unknowns in future IPCC forest product assessments are presented (Section 15.7).

15.2.   Present and Future Global Forests

Kirschbaum *et al*. (see Chapter 1) describe the distribution and characteristics of natural forests and discuss the expected responses by forest ecosystems to changing atmospheric chemistry and climate. In Chapter 24, Brown *et al*. examine the potential gain in forest area and density that forest management potentially can provide. In addition, we examine the possibility that forestry and forest management, and several other kinds of land use, may be as important or more important than climate in determining the future spatial and temporal distribution of forests. The interactions of these climatic and management changes will generate impacts that are not

necessarily intuitively obvious. Therefore, to be useful, the assessment must at least quantify the changes in wood products should current conditions of change continue unabated (business as usual).

15.2.1.   Present Characteristics of Forests

Globally, forests in 1990 covered one-fourth to one-third of the earth's land surface (34 million km^2, FAO, 1993a; 41 million km^2, Dixon *et al*., 1994; see Chapter 1 for a detailed description). Although the great majority of these forests can be considered as managed to some degree, only about 4% of forests consist of intensively managed plantations (1.35 million km^2, Kanowski *et al*., 1990; 1.12 million km^2, Dixon, *et al*., 1994). WRI (1994) cites a doubling of forest plantations during the decade from 1980 to 1990, with three-fourths of all plantations being in Asia. The plantations may produce a disproportionate amount of forest products. About 30% of industrial timber production (industrial roundwood, i.e., non-fuelwood raw logs) in Latin America, for example, may have originated on plantations (McGaughey and Gregerson, 1982). Brown *et al*. (Chapter 24) point out that about 11% of the world's forests undergo active management; this includes 20% of mid-latitude and 17% of high-latitude forests but only about 4% of low-latitude forests.

FAO estimates that globally, forest products were worth about $418 billion in 1991; this amounted to 4% of the gross domestic product (GDP) of developing countries and 1% of the GDP in developed countries (FAO, 1993a). Although most forest products were consumed locally, total annual exports of logs and wood products between 1986 and 1988 were estimated at $68 billion, of which $10 billion was earned by developing countries (Sharma *et al*., 1992). Many developing (tropical) countries rely heavily on their forest resources for obtaining capital. For example, 1991 forest product exports from Cambodia represented 43% of all trade; from the Congo, 16%; and from Indonesia, 12% (FAO, 1993a).

15.2.2.   Projecting Future Forest Characteristics

Numerical projections of forest area and growing stocks require us to combine a spatially explicit mathematical model of forest response to climate and land use with a quantitative scenario of climate and land-use change. Few vegetation models are available from which to choose. There currently are no forest response models that simulate the processes controlling the change of forest productivity or geography over time ("transient" models), and that are globally comprehensive (see Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, of the IPCC Working Group I volume).

Static responses of forests—those that would be expected at some time following cessation of directional environmental change (Prentice and Solomon, 1991)—can be projected by several available models. Their fundamental flaw is that dynamic equilibrium of forests cannot be expected for centuries

---

Box 15-1. Use of Static Models to Estimate Future Forest Production

The application of the BIOME or IMAGE model (Tables 15-1 through 15-4) or other static vegetation models (see Chapter 1 of this volume, and Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, of the IPCC Working Group I volume) to estimate potential forest changes under different but stable modeled climate omits potential variables that could be critical to future forest distributions and productivity. The following weaknesses are most important:

- There is no indication that a stable climate will appear in the foreseeable future. Indeed, the global change problem to be assessed involves rapidly changing climate, not stable climate, during the next 50 to 100 years. The static models do not simulate impacts of rapid climate change on slowly responding forests, and current efforts aimed at parameterizations of the process will beg the question.
- Static models do not simulate tree mortality. In a warmer and potentially drier world, the geography of forest ecosystems is expected to shift, as it has many times during climate changes of the past (e.g., Huntley and Webb, 1989). This may be detected initially as negative or positive changes in seedling survival, growth and productivity of established trees, and eventually by forest decline as the environmental variables exceed species tolerances. Such forest decline is likely to be amplified by increases in tree mortality events (dieback), disease and insect outbreaks, fire, and damage associated with extremes in weather, none of which are simulated by the static models.
- Static models assume that trees instantaneously occupy new, climatically suitable areas. However, current projections of climate change appear to be too rapid to allow population geography to adjust: If the Holocene tree species migration rate of 0.2–0.4 km/yr (Davis, 1976, 1983; Huntley and Webb, 1989, suggest 0.1 to 1 km/yr based on examination of extant paleoecological data) records maximum tree migration rates, trees may be unable to attain the 4–6 km/yr rate of climate change expected (Solomon *et al.*, 1984). As a result, large areas of low productivity or degraded forest (forest lacking a full complement of growing stock and tree species, consisting instead of slowly growing and dying trees made ecologically inappropriate by climate change) could be present for centuries.
- Static models assume that new forested areas instantaneously grow to maturity and can be harvested. Thirty to 50 years or more of relatively stable climate are required to reach a harvestable condition of most species once the tree is established. Therefore, most of the new areas capable of supporting forests may consist of young, immature trees. Establishment of these trees under the expected regeneration-unfriendly conditions is potentially an even more serious problem.
- Static models do not account for differences in short- and long-term forest productivity. However, a forest in decline in the short run (50–70 years) will increase the available wood supply. If there are large areas of dead or dying trees, much of this wood probably will be harvested or salvaged. In the long run (>75 years), however, roundwood availability could decrease because of the immaturity of new species populations.
- Static models assume that the soil conditions will be suitable for new tree invasions. However, in boreal regions, permafrost and excess surface water dominate many landscapes, prohibiting uptake of nitrates. Recent glaciation at high latitudes has endowed large areas with thin soils or bare rock. In many tropical areas, prior intensive agriculture has so depleted the soil of phosphorus that tree growth is exceedingly slow. These soil features could form major barriers to immigration and growth even at the slow rates projected by models, making it unlikely that the forest tree populations will be able to migrate at their measured rate of 0.2–0.4 km/yr or reach maturity at their natural rate of 20 to 50 years.

(e.g., Solomon, 1986; Bugmann, 1994), following an environmental equilibrium which itself is not likely in the foreseeable future (see Box 15-1).

Although the static models cannot be used to identify what vegetation units will replace current ecosystems, the models can define which ecosystems will be inappropriate for the new climates and hence are vulnerable to climate change (e.g., Solomon and Leemans, 1990; Chapter 1). This requires only the very simple and robust assumption that climatic limits to forest growth implied by current geography will operate similarly in the future as well. Even this simple assumption may not be entirely correct because of potential changes in

climate response patterns of plants induced by increased atmospheric CO_2.

One static model (BIOME 1.1, hereafter BIOME; Prentice *et al.*, 1992,1993) was conceived specifically for assessing geographically distributed responses of vegetation types to expected climate changes. BIOME is unlike other static models in that it is based on specific physiological responses of plants to climate. These responses define a set of plant functional types (PFTs). Each PFT is characterized by a minimal (and different) set of known climate thresholds (minimum winter temperatures, summer warmth, evapotranspiration). BIOME was modified to include climate-dictated potential

agricultural land use as a plant functional type (Cramer and Solomon, 1993).

BIOME cannot be used to assess interactions among forestry, land use, and climate change. However, the BIOME vegetation classification has been incorporated into a model of interacting population (including associated natural resource utilization), land use, vegetation, and climate (IMAGE 2.0, hereafter IMAGE; Alcamo, 1994). Land use (agriculture) is modeled as a function of food demand by populations that vary in density over time, and in resource demand from one region to another. Land use is further modeled as constrained by climate and soils.

IMAGE has been used to project the implications of these population-land use-climate interactions on the geography of forests (Zuidema *et al*., 1994; Leemans and van den Born, 1994). The IMAGE projections generate an annual climate change from greenhouse gas concentrations; by the year 2050, this produces a climate essentially indistinguishable in its forest effects from those produced by the IS1992a future scenario (IPCC, 1992). However, IMAGE has been applied without feedbacks between changed climate and changed wildland vegetation (i.e., BIOME-dictated wildland vegetation does not respond to climate change). Therefore, its effectiveness is reduced where land use is unimportant. Hence, we projected global wood product availability into the future with both BIOME vegetation responses from Solomon *et al*. (1993) and IMAGE land cover change scenarios from Zuidema *et al*. (1994).

15.2.3. *Projecting Future Availability of Forest Products*

The forest area of ecosystems projected by BIOME for the present and for the year at which climate reflects a doubling of greenhouse gases (GHGs) is shown in Figures 1-5 and 1-8 (see Chapter 1) and is presented in Table 15-1. Note that estimated present forested areas (Dixon *et al*., 1994) and modeled present

Table 15-1: Tropical, temperate, boreal, and global forested areas in 10^6 km² under different future climate scenarios, at the year of a doubling of atmospheric CO_2, and percentage differences between current and future climates—projected by the BIOME 1.0 model.

	Present Area Est.[1]	Modeled[2]	GFDL Area	GISS Area	OSU Area	UKMO Area
Tropical Forests	17.6	36.8	40.6	42.9	41.3	41.4
Temperate Forests	10.4	10.6	15.7	15.7	13.3	16.1
Boreal Forests	13.7	16.7	8.4	11.5	13.5	9.1
All Global Forests	41.7	64.1	64.7	70.1	68.1	66.6

[1]From Dixon *et al*., 1994.
[2]From Solomon *et al*., 1993.

Table 15-2: Tropical, temperate, boreal, and total global forested areas in 10^6 km² under a single, self-generated future climate and land-use scenario, at different years, projected by the IMAGE 2.0 model (from data of Zuidema et al., 1994).

	Area of Forest at Year			
	1990	2000	2020	2050
Tropical Forests	27.6	25.0	21.0	14.4
Temperate Forests	5.4	4.1	4.9	5.3
Boreal Forests	13.8	14.3	15.2	15.3
All Global Forests	46.8	43.4	41.1	35.0

forested areas (Solomon *et al*., 1993) are similar except for a serious discrepancy in the tropics. There, the differences are in both definition (each defines "forest" differently) and in model capability (BIOME is less accurate at distinguishing between tropical forest and tropical savanna; Prentice *et al*., 1992).

The major pattern to emerge from comparison of all four climate scenarios with modeled present area is a moderate increase in area occupied by tropical forests, a strong increase in area occupied by mid-latitude temperate forests, and a similarly severe decline in area occupied by boreal forests. The simulated increase of temperate forest area is almost entirely at the expense of boreal forest area, which is reduced by a lack of very high latitude area to occupy, by loss of area to invading temperate forests at lower latitudes, and by the expansion of agriculture into areas now possessing too short a growing season to allow agriculture.

Table 15-2 presents forested areas in tropical, temperate, and boreal zones projected by IMAGE at 1990 and at 2000, 2020, and 2050. The singular climate scenario is generated within IMAGE, based on annual increments of GHGs generated by modeled energy use, land use fluxes, ocean uptake of CO_2, and so on.

The areas of tropical, temperate, and boreal forests estimated for the present by the two models differ substantially. BIOME initially estimates that 37% more land is in forests than does IMAGE. The differences appear to arise from a much larger agricultural area calculated in IMAGE than in BIOME. It seems likely that BIOME results are less accurate in temperate and tropical areas because IMAGE agricultural area of 1990 is very similar to that measured in FAO statistics (Zuidema *et al*., 1994), and the current forested area of IMAGE is much closer to that estimated by Dixon *et al*. (1994; see Table 15-1). As one would therefore expect, the greatest difference in 1990 zonal composition between BIOME and IMAGE areal projections is in temperate regions (16.5% vs. 11.6% of forests, respectively) where the greatest density of agricultural land use is found, followed by boreal regions (26.1% vs. 29.6% of forests, respectively) where the lowest density of agricultural land is found. Even if land use were simulated similarly in both models, one would expect the proportions of land in each zone to differ because IMAGE

defines the current zones based on national boundaries as well as on the climatic criteria used by BIOME.

The area and geographic distribution of forest changes projected by IMAGE at the year 2050 (Table 15-2) are in sharp contrast to those generated by BIOME at a doubling of GHGs (a point that might be reached by the year 2050; Manabe and Wetherald, 1993). Where BIOME indicates a total global increase in forested area from 1 to 9%, IMAGE calculates a decline of 25%. The large increase in temperate forest area in BIOME simulations becomes a slight decline in IMAGE. Both models project forest gains in temperate regions of North and South America and Europe, but in IMAGE, much land is lost to increased agriculture in Asian temperate regions. A decreasing demand for agricultural land in the developed countries of temperate regions results from slow population growth in Europe and North America and the projection into the future of increases in agricultural efficiency encountered during the past few decades (Zuidema *et al*., 1994).

The contrast between IMAGE and BIOME projections for the future is greatest in the tropics. Tropical Africa and Asia, where human population growth is greatest, are simulated by IMAGE as losing large amounts of tropical forests and woodlands (Table 15-2). Moderate increases in tropical forests projected by BIOME (Table 15-1) disappear when the need for agricultural land is factored into the calculation, as it is in IMAGE.

Differences in projected boreal forest area are also great. The BIOME losses of 20–50% (Table 15-1) become increases of 10% in boreal forest land (Table 15-2) by IMAGE. BIOME assumes that 50% of the area in which climate permits agriculture will be farmed and that climate changes redistribute mature biomes on the remaining land. IMAGE assumes that declining agricultural demand will allow regrowth of climatically appropriate forests on abandoned farmland but that forests will not be redistributed on undisturbed lands regardless of new climate conditions. This has the effect of eliminating instant forest migration/maturation on lands undisturbed by intensive land use—which are the vast majority of lands in boreal regions, much less in temperate regions, and the minority of lands in many tropical regions. This assumption should be more correct than the assumption of instantaneous migration during the simulated 60 year period (see Box 15-1). Few tree populations in the past 10,000 years have required less than a century to migrate latitudinally across even one of the 55 km pixels simulated by both BIOME and IMAGE (Davis, 1976, 1983; Huntley and Webb, 1989; Huntley, 1990). Fewer still can be expected to form mature, dense populations and forest ecosystems in new locations during that same 55 years.

The land cover and use changes projected by IMAGE appear far more important during this transition period of 60 years than do the effects of concurrent climate change in BIOME. This reflects in part the weak response to climate that IMAGE generates and its assumption that a significant amelioration of climate impacts will result from strong effects of carbon fertilization, water use efficiency, and other feedbacks (Zuidema *et al*., 1994). This assumption is not included in BIOME.

Although there is no definitive evidence that this effect occurs in forest ecosystems, even the greatest benefits claimed for the effect may not be significant (Chapter 1).

Instead, land use must be the most important agent of change in any vegetation replacement scheme based on the relationship between the large magnitude of current global vegetation replacement induced by the current population and the doubling of human population every 35–40 years. We know of no processes (technological or natural) that have been quantified (i.e., that can be included in a simulation) that would ameliorate this enormous impact. Using "back of the envelope" calculations, Sharma *et al*. (1992) conclude that population pressures could reduce forest area 30% by 2025, a value similar to the 24% decline by 2020 estimated by IMAGE (Table 15-2). No other published research of which we are aware takes this land use impact into account in projecting future characteristics of the global terrestrial biosphere.

In sum, without accounting for human demographics and agricultural land use, climate change alone would be responsible for an increase of 1–9% in land suitable for forests, with the largest gains in temperate regions. Projections that simulate future human needs for agricultural land but lack significant impacts of concomitant climate change generate a decline of 25% in forest area by the year 2050, with the greatest losses in the tropics. Because vegetation presence or absence within the envelope of appropriate future climate will be determined by land use at that time, it is the land use projections that must be given the most serious consideration.

The IMAGE projections of forest area have been used to estimate the potential supplies of forest products (from growing stock volume) by assuming that the ratio of forest area to growing stock today will also apply in the future (Table 15-3). We emphasize that the inaccuracies induced by the transient processes discussed in Box 15-1, and those detailed in the following paragraphs, are likely to change this ratio in the future. It is impossible to estimate, however, whether growing stock per unit area will increase or decrease.

Because the volumes in Table 15-3 are related to areas in Table 15-2 (data for the tropical, temperate, and boreal regions in

Table 15-3: *Current and future timber availability (growing stock) in 10^9 m^3, based on 1980 productive forest volume (Sharma, 1992) and percentage changes in forest area in IMAGE (Zuidema et al., 1994).*

Region	Volume of Forest at Year			
	1980	2000	2025	2050
Tropical Forests	146.7	132.8	111.6	76.5
Temperate Forests	41.3	31.4	37.5	40.6
Boreal Forests	90.0	93.2	99.1	99.7
All Global Forests	278.0	257.4	248.2	216.8

Table 15-2 are drawn from individual countries, and in Table 15-3 from the 13 groups of countries), patterns of change are also similar: tropical forest growing stocks decline by almost a half; temperate forests initially decline, then recover by the year 2050; and boreal forests increase slightly over time, with global growing stock volume down by about 22% in the year 2050 (Table 15-3).

The estimates of potential wood availability do not include enhancement of standing stocks from annual forest growth and from tree plantations developed to mitigate atmospheric CO_2 concentrations (see Chapter 24). Measurements of current annual forest growth in tropical regions average 2% of standing stocks (DeBacker and Openshaw, 1972), about 3% of exploitable growing stock in temperate countries, and 1.5% in boreal countries (FAO, 1992). These values would result in an increase in availability of wood products of about 2% (4.24 x 10^9 m³) above the 216.8 x 10^9 m³ presented in Table 15-3 by the year 2050.

The annual growth increment assumed in the wood availability projection is unlikely to remain constant. For example, Chapter 24 points out that tropical forest productivity may continue to be degraded by illicit and selective fellings. Also, forest growth may decline and mortality may increase from increasingly inappropriate climate (Solomon and Leemans, 1990; see also Chapter 1). This growth loss also was not included in the calculations that produced Table 15-3. Solomon (1986) used a transient forest response model to calculate an approximate 10% decrease in annual biomass increment at 21 locations in temperate and boreal forests of eastern North America at the time of CO_2 doubling. There were 50% decreases in simulated temperate forests, while boreal sites had increases of severalfold where forests replaced open shrublands.

The opposite effect on annual growth increment is also quite possible (see Chapter 9, *Terrestrial Biotic Responses to Environmental Change and Feedbacks to Climate*, of the IPCC Working Group I volume). Annual growth increment may increase in all zones from the fertilization effect of increasing atmospheric CO_2; increased efficiency of water use; and, particularly at high latitudes, globally warmer temperatures. These enhancements are discussed in detail in Chapter 1, which provides no estimate of the impact on growth increment. However, others (e.g., Melillo *et al*., 1993) have calculated from carbon flux models that growth increases of 16% may accrue by the time a doubling of atmospheric CO_2 concentrations is reached.

Growing stock volume also might be significantly enhanced through concerted national and international programs to mitigate atmospheric carbon emissions through development of forest plantations for carbon storage and for substitution of fossil fuels with biomass. The maximum increments would vary each year over the life of any proposed program. Chapter 24 uses these estimates, aimed at generating the maximum possible biomass increment (Nilsson and Schopfhauser, 1995), to project potential carbon storage from mitigation measures. Nilsson and Schopfhauser (1995) estimate that about 1.8 x 10^9 m³ could be

incremented annually by the year 2025 (0.7% of supplies shown in Table 15-3), with a peak value of 3.11 x 10^9 m³ by the year 2055 (1.4% of supplies in year 2050, Table 15-3). This assumes that annual increments will remain constant rather than declining from stress or increasing from CO_2 fertilization.

If the growing stock enhancement for the year 2050 produced by extension of current annual growth increment (4.24 x 10^9 m³) were combined with that produced by optimum management for the year 2055 (3.11 x 10^9 m³), forest volumes would decline 19% from 1980 levels by about 2050, rather than declining 22% as calculated in the absence of these factors. Present research results are inadequate to determine whether one should accept or reject either or both of the enhancement factors.

15.2.4. Projecting Future Need for Forest Products

The annual need for forest products must be determined differently from the availability of forest products. One can assume that the need for forest products will be largely independent of climate change and land use effects, at least until available timber supplies have been nearly consumed, forcing prices so high that users cannot afford to purchase them. The simplest assumption is that the need for wood is proportional to population size and associated regional prosperity, although FAO (1993a) depends on gross domestic product (GDP) in more complex and assumption-laden demand models for forest products (Baudin, 1988).

Considering the uncertainties associated with projecting forest product needs to the year 2050, we chose the simpler assumption. Future need for fuelwood/charcoal and industrial roundwood (the two components of roundwood) was calculated (Table 15-4) based on future population estimated for each of the 13 global regions in the IMAGE conventional

Table 15-4: *Current and future need for forest products in 10^9 m³, based on regional population projections (Alcamo et al., 1994) and regional forest product consumption (FAO, 1993a).*

	Year			
	1990	2000	2025	2050
Industrial Roundwood				
Tropical Regions	0.28	0.35	0.52	0.65
Temperate Regions	0.89	0.95	1.04	1.04
Boreal Regions	0.43	0.45	0.49	0.49
Total Global Volume	1.60	1.75	2.05	2.19
Fuelwood and Charcoal				
Tropical Regions	1.37	1.70	2.63	3.41
Temperate Regions	0.37	0.42	0.49	0.51
Boreal Regions	0.01	0.01	0.01	0.01
Total Global Volume	1.75	2.12	3.13	3.93
Total Volume	3.35	3.88	5.18	6.12

wisdom scenario (Alcamo *et al.*, 1994; Table 3), and the current per capita consumption of forest products in each of these regions (FAO, 1993a).

Current annual global need is approximately 1% of potential global growing stocks (derived from values for product availability in Table 15-3 and for product need in Table 15-4), comparable to values for individual regions calculated by others (e.g., Kauppi *et al.*, 1992; Dixon *et al.*, 1994; Nilsson and Schopfhauser, 1995). Need is projected to reach nearly 3% of global productive standing stocks by the year 2050 (6.12 x 10^9 m³), as need almost doubles and global growing stock declines by one-fourth or one-fifth. In tropical regions, where as much as 90% of forest production is consumed as fuelwood (FAO, 1993a), need for fuelwood reaches nearly 5% (34.1 x 10^8 m³) of growing stocks by 2050.

The projected annual need for industrial roundwood and fuelwood/charcoal is well within annual increments projected for growing stocks in boreal and temperate countries. In tropical countries, however, a wood product availability shortfall of some 2% of total standing stocks occurs by 2050; that is, 2% more wood is needed than is being grown each year. If fossil fuels are substituted with fuels from biomass, the shortfall is likely to be more severe. The need for forest products will not necessarily coincide with demand for forested land for agriculture. For example, trees felled for agriculture in Table 15-3 will not all be used to meet the need for forest products in Table 15-4. Hence, the need estimated here is a minimal value and is probably a significant underestimate of growing stock losses to consumption of both roundwood and agricultural land.

Shortages will be more severe in densely populated countries like India, Bangladesh, Pakistan, and China. Shortages may be insignificant in sparsely populated countries such as Brazil, Zaire, and Tanzania. Obviously, continuation of the shortfall would eventually consume the tropical forests in the most impacted regions. Before that occurred, increased value from decreased availability would drive fuelwood prices beyond the reach of all but the richest users, resulting in replacement of fuelwood by less satisfactory products (crop residues, dried livestock dung, etc.) in those areas.

A more sophisticated approach to estimating need—utilizing economic, technological, and political developments to define economic supply and demand, excluding effects of climate-controlled standing stock changes—was generated for the current chapter based on several data sources (Table 15-5).

The economy-based estimates of demand include only industrial roundwood, projected to the year 2020. The approach began with the same current global need (1.60 x 10^9 m³) as did Table 15-4. By the year 2010, however, economy-based estimators project a much greater need for industrial roundwood than does Table 15-4 (1.75 x10^9 m³), amounting to 2.15–2.67 x 10^9 m³ (FAO, 1993a, also projected a consumption of 2.67 x 10^9 m³ by the year 2010). Need projected by the economy-based method is 2.55–3.16 x 10^9 m³ by 2020 (compared with the much lower estimate of need of 2.05 x 10^9 m³ by 2025 in Table 15-4).

Table 15-5: *Economic supply and demand for industrial roundwood to the year 2020 in 10^9 m³, based on analysis of several authors by Nilsson (1994).*[1]

| | **Year** | | |
	1991	2010	2020
Global Demand	1.60	2.15–2.67	2.55–3.16
Tropical Supply	0.28	0.27–0.29	0.31–0.33
Temperate Supply	0.81	1.0–1.12	1.14–1.18
Boreal Supply	0.51	0.56–0.73	0.64–0.79
Global Supply	1.60	1.83–2.14	2.09–2.3

[1] Arnold, 1992; Backman, 1994; Backman and Waggener, 1991; FAO, 1991, 1993a, 1993d, 1994; ITTO, 1993; Kallio *et al.*, 1987; Kuusela, 1994; Nilsson *et al.*, 1992a, 1992b, 1994; Perez-Garcia, 1993; Sedjo and Lyon, 1990; Shvidenko and Nilsson, 1994; Thunberg, 1991, 1993; USDA Forest Service, 1990, 1993.

Although the FAO (1993a) consumption projections only extend to the year 2010, they also are based on economic, technological, and political criteria. The FAO generated global fuelwood and charcoal need increases of 31% by 2010 (compared to the 21% increase at 2000, and a 79% increase by 2025 derived from data in Table 15-4). Thus, the economy-based estimates do not disagree, and suggest that population-based estimates of need may be conservatively low.

In summary, the availability of forest products in the year 2050, as limited by climate and land use, appears to be adequate to meet projected needs in temperate and boreal regions but not in tropical regions. There, calculated consumption appears to define a serious shortfall of future availability. This conclusion is based on an obvious increase in demand, especially for fuelwood. Also, an increasing population may convert forests to farms to provide food and may be forced to rely on industrial roundwood for export income. The fuelwood forest resources are primarily of benefit to less-developed tropical countries, and their loss may well be important for populations in the most crowded countries. The developed countries of temperate and boreal regions may not be significantly affected by losses of the roundwood supplies they purchase from the tropics because these can be obtained from regions of low population density (and, hence, of low fuelwood consumption). Additionally, the developed countries are able to substitute other products for the wood products in current use. For example, timber in residential and commercial buildings currently is being replaced by styrofoam blocks filled with reinforced concrete and by steel structures in some parts of the United States and Europe.

15.3. Evaluation of Tropical Wood Availability and Consumption

Analyses of environmental change scenarios presented in Section 15.2 indicate that land use will be very important for

tropical forest product availability during the next century. They suggest that the availability of forest products could decline by about one-half from land-use pressures, even though changes in climate and atmospheric chemistry during this period appear likely to increase the area where tropical forests can potentially grow. The analyses in Section 15.2 contrast the potential decline in forest volume with the more than three-fold increase in need for forest products, especially, for fuelwood, to support local subsistence. The scenario indicates that by the year 2050, tropical regions could be subject to serious deficiencies—up to 2% of standing stocks—between annual availability and need. The discussion in Sections 15.3.1 through 15.3.3 evaluates those conclusions.

15.3.1.   Critical Considerations

Two primary forces are currently involved in tropical forest change and are likely to continue in importance in the future. First, human population growth in developing countries, which are primarily tropical countries, is 2 to 3% annually, and population is expected to reach 8.7 billion by the middle of the next century (UNFPA, 1992). If tropical regions undergo economic prosperity during the twenty-first century, the need for forest trees and products could increase drastically to generate urban structures and jobs for increasing urban populations. On the other hand, if prosperity falters and large numbers of destitute people seek subsistence unavailable in cities and urban areas, forests and wood supplies are likely to undergo considerable degradation as humans migrate into forests. No matter what future changes in climate and uses of tropical forests occur, effects of the rapidly growing and dense populations in tropical regions will amplify those changes.

Second, the rate of deforestation is very rapid and likely to continue so. It was 15.4 Mha annually (of 1,756 Mha, or 0.8%) for the period 1981–90—higher than in the previous decade (FAO, 1993b). Degradation of remaining forests (such as change from closed to open forests) due to grazing, fires, excessive logging, and fuelwood gathering leads to loss of plant diversity and standing biomass (i.e., forest degradation; Brown *et al*., 1991; Flint and Richards, 1991). For example, in Africa, much of the change in closed forest cover of 1.5 Mha from 1981 to 1990 was directly attributable to local population growth (FAO 1993b): 34% was from conversion of forests to short fallow agriculture, which reflects the needs of rural populations; 25% was change of closed forests to open forest or forest degradation resulting in loss of tree canopy due to human pressure; 19% was change from forests to fragmented forest interspersed with agrarian land uses, which represents gradual deforestation because these fragments are eventually converted to agriculture; and 16% was change of forest area to other forest cover.

15.3.2.   Availability of Tropical Forest Products

Estimates of deforestation rates vary but are uniformly large. FAO (1993a) calculated annual deforestation of 15.4 Mha

1981–90. The IS1992a scenario projected a forest clearing rate of 20 to 23.6 Mha per year by 2025. In that scenario, 73% of all tropical forests were expected to be cleared by 2100 (IPCC, 1992).

In addition, future forest decline may be accelerated by state control over forests and the collapse of traditional community control and management systems over forests (Gadgil and Guha, 1992). This has contributed to forest degradation in the past, and there is no reason to suspect that it will decline in the future. These forces will shape the expected uses of tropical forests for hundreds of years.

The increasing human activity in tropical forests will affect more than just the current standing stocks. Tree felling and wood extraction in the tropics commonly destroy one-tenth to one-third of the advance regeneration and growth in remaining trees (FAO, 1993b). Fragmentation and degradation of forests due to expanding agriculture, need for wood by human population, and livestock grazing pressure will seriously affect forest regeneration, particularly in tropical Asia and Africa. Soil moisture deficits projected for Africa and part of Brazil (IPCC, 1992) will severely hamper forest succession. Increased frequency of forest fire will also reduce the chances of forest regeneration.

Domestic animals are an important factor, reducing forest regeneration by browsing on seedlings and by trampling seedlings and compacting soils. Livestock, including cattle, sheep, and goats, are increasing in Africa and Latin America. In India, for example, the density of domestic livestock is 6 animals/ha of forest (405 million animals in 1982 on 64 Mha). In Africa there is 1 animal/ha of forest (see Figure 15-6 and FAO, 1993b). The total livestock population globally is expected to increase by a factor of three by 2050 (Zuidema *et al*., 1994). Thus, the total livestock population in Africa would be 1.69 billion by 2050, grazing on declining forests and pasture land.

The IPCC (1992) Response Strategies Working Group has estimated that the need for cropland will increase along with the world's rising population. Such an increase might require about 50% more land to be in crop production by 2025, a figure considerably higher than the estimates generated by the IMAGE model and used in estimating growing stock volume in Section 15.2.3. The cropland in Africa alone is projected to increase from 163 Mha in 1990 to 347 Mha by 2025 (Sauerbeck, 1993).

15.3.3.   Need for Tropical Forest Products

Tropical forests provide a range of economic, social, and environmental services to humans. For simplicity, only the major economic products are included below. The product functions could be classified as subsistence (e.g., wood and charcoal used for cooking) and commercial (e.g., industrial wood and sawn wood). Among subsistence products, only in Brazil is charcoal used as a commercial fuel in industry on a large scale. The commercial products, however, are traded within and between countries.

The forest product consumption values estimated in Section 15.2.4 have been expanded in Table 15-6.

Note that estimated need for fuelwood in the tropical countries increases by about 2.5 times to 2050, but in Africa it increases by 3.3 times (Table 15-6). Yet fuelwood availability in Africa, like the rest of the tropics, is expected to decline by about half during the same time period (Table 15-3). Hence, the projected deficit of need over availability of tropical fuelwood may be most critical in tropical Africa. In addition, export of industrial roundwood, which might be used to offset fuelwood deficits, is already very low (Table 15-6), with 89% of African forest harvest being devoted to fuelwood (FAO, 1993a). Examination of tropical forest area changes projected in Table 15-2 and population changes used in the IMAGE projections (Alcamo *et al.*, 1994) indicates that the fuelwood need problem will increase in severity, as the current 0.84 ha of forested land per capita (FAO, 1993a) declines to 0.13 ha per capita by 2050.

The projections made in Table 15-6 do not consider various factors like tropical forest destruction, much of it for increases in livestock, or forest degradation (legal and illicit removal of trees). The projections also do not include afforestation/reforestation, slowing of land needed for agriculture by enhanced crop productivities, or changes in rates of use of different forest products as countries industrialize (such as decline in fuelwood use but increase in use of industrial wood).

Non-timber forest products are particularly important in tropical regions. The tribal and rural communities in tropical countries gather a large range of non-timber forest products for subsistence consumption as well as for commercial purposes (e.g., food, fodder, oil seeds, gum, nuts, rattan, bamboo, and raw material for a range of industrial products, as well as locally used products like baskets, mats, tools, leaf plates). For example, the value of rattan extraction in Southeast Asia was $275 million in 1990; the value of Brazilian nuts was $72 million (FAO, 1993c).

The impacts of climate change itself (forest dieback, retreating forest boundaries, increased insect pest and fire incidence; see Chapter 1) and the adaptation measures to mitigate the effects of climate change such as short-rotation forestry (Chapter 24, this volume), will reduce the availability of non-timber forest products. Declines in biodiversity in tropical forest due to climate change through increased variance in seasonality (Hartshorn, 1992) and increased turnover rates (Phillips and Gentry, 1994) also may reduce the availability of the large diversity of plant and animal products from forestry. This latter process may not occur universally, as shown in certain limited areas of Venezuela (Carey *et al.*, 1994).

The replacement of tropical forests with non-forest land uses, coupled with increased need for forest products, will not necessarily generate losses in tropical forest volumes. For example, a conservation and large afforestation effort has stabilized the area under forest in India at about 64 Mha since 1980 even though the population is growing at more than 2% annually (see Box 15-2).

Plantation forestry for all purposes (mitigation of atmospheric CO_2, wood for pulp, sawnwood, fuelwood, etc.), using degraded lands, could become one of the most important counteragents to deforestation. Estimates in Table 24-4 (Chapter 24) indicate that potential added tropical forest wood stocks could average 300 Mt/year (16.42 Gt over 55 years beginning in 1995).

Section 15.2.3 notes that between 18 and 31×10^8 m³ annually (0.7 to 1.4 % of standing stock at the time of measurement) is the most one can expect from plantations designed to mitigate atmospheric carbon. Yet plantations may be much more significant in alleviating the need for forest products in the future. The area established as plantation in 90 tropical countries by 1990 was 44 Mha (FAO, 1993b), with India accounting for nearly 40% of the total area, followed by Indonesia and Brazil. Tropical countries are implementing large afforestation programs. India averaged 1.44 Mha annually in the decade 1981–1990 (FAO, 1993b) and now is planting about 2 Mha

Table 15-6: *Current and projected forest product needs in the tropics (10³ m³), based on per capita consumption estimates from FAO (1993a) projected to 2020 and 2050 with UN (1993) population estimates.*

Product	Region	1991	2010	2020	2050

Box 15-2. Forest Conservation in India

Tropical deforestation for the period 1981–90 is estimated to be 15 Mha annually (FAO, 1993b). In addition, the IMAGE 2 model projects increasing deforestation (Table 15-2) from the simple assumption that larger populations will increase the demand for land, thus increasing deforestation of that land. However, the reality in India presents a contrasting picture.

Since 1980 India has periodically assessed its area under forests through its National Remote Sensing Agency (NRSA). The area under forests was assessed for the periods 1981–83 (FSI, 1988), 1985–87 (FSI, 1990), 1987–89 (FSI, 1992), and the latest for 1989–91 (FSI, 1994).

The area under forest in India since 1982 has been stable at 64 Mha (Table 15-7). The forest conservation achieved in India is significant because the population density in India is high (257 persons/km²) with a large rural population (627 million in 1991) depending on biomass, and an annual population growth rate of 2.12% during 1981–91.

Notably, the area under dense forest (>40% tree crown cover) increases in each assessment, suggesting an increase in carbon stocks sequestered by Indian forests. Responsible factors include the Forest Conservation Act of 1980, which bans all conversion of tropical forest land to non-forest uses, and the world's largest afforestation program (FAO, 1993b). This exemplifies the adaptation potential of tropical countries to declines in forest areas and demonstrates the limitations of projections of future forest area based on population growth rates, such as those from IMAGE (used to construct Tables 15-2 and 15-3).

Table 15-7: *Area under forest in India, in 10^3 ha, according to assessments of the National Remote Sensing Agency (the year refers to the mid-year of assessment; Ravindranath and Hall, 1994).*

Forest Category	1982	1986	1988	1990
Dense Forest (Crown Cover >40%)	36.1	37.8	38.5	38.6
Open Forest (Crown Cover 10–40%)	27.7	25.7	25.0	25.0
Mangrove Forest	0.4	0.4	0.4	0.5
Total Forested Area	64.2	63.5	63.9	64.1

annually (IPCC, 1992). The dominant species planted in India are largely short-rotation exotics, as they are elsewhere in the tropics (Ravindranath and Hall, 1995).

In India and Brazil, the choice of short-rotation forestry will only meet the need for industrial wood and fuelwood (and charcoal), not for sawn logs for structural uses. Thus, forest plantations (largely softwood) are no substitute for logging in forests for hardwoods. Climate change can worsen the situation by affecting forest regeneration due to warming and decreased availability of soil moisture. There is a possibility that a large area could be planted to hardwoods and long-rotation plantations such as teak.

In summary, the shortfall of wood during the 21st century, projected for tropical areas in Section 15.2.4, appears to underestimate the potential problem. Tropical countries will face serious shortages in forest products required for subsistence (fuelwood, wood and fibers for construction, fruits and nuts for food). However, wise land-use policy may mitigate some of the forest losses.

15.4. Evaluation of Temperate Wood Availability and Consumption

The scenarios discussed in Sections 15.2.3 and 15.2.4 suggest that temperate forests could cover about as much land by 2050 as they do today, and that current consumption (3.1% of standing stock, based on Tables 15-3 and 15-4) may increase only slightly by 2050 (3.8% of standing stock). With a 3–3.5% annual growth increment in temperate zone trees (FAO, 1992), and with an increasing proportion of need being met by imports from outside the temperate zone (FAO, 1993a), the scenario analysis in Section 15.2 indicates that temperate-zone forests are likely to continue meeting the need for forest products on a sustainable basis for at least the next century. The discussion in Sections 15.4.1 through 15.4.3 examines that conclusion in detail.

15.4.1. Critical Considerations

Perhaps the most important characteristic for defining forest product availability in temperate zones, now and in the future, is that

temperate zones are most appropriate for mechanized agriculture of monospecific crops; hence, mankind has altered the natural vegetation there both intensively and over a relatively long time. Consequently, at 0.71 billion ha (compiled from FAO, 1993a; Puri *et al.*, 1990; World Bank, 1993; Chadha, 1990; Khattak, 1992; Helvetas and Swiss Development Corp., 1989; Goskomles SSSR, 1990; Kurz *et al.*, 1992; Xu, 1994), temperate forests cover only about half of their potential area, and the remaining forests often differ quite considerably from the original state (Stearns, 1988; Deutscher Bundestag, 1991; Röhrig, 1991).

The prosperity of the developed countries which permits development of mechanized agriculture also gives most countries of the temperate zone greater capability than those in other zones to manage forests to avoid future disturbances (fire, insect attack, mortality from rapid and chronic climate change, and so forth) and to enhance growth (artificial tree migration, plantation establishment, post-establishment thinning and fertilization, and so on).

The capabilities of developed nations which buffer temperate forest product availability from environmental threats also provide a buffering of need for forest products from shortfalls in availability. First, these countries have the wealth to purchase wood products outside the temperate zone. Today, temperate countries consume 80% of the total value of world imports of forest products but supply only 50% of the value of its exports. Second, temperate countries have access to technology that allows product substitution when local availability is inadequate and interzonal trade is too expensive. Pressed fiberboard replaced some weak plywood supplies during the 1970s in the United States (Rose *et al.*, 1987), for example, and currently, increasingly expensive lumber is being replaced in some residential structures with steel, concrete-filled plastic foam, or similar non-forest products.

15.4.2. Availability of Temperate Forest Products

Harvests from temperate-zone forests of all types are used mainly for industrial purposes (Table 15-8), although there are great differences between the two Asian regions in Table 15-8 and the other regions. In Europe, the United States, and the temperate Southern Hemisphere, the industrial wood portion of the total is about 80%, whereas in Asian temperate regions it is only 8.6% (tropical) and 38.0% (temperate) (Table 15-8). Overall, temperate-zone use of forest products focuses on industrial wood.

The scenario analysis above defined no significant climate or land-use related declines in future forest availability. Forest survey measurements are consonant with this analysis. Considering that carbon storage from net ecosystem production in European forests increased about 30% between the early 1970s and the late 1980s and is further increasing, the wood resource is seen as plentiful for the foreseeable future, if no unexpected catastrophic events occur (Kauppi *et al.*, 1992). The remarkable net ecosystem production (NEP) increment in the last two decades may relate less to intrinsic productivity of forests than to increased forest area generated as European agriculture decreased while imports of less-expensive foreign lumber increased (more than one-third of global industrial roundwood imports in 1990; approximately 10% less than Japan imported, and six times the imports by North America; FAO, 1993a). If so, change in land-use policy or in costs of imported roundwood would have a great impact on European NEP and forest availability.

Climate effects may be indirect. In Europe, migration of the Mediterranean tree species to the north may be hampered because most of them are not adapted to the prevailing acidic soil conditions in the northern areas (Ulrich and Puhe, 1993). In the worst case, this may result in losses of some species, with negative effects on biodiversity and wood availability.

Frequent extreme events affecting wide regions—like storms or insect infestations—leading to great amounts of wood that must be harvested, may have a great influence on annual cut and the economic situation of forestry. For example, the price index for timber in the Federal Republic of Germany (FRG) declined from 116% in 1990 to 79% in 1991 as a result of hurricane Wiebke, which caused large windfalls in many parts of

Table 15-8: *Current production and consumption, and projected need for industrial roundwood and fuelwood in 10^6 m³ (FAO, 1993a).*

| Region | Production 1991 | | Need 1991 and 2010 | | | |
| | Industrial Roundwood | Fuelwood and Charcoal | Industrial Roundwood | | Fuelwood and Charcoal | |
			1991	2010	1991	2010
West Europe[1]	138	28	144	207	29	30

western Europe (Stat. Bundesamt, 1992). Pests can largely dictate where and how many trees must be harvested. If climate-induced changes cause extensive sanitary fellings, this may reduce revenue per unit of wood and hence reduce incentives for intensive management and investment (Pollard, 1993).

One of the most important anthropogenic effects on forest product availability in temperate zones in the past has been intensive land use. Nevertheless, until now in Europe, stable food demand, substantial producer subsidies, and high productivity increases have generated enormous surpluses of agricultural products. As a consequence, the use of arable land decreased substantially in these regions. The situation is similar in the United States and Japan. In the European Community (EC) up to 44 Mha could go out of agriculture without substantial decreases in productivity (Eisenkrämer, 1987; Delorme, 1987). Therefore, in western Europe the common agricultural policy of the EC will be a more important driving force for future changes in land use than climate-induced ecosystem changes (Kitamura and Parry, 1993). This phenomenon is abstracted in IMAGE model projections (Table 15-2) and is responsible for the simulated increase in temperate forest area in Europe (Zuidema *et al.*, 1994).

IMAGE projections suggest a 2% decrease in total area of temperate forests between 1990 and 2050 (Table 15-2). However, if only the temperate deciduous forests are considered, the forested area increases by 60.5 Mha (89%) from 1990 to 2050 (Zuidema, 1994). In contrast, temperate forest area projected by BIOME under four different climate scenarios increases between 25 and 52% by the time the climate resulting from a doubled CO_2 concentration occurs (Table 15-1). If either the BIOME projections for all temperate forests or the IMAGE projections for temperate deciduous forests becomes reality, a wood availability increase of one-tenth to one-half will result.

15.4.3. *Need for Temperate Forest Products*

Current production and consumption of roundwood in the temperate zone are fairly balanced (Table 15-8). Nevertheless, there are also countries where consumption greatly exceeds production (e.g., Japan, China, Austria, Italy). Projections for 2010 (FAO, 1993a) indicate that the need for industrial roundwood will increase between 38% (temperate South Asia) and

96% (temperate East Asia). It is likely that need will increase everywhere for particular wood types (softwood logs and pulpwood), whereas in some regions (Japan and western Europe) need for all kinds of wood products will increase. As a consequence, future increases in consumption must be met partly by increases of imports. A great portion of these may come from other temperate forested countries, such as Canada, New Zealand, and Chile, but also from plantations in the tropical zone.

Fuelwood consumption in temperate zones is not as important as it is in tropical and subtropical countries. The only exception to this may be China, where 32.5% of the wood production in 1988 was consumed for fuelwood (Xu, 1994). Nevertheless, in temperate South Asia and North America, significant increases (38% and 51% respectively) in fuelwood consumption by 2010 are expected (Table 15-8).

In the developed countries of the temperate zone there is a high and growing need for assets that support a high quality of life. This has produced a change from the wood production point of view to a multiple-use perspective (FAO, 1993c). These needs are not considered in the scenario analysis of Section 15.2 but will generate considerable change in wood availability (much of it being removed from accessibility) and need. The non-wood functions (soil protection, recreation, biodiversity, and cultural uses) and goods and services (fruits, honey, water supply, and so on) are of very high importance. Table 15-9 gives an overview of the importance of main forest functions in some temperate regions.

Table 15-9 shows that in Europe and the United States, other functions than wood production have high importance in relevant areas. For most of the developed temperate-zone countries, it is the explicit policy to emphasize non-wood functions of their forests, especially functions of water protection and recreation (FAO, 1993c). The economic evaluation of these benefits is much more complex than that of wood production because, for most of these values drawn from the forests, supply and demand generally are not regulated by market mechanisms. There are only a few non-timber products that have a direct economic importance for individual countries—for example, cork in Portugal and Spain, chestnuts in Italy, or Christmas trees in Denmark—but they have immediate effects on local people and communities.

Table 15-9: *Importance of forest functions by area as a percentage of total forest land (FAO, 1993c).*

15.5. Evaluation of Boreal Wood Availability and Consumption

The scenario analysis of Section 15.2 presents a dichotomy in expectations for wood availability in the boreal zone. The climate-only scenarios (Table 15-1) assumed that agriculture occupies 50% of the land permitted by its climatic potential, boreal forest displaces nonforested tundra, and temperate vegetation replaces much of the current lower-latitude range of boreal forests. This scenario suggests that boreal forest areas will shrink between 20 and 50%, depending on the climate change scenario used, by the time a doubling of GHGs occurs sometime in the next century. The scenario driven primarily by land use (Table 15-2) included agricultural land area that was linked to a declining population and demand for food, and allowed little climate-induced change in forest geography, except in the few areas that shifted out of agricultural production. That scenario suggested that boreal forests would increase in area by 10 or 11% by the year 2050.

At the same time, the population-based need estimates indicated a relatively constant need of 0.5% of availability (Tables 15-3 and 15-4)—considerably less than the sustainable harvest to be expected of available supplies, even under the most deleterious climate-only scenario. These are the suppositions to be examined in Sections 15.5.1 through 15.5.3.

15.5.1. Critical Considerations

More than any others, the boreal forests are subject to periodic damage from large-scale disturbances such as fire, long-term drought, windstorm, and insect infestations. Even chronic and uniform climate warming is likely to cause increasing frequencies of irregular, large-scale, and widespread catastrophic disturbance events in which large areas of forest are destroyed in a single growth season. Recovery from these events may take centuries (Payette *et al.*, 1989), and the resulting availability of forest products as sanitation and salvage fellings will thus be very irregular. Therefore, the shortcomings of the static vegetation models described in Box 15-1 are very relevant to boreal forests.

15.5.2. Availability of Boreal Forest Products

Growth increments in natural forests accrue only about 1.5% each year, but active management of the boreal forests yields much higher increment and growing stocks (Kuusela, 1990). In Sweden, active management has raised the average growing stock from 72 m³/ha in 1925 to 97 m³/ha in 1985, and the stock is estimated to reach 125 m³/ha in the year 2050.

The long-term sustainable timber supply from a biological point of view has been estimated with different degrees of sophistication in the boreal countries. The sustainable harvest level is often called the annual allowable cut (AAC). This comprises 910–930 x 10⁶ m³/yr for the next 50–100 years [Runyon (1991), OMNR (1992), and Booth (1993) for Canada;

Nilsson *et al.* (1992a) and Hägglund (1994) for Nordic countries; Isaev (1991), Nilsson *et al.* (1992b), and Backman (1994) for the former Soviet Union]. The long-term economic wood supply takes the economic conditions into account and is lower than the AAC (580–630 x 10⁶ m³/yr; *ibid*). Comparison of these values, or of the approximately 100 x 10⁹ m³ of growing stock in boreal forests (90 x 10⁹ m³ tabulated in Table 15-3), to the annual harvests of 750 x 10⁶ m³, indicates that long-term sustainable biological availability substantially exceeds the prospective need for wood in the boreal zone.

Arnold (1992) found a number of broad trends in the long-term future supply of forest products (50-year time horizon) based on analyses of existing studies:

- There will continue to be a major shift from old-growth supply to planted and second-growth supply.
- There will be large resources in boreal forests to support expanded production if need requires.

The following constitutes a broad summary of global forest product availability based on a number of studies (Cardellichio *et al.*, 1988; Kallio *et al.*, 1987; Sedjo and Lyon, 1990; Arnold, 1992; Nilsson *et al.*, 1992a; Thunberg, 1993; Perez-Garcia, 1993; OMNR, 1992; Backman, 1994):

- The availability of coniferous wood (softwood) from North America is expected to decrease due to younger age class structure and tightening environmental regulation.
- Russia will be dealing with a restructuring of its entire society for a long time and will be hard-pressed to sustain timber production at current levels.
- Europe will probably need more than it supplies.

The overall conclusion from these analyses is that the major supply in the near to medium term will come from the traditional wood supply regions, but within 50 years an increase of production through plantation forests may be required (some 150 million ha).

Chapter 1 and Section 15.2 both discuss expected changes in climate and responses by natural forest ecosystems. In a warmer and drier boreal zone, it is likely that geographic boundaries of boreal forest ecosystems will shift (Emanuel *et al.*, 1985a, 1985b; Solomon, 1992; Smith and Shugart, 1993). While the forest ecosystems adapt to climate changes, ecosystems will be in disequilibrium as existing species are replaced by new species more adapted to the environment. Soil conditions that lack the requirements of invading species in many areas will exacerbate this condition. The area of forest affected will greatly depend on the magnitude and rate of the climate change. A likely result of any future climate change is that during the next 50 years the wood availability in the boreal zone will increase. However, it should be pointed out that forest management and protection may have to be intensified substantially during this period, which will be costly (Nilsson and Pitt, 1991; Apps *et al.*, 1993).

As illustrated earlier (Table 15-2), future changes in land use driven by economic factors could increase forest land in the boreal zone in the future (Waggoner, 1994; Nilsson *et al.*, 1992a; Zuidema *et al.*, 1994). Air pollutants are thought to be a problem in the boreal zone today (Nilsson *et al.*, 1992a, 1992b; de Steiguer, 1993); if so, they would affect wood availability as well as the availability of non-wood products in the boreal zone in the mid-term.

In the long run (>50 years), effects of climate change on wood availability could be significant as the availability of wood from existing species runs out and new species are insufficiently developed to provide a new source of supply. Yet in terms of the sustainable use of forests (i.e., of need, discussed in Section 15.5.3), the scenario estimates of availability until 2050 and those that would result from quantification of climate change effects both suggest an excess of availability over need. However, it is also important to emphasize that a significant portion of harvested supply in the future could evolve from irregular, widespread, and catastrophic mortality events that cannot be simulated or predicted by current modeling methods.

15.5.3. *Need for Boreal Forest Products*

The consumption of forest products by the sparse population of boreal regions can hardly affect boreal forest stocks. Future population estimates suggest little change in population under current immigration policies (e.g., Alcamo *et al.*, 1994). Instead, assessment of needs from boreal regions must focus on trade in forest products and on the resulting economic forces that will continue to define the need for boreal forest products.

Need for forest industry products is determined by changes in population, income, and price and by technological change. Past consumption can only be disaggregated to relevant end uses (preferences) in the more developed countries, and useful predictions can only be made for short periods in the future. Forest products are international commodities, and need and availability in one region depend on developments elsewhere on the globe.

The boreal forests have played an important role as suppliers of raw material for forest industrial products globally and of so-called non-wood benefits. The production of industrial roundwood from the boreal forests in 1991 corresponds to some 33% of world production. The consumption figures presented by FAO for the year 2010 are regarded as strong overestimates among industrial experts; those presented in Table 15-10, calculated as described in Section 15.2.4, may be more realistic.

The most crucial role of boreal forest products is probably the balance of payments. The boreal countries are major net exporters of forest products. More than 20% of the world's forest industry product value stems from the boreal forests. Table 15-11 indicates that for Canada and the Nordic countries (especially Norway and Finland), a very significant portion of their trade involves forest products. It seems likely that wood

Table 15-10: *Industrial roundwood consumption projected to 2020 in boreal regions, in 10^6 m³, based on analyses in Table 15-5.*

	Year		
	1991	2010	2020
Coniferous (Softwoods)	452	434–588	496–611
Deciduous (Hardwoods)	60	123–145	141–181
Total Boreal Demand	512	557–733	637–792
Global Need	1602	2145–2674	2551–3156

exports eventually will increase to even greater importance in the former Soviet Union (FSU).

Arnold (1992) examined long-term trends in need for forest products. Among the most important conclusions relating to boreal wood consumption are the following:

- Global need for industrial wood has been projected to grow by 35 to 75% over the next 50 years.
- Consumption will continue to be concentrated in the developed world, but a substantial part of the increase in consumption will occur in the developing countries.
- Need for roundwood will grow more slowly than need for finished wood products due to technological development.
- Use of nonconiferous (hardwood) species will grow faster than for coniferous (softwood) species.

As in temperate regions, boreal-region forests no longer are viewed as simply a provider of raw materials for industry and a stimulus in the general economy of a country (Westoby, 1962). Today, the nonmarket forest production properties (climate change, biodiversity, global tourism, non-wood products, erosion, water supply) are among the most prominent issues in world forestry (Hyde *et al.*, 1991). The boreal forests promote a large variety of global as well as local and regional non-wood products. However, the extent and value of these services are

Table 15-11: *Economic importance of the forest sector in boreal countries in million U.S.$ (FAO, 1993a).*

	Prod.	Consum.	Import	Export	% of Trade	% of GDP
Canada	30482	15931	1840	16931	13	5
Nordics[1]	22115	4876	2388	19628	4–36	2–7

[2]Former Soviet Union.

uncertain because most of them are not connected by any market mechanism. The boreal countries also have stated that future boreal forest policies will place emphasis on non-wood functions.

Economic analyses of the current impact of the non-wood functions on the macro-economy in the boreal countries are limited in scope and uncertain. Hultkrantz (1992) and Solberg and Svendsrud (1992) estimated the value of the non-wood products at 35–75% of the industrial forest sector value (adjusted GDP-calculation) for Sweden and Norway, respectively. Based on the earlier discussion, we conclude that this value will increase in the future in the boreal zone. In the long run, forest management for non-wood products may well become a more valuable activity than logging.

In the future, increased conflicts in the boreal forests are expected between traditional forestry and requirements for wilderness areas, between timber production and biodiversity, and between applied forest technology and landscape development. There will be increased public concern regarding the health and survival of the forests. The forecast reconstruction of the structure of the forest industry will generate regional unemployment and social strain in the boreal countries. There are approximately one million aboriginal people living in the boreal zone. The cultures and economies of these people are intricately adapted to the natural environment, and they depend upon it for self-perpetuation.

The forest industry has restructured extremely quickly during the last 20 years in the boreal countries due to economic development, technological development, market conditions, and internationalization. This kind of structural change is expected to continue in the future. Technological development is also very rapid in the forest sector, especially in the forest industry. Most of the lumber grades known today in the forest industry were not known 20 years ago. This development is also expected to continue in the future.

Many of the changes taking place in the forest sector of the boreal countries are based on the changed end-use preferences. Preference changes, based on shifts in knowledge, values, consumption, and so forth, have happened within a few years (e.g., bleached to unbleached paper, clearcuts to landscape planning), and they influence the whole forest sector. Preference shifts will continue to permeate the future societies of the boreal zone.

What, then, will be the constitution of overall forces on the forest industry? Most obviously, forces other than climate will probably overshadow the impact of ecosystem responses to climate early on (the next 50 years). A major question involves the impact on economic considerations of non-wood functions like biodiversity, landscape conservation, soil carbon capacity, and sustainable watershed development, which could significantly reduce available timber supplies. Unfortunately, we lack benchmarks for measuring the impact of climate change on these functions. In the long run (>50 years), and based on today's knowledge, the situation could be reversed; ecosystem

changes induced by shifting climate might overshadow the impact of the other driving forces in the boreal forests.

In summary, the conclusions from scenario analysis about boreal timber availability and need that begin Section 15.5 appear to be very unrealistic. First, timber availability may be more strongly affected by environmental changes in boreal regions than in other zones: increased mortality and slowed forest succession from rapidly warming climate and large-scale disturbances; and enhanced growth from warmer growing season temperatures and increased atmospheric CO_2. These variables are not simulated by the models that produced the scenarios in Section 15.2. Second, boreal forest timber need is controlled by trade in forest products outside the zone. Hence, economic considerations drive need and its subsequent implementation—that is, harvest of timber. The models underlying the scenarios in Section 15.2 contain no consideration of forest economic or trade processes or implications, and therefore are not capable of realistic analysis of boreal forest product need in the future. The economics of wood consumption and the analysis of temperate and tropical zone timber needs, discussed in Sections 15.3 and 15.4, suggest that serious shortfalls of boreal industrial roundwood could occur during the twenty-first century. This would result if future temperate and tropical zone consumption of boreal softwoods expands beyond available wood capacities.

15.6. Adaptation and Coping Options

In the short term, timber supplies from all zones can be readily assured in intensively managed forests. The use of forest plantations to mitigate increasing atmospheric CO_2 and to generate fuels from biomass is a subject of Chapter 24. Unfortunately, past intensive management, especially fire suppression and tree selection at species and intra-specific levels, has created forests that now may be more vulnerable to fire, pests, and pathogens (Schowalter and Filip, 1993), although others dispute that conclusion. Given the current degree of uncertainty over future climates and the subsequent response of forest ecosystems, adaptation strategies (those enacted to minimize forest damage from changing environment) entail greater degrees of risk than do mitigation measures (those enacted to reduce the rate or magnitude of the environmental changes). Emerging principles of risk assessment and management should guide the choice and implementation of "no-regrets," "proactive," and "reactive" options for adaptation (Gucinski and McKelvey, 1992).

15.6.1. Harvest Options

Certain standard harvest options appropriate for ameliorating effects of climate change are suggested:

- **Sanitation Harvests**—Increased timber losses are expected from pests, diseases, and fire because the trees themselves may be stressed by warmer conditions and the greater moisture deficits expected to accompany

warming (see Chapter 1), and land clearance for tropical agriculture. Extensive sanitary felling can produce large volumes of timber, reducing revenue per unit of wood and reducing incentives for intensive management, while disrupting future timber availability.

- **Changing Harvesting Method**—Harvesting and even site preparation may be quite dependent on cold winters in northern regions where forests occur on predominantly swamp lands that can only be accessed when frozen (Pollard, 1987). Use of ecosystem protection approaches (e.g., Franklin, 1989; Clark and Stankey, 1991) can be particularly useful in light of multiple-use needs in temperate and boreal regions and the need for mixes of species and ages in all zones to prepare for several different outcomes of environmental change.
- **Shortening Rotations**—Reduction of rotation age is a simple tactic for reducing exposure of maturing timber stocks to deteriorating conditions, as well as increasing opportunities for modifying the genetic makeup of the forest. Gains may be offset by diminished timber quality, a lower mean annual increment, and impacts on other values such as certain game species and aesthetic qualities. Short-rotation plantations in tropical regions are an important option in meeting local fuelwood needs, coincidentally relieving pressure to harvest more pristine forests.
- **Increased Thinning**—The stimulation of tree vigor following stand thinning has special application under increasing moisture deficits. The modification of forest microclimate by thinning offers considerable potential for the management of pests (Amman, 1989; Filip *et al.*, 1992; Paine and Baker, 1993).

15.6.2. Establishment Options

Establishment options that can be quite effective in reducing effects of climate change are selected from common silvicultural practices:

- **Choice of Species in Anticipatory Planting**—Mixed species for current planting should be considered wherever possible, as a means to increase diversity and flexibility in adaptive management. Critical non-timber values such as snow retention, soil stability, water quality, and carbon storage should be taken into account.
- **Vulnerability of Young Stands in Anticipatory Planting**—The planting of species and varieties better adapted to future conditions may well increase vulnerability of the resulting stands during their early establishment. Selection of provenance offers an important tactic to reduce the vulnerability.
- **Assisting Natural Migrations in Protected Areas**—Protected areas are the richest sources of genetic materials and warrant expansion into comprehensive systems. To be effective they must function in landscapes where ecological integrity is sufficient to permit the movement of living organisms; there must be a comprehensive approach to both commodity and reserved lands (Franklin *et al.*, 1990).
- **Assisting Natural Migrations by Transplanting Species**—Large numbers of seedlings raised in nurseries many hundreds of kilometers from planting sites can be planted in the millions per day (Farnum, 1992). Optimism must be tempered by experience, however: Forest managers have been attempting to reforest Iceland for the past 50 years without much apparent success (Loftsson, 1993).
- **Gene Pool Conservation**—Specialist species (indicated by restricted geographic ranges) will be most at risk, and their only chance of surviving may be through conservation in forest reserves, arboreta, and conventional seed banks and cryogenic storage.

15.7. Research Needs

New research products needed to conduct an accurate assessment of socioeconomic impacts of forest responses to climate change have become obvious from the foregoing analysis. The assessments are, and will be, based on quantitative scenarios of changing availability of and need for forest products and amenities. Validity of scenarios is critical if they are to function as descriptions of the implications of current knowledge for future conditions. In all regions, scenarios were inadequate because the effects of increasing CO_2 and forest dieback could not be quantified. In tropical regions, the scenarios were deemed inadequate because they probably underestimated the regional and local importance of land use on timber availability. In temperate regions, the scenarios were incapable of quantifying the buffering effects on timber needs, offered by shifting technology aimed at product substitution and on availability by intense mechanical management of forests. In boreal regions, the scenarios excluded transient responses of timber availability to environmental change and extraregional responses of timber needs by economic processes, which replace local forest product demand there. All regions probably will undergo changes that could not be expected only from the variables considered in this assessment. Thus, research required for an adequate assessment includes both environmental monitoring and data collection, and development of models to project future impacts.

15.7.1. Data Monitoring and Collection

All countries need to produce accurate national forest inventories. Some countries maintain such inventories, but they often use different periods and research designs. For example, in Europe, information from repeated surveys is available only from one-third of the forest area (Kauppi *et al.*, 1992). In addition, existing inventories do not consider regeneration properties, such as frequency of flowering, seed production, or seedling establishment. With regard to climate change, these factors are very important because early life stages are most sensitive to variation in temperature and moisture conditions.

An obvious need involves the collection and analysis of data regarding the beneficial effects of atmospheric CO_2 concentrations. As Chapter 1 points out, information from a single season of monitoring tree seedlings in greenhouse pots is inadequate to document the decadal-scale responses by mixed assemblages of growing and mature trees in ecosystems. Our analysis in Section 15.2 highlights the uncertainties regarding the impacts of these effects, which preclude confidence in estimates we generated of future forest product supplies.

15.7.2. Global Modeling

The analyses generated for this assessment repeatedly demonstrated the absolute necessity for development of models describing transient responses of forests to rapid environmental change. Indeed, as Box 15-1 indicates, the problem to be assessed involves impacts of rapidly changing climate during the next century, not stable climate, and involves variously lagged forest response variables, not responses in lock-step with climate change. We lack models of vegetation response to climate that incorporate the real drivers of future vegetation dynamics: Transient processes involving differential rates of mortality, establishment, and growth; climate control of forest establishment and succession; absence and slow introduction of seeds of trees from provenances, varieties, and species appropriate for the available climate; and so on. For this "transient" assessment, the static model estimates of forest growth over the next 50 to 75 years are woefully inadequate.

A second kind of critically absent model is a forest economics simulation capability that is linked to environmental change. The global trade model developed at the International Institute for Applied Systems Analysis (e.g., Dykstra and Kallio, 1987) is an example of the integrated supply and demand model needed; however, it does not project climate-controlled or land-use-constrained wood availability. Instead, a forest trade model embedded in a global integrated assessment model like IMAGE may be the most appropriate vehicle for calculation of the impacts of climate-ecological-economic relationships.

A third form of model conspicuously absent is a climate model that could provide *regional* estimates of the climatic change implied by increasing GHG concentrations. The existing climate models are not able to generate reliable estimates on regional temperature, precipitation, and hydrology. Yet much of the forest response that is relevant to socioeconomic assessment varies significantly from one locale or region to another. In addition, in order to assess the quantitative implications of ecophysiological processes under chronic climatic change, climate models must describe the regional and seasonal changes of temperature and precipitation.

CONTENTS

EXECUTIVE SUMMARY

Any effects of climate change on fisheries will occur in a sector that already is characterized on a global scale by full utilization, massive overcapacities of usage, and sharp conflicts between fleets and among competing uses of aquatic ecosystems. Climate-change impacts are likely to exacerbate existing stresses on fish stocks, notably overfishing, diminishing wetlands and nursery areas, pollution, and UV-B radiation. The effectiveness of actions to reduce the decline of fisheries depends on our capacity to distinguish among these stresses and other causes of change. This capacity is insufficient and, although the effects of environmental variability are increasingly recognized, the contribution of climate change to such variability is not yet clear.

While overfishing has a greater effect on fish stocks today than does climate change, progress is being made on the overfishing problem. Overfishing results from an institutional failure to adjust harvesting ability to finite and varying fish yields. Conventional management paradigms, practices, and institutions—inherited from the period when fish stocks were plentiful—are not appropriate for the new situation of generally full exploitation, especially of important fish stocks. Although the Law of the Sea represents an important step in the proper direction, only a few countries have adopted the institutional arrangements needed to regulate the access of fishing fleets to critical areas. The United Nations (UN) Conference on Highly Migrating and Straddling Stocks and the Food and Agriculture Organization (FAO) Code of Conduct for responsible fisheries are likely to accelerate the adoption and effective implementation of regulatory mechanisms. Should climate change develop according to IPCC scenarios, it may become even more important than overfishing over the 50- to 100-year period covered by this 1995 climate assessment.

- Globally, under the IPCC scenarios, saltwater fisheries production is hypothesized to be about the same, or significantly higher if management deficiencies are corrected. Also, globally, freshwater fisheries and aquaculture at mid- to higher latitudes could benefit from climate change. These conclusions are dependent on the assumption that natural climate variability and the structure and strength of wind fields and ocean currents will remain about the same. If either changes, there would be significant impacts on the distribution of major fish stocks, though not on global production (Medium Confidence).
- Even without major change in atmospheric and oceanic circulation, local shifts in centers of production and mixes of species in marine and fresh waters are expected as ecosystems are displaced geographically and changed internally. The relocation of populations will depend on properties being present in the changing environments to shelter all stages of the life cycle of a species (High Confidence).
- While the complex biological relationships among fisheries and other aquatic biota and physiological responses to environmental change are not well understood, positive effects such as longer growing seasons, lower natural winter mortality, and faster growth rates in higher latitudes may be offset by negative factors such as a changing climate that alters established reproductive patterns, migration routes, and ecosystem relationships (High Confidence). Changes in abundance are likely to be more pronounced near major ecosystem boundaries. The rate of climate change may prove a major determinant of the abundance and distribution of new populations. Rapid change due to physical forcing will usually favor production of smaller, low-priced, opportunistic species that discharge large numbers of eggs over long periods (High Confidence). However, there are no compelling data to suggest a confluence of climate-change impacts that would affect global production in either direction, particularly because relevant fish population processes take place at regional or smaller scales for which general circulation models (GCMs) are insufficiently reliable.
- Regionally, freshwater gains or losses will depend on changes in the amount and timing of precipitation, on temperatures, and on species tolerances. For example, increased rainfall during a shorter period in winter still could lead to reduced levels in summer in river flows, lakes, wetlands, and thus in freshwater fisheries (see Chapter 10). Marine stocks that reproduce in freshwater (e.g., salmon) or require reduced estuarine salinities will be similarly affected (High Confidence).
- Where ecosystem dominances are changing, economic values can be expected to fall until long-term stability (i.e., at about present amounts of variability) is reached (Medium Confidence). National fisheries will suffer if institutional mechanisms are not in place that enable fishing interests to move within and across national boundaries (High Confidence). Subsistence and other small-scale fishermen, lacking mobility and alternatives, often are most dependent on specific fisheries and will suffer disproportionately from changes (Medium Confidence).
- Because natural variability is so great relative to global change, and the time horizon on capital replacement

(e.g., ships and plants) is so short, impacts on fisheries can be easily overstated, and there will likely be relatively small economic and food supply consequences so long as no major fish stocks collapse (Medium Confidence).

- An impact ranking can be constructed. The following items will be most sensitive to environmental variables and are listed in descending order of sensitivity (Medium Confidence):
  - Freshwater fisheries in small rivers and lakes, in regions with larger temperature and precipitation change
  - Fisheries within Exclusive Economic Zones (EEZs), particularly where access-regulation mechanisms artificially reduce the mobility of fishing groups and fleets and their capacity to adjust to fluctuations in stock distribution and abundance
  - Fisheries in large rivers and lakes
  - Fisheries in estuaries, particularly where there are species without migration or spawn dispersal paths or in estuaries impacted by sea-level rise or decreased river flow
  - High-seas fisheries.

- Adaptation options providing large benefits irrespective of climate change follow (Medium Confidence):
  - Design and implement national and international fishery-management institutions that recognize shifting species ranges, accessibility, and abundances and that balance species conservation with local needs for economic efficiency and stability
  - Support innovation by research on management systems and aquatic ecosystems
  - Expand aquaculture to increase and stabilize seafood supplies, help stabilize employment, and carefully augment wild stocks
  - In coastal areas, integrate the management of fisheries with other uses of coastal zones
  - Monitor health problems (e.g., red tides, ciguatera, cholera) that could increase under climate change and harm fish stocks and consumers.

16.1.   Current Status of Fisheries

16.1.1.   *World Fisheries Conditions and Trends*

Marine fishing generates about 1% of the global economy, but coastal and island regions are far more dependent on fishing. About 200 million people worldwide depend on fishing and related industries for livelihood (Weber, 1994). Marine fish account for 16% of animal protein (5.6% of total) consumption, but developing countries are more dependent on this protein source (Weber, 1993, 1994). Marine catches peaked in 1989 at 85 million tons; freshwater catches were 6.4 million tons, about 7% of the total (FAO, 1993). The potential sustainable yield of marine food fish may be about 100 million tons (Russell and Yonge, 1975); the limit may have been reached. Some 40% of total world production enters international trade (FAO, 1992a), with the top fishing nations being China, Japan, Peru, Chile, Russia, and the United States (FAO, 1993).

World fisheries are characterized by a general state of full or overexploitation of wild stocks and excess harvesting and processing capacities. Some small pelagics, some very-deepwater fish, and some oceanic tunas and Antarctic krill are among several exceptions. Globally, fishing costs are about 20% greater than revenues, with much of the deficit provided by national subsidies (FAO, 1992a). The World Bank (1992) and FAO (1992b) estimate total economic rent and subsidy losses at $79 billion annually, and the situation is likely to worsen.

The quantity of landings is declining (Garcia and Newton, 1994) in 13 of the 15 major marine areas. Only Indian Ocean fisheries continue to increase. Further, there is a deterioration in quality caused by declines in the sizes of highly valued species and a move to bulk landings of lower-value species (Regier and Baskerville, 1986). Thirty percent of global fishery catches are discarded because they are too small, they are prohibited from being landed, or no profitable market exists (Alverson, 1994). This practice of discarding by-catch is more common in industrial fisheries than artisanal ones. Most important stocks are fully or overexploited (Sissenwine and Rosenberg, 1993). In most regions, there is little or no surplus biomass to buffer climate-induced fluctuations in stock abundance relative to current demand. Reduced numbers of year classes also increase stock variability and risk of collapse.

This situation is rooted in the ocean's finite production capacity and in the deficiencies (including concepts and enforcement) of current institutions for adjusting fishing capacities to stock productivity. Present systems were developed when underutilized stocks were available and freely accessible to large-scale fishing operations. Most have not been adjusted to the situation of resource scarcity. Adoption of the UN Convention on Law of the Sea and Exclusive Economic Zones, generally out to 200 miles, has led most countries to control foreign fleets and is a critical step toward improved institutions. However, few countries have taken steps to improve domestic management, even though 90% of production comes from EEZs (Sherman and Gold, 1990; FAO, 1993).

With the advent of EEZs in the mid-1970s, foreign fleets received allocations of stocks that exceeded domestic capacities. Domestic capacity then rapidly increased, often via joint-venture (JV) partnerships with foreign companies. Upon reaching full domestic exploitation through direct replacement and domestic-controlled charters, most JVs were phased out. JVs have not disappeared, however, and foreign fishing continues in some developing regions. Less desirable species and areas or certain species taken by specialized fleets working both international waters and EEZs are most of what remain available to foreign licensed fleets.

Access to high-seas, highly migratory, and straddling (EEZ/high seas) stocks remains mostly open and free, although participants in some fisheries voluntarily limit catches. Without management, fishing cannot be adequately adjusted to average stock abundances, let alone to fluctuations. The 1995 UN Conference on Highly Migrating and Straddling Stocks and the FAO Code of Conduct for responsible fisheries are likely to accelerate the adoption and effective implementation of regulatory mechanisms. With effective management, depleted fisheries could yield another 20 million tons annually (Weber, 1994).

Competition occurs at all levels: countries fishing the same stock, a single country involved in different fisheries in its own or others' waters, and different fishing methods competing within a fishery. In most cases, excess catching power is deployed, and conflicts among competitors often become acute and pervasive.

With few exceptions, governments have not recognized the customary use-rights of traditional fishing communities. Growing demands for fish, water, and space; encroachment by large-scale fishing and aquaculture operations; population concentrations; urban expansion; pollution; and tourism already have harmed small-scale fishing communities in shallow marine waters, lakes, and rivers. These fishers have limited occupational or geographic mobility. With climate change, global and regional problems of disparity between catching power and the abundance of fish stocks will worsen—particularly the interaction between large mobile fleets and localized fishing communities. Aquaculture will develop in new areas, sometimes assisting, sometimes disrupting existing artisanal fishers.

The productivity of freshwaters and sea margins has become stressed by human density and societal actions to benefit non-fisheries sectors. For example, freshwater diversions for agricultural use have resulted in water-level and salinity changes, leading to ecological disasters in the Aral, Azov, and Black seas, and San Francisco Bay (Caddy, 1993; Mee, 1992; Rozengurt, 1992). The artificial opening of the sand barrier at the mouth of the Cote d'Ivoire River to clear floating weeds allowed seawater to enter the lower part of the river and has changed species dominances (Bard *et al*., 1991; Albaret and Ecoutin, 1991).

On the Nile, the Aswan dam so thoroughly regulates flows that the delta has become degraded ecologically. Local sardine

populations that once thrived and provided food for the region have collapsed with the decline in local primary production that depended on the strong surges of flood waters and their pulses of nutrients (Sharp, 1994). Where the Sahelian drought is causing increased salinity in the lower parts of Senegalese rivers, a dam erected near the mouth of the Senegal to stop the rising salinity and ease severe problems to local agriculture prevents fish migration (Binet *et al*., 1995). Hydroelectric dams in the Dneiper River basin have suppressed spring flows, increased salinities, and left local marshes unflooded at the time of peak fish migration, decreasing fish landings by a factor of five (Mann, 1992).

Problems are markedly more acute in smaller water bodies and fragile coral reefs, especially in areas of high human density. In these areas, habitat degradation often is more important than overfishing. As stresses intensify, impacts that for a long time were limited to freshwaters and littoral areas are now observed in closed and semi-enclosed seas (FAO, 1989b; Caddy, 1993). Some semi-enclosed seas, such as the Mediterranean, Black, Aegean, and Northern Adriatic, are already eutrophic. The diversity of uses in these areas also has introduced "one of the most pervasive and damaging anthropogenic impacts on the world's ecosystem" in the form of nonindigenous species (Mills *et al*., 1994). Many of these organisms already have extensive invasion histories, are easily transportable, are highly fecund, and tolerate a wide range of environmental conditions. Their damaging effects on indigenous populations may only be enhanced by ecosystem fluctuations accompanying climate change.

Fish habitats are downstream of many impacts, and fish integrate the effects. Fish are symbolic in depicting the health of ecosystems and our ability to manage our resources. Lake Victoria exemplifies this situation and shows how caution must be exercised in introducing nonindigenous species to adapt to, or take advantage of, climate change (see Box 16-1).

Scientists are unable, in most instances, to quantify efficiently each of the man-made and natural stresses on fish stocks. This major constraint on integrated management of water bodies is exemplified by the U.S. fishery for yellowtail flounder on Georges Bank at the southern edge of the species range. The species does not do well when the waters are warm. If there is warming and efforts to rebuild the stock in U.S. waters suffer, it will be difficult to differentiate climate change from fishing as the primary cause (Anthony, 1993).

National and international trends appear to lead to more rational means of management and improved institutions. Among the more advanced concepts is that of Individual Transferable Quotas (ITQs)—in which a science-based catch quota is set and enforced, and fishers can buy and sell percentages of the quota. ITQ systems are being implemented in many areas. Most major fisheries in New Zealand, Canada, Chile, and Iceland; several in Australia; and two in the United States are under ITQ arrangements, with others under discussion (Sissenwine and Rosenberg, 1993).

Box 16-2 contains a regional case study. It is not unique. The steady decline of northeast Atlantic catches since the mid 1970s, the recent banning of cod fishing by Canada, and other situations also could serve as examples.

16.1.2. Aquaculture

Recent growth in total fisheries production is from aquaculture. Aquaculture has grown rapidly during the last few decades and accounts for about 10% of the total world fish production,

---

Box 16-1. Lake Victoria

Climate change will add to stresses now affecting large lakes and their fisheries. Lake Victoria has reached ecological devastation. Surrounded by urban and agricultural development, it suffers from high nutrient loading, causing eutrophication. Deforestation and erosion are putting sediments into the waters; papyrus swamps are declining with overharvesting; and snails are increasing in abundance. Landing beaches and piers are useless as water continues to recede from the shore. Exposed sand is being harvested, leading to the destruction of spawning grounds and fish refugia. Additionally, introduction of Nile perch contributed to the upset of the productive natural ecosystem and the socioeconomic balance of the region, as summarized below (Barel *et al*., 1985; Ssetongo and Welcomme, 1985; Acers, 1988; Ogutu-Ohwayo, 1990a, 1990b; Bruton, 1990; Achieng, 1990; Kaufman, 1992):

- The former multispecies fishery has been reduced to three species, due largely to predation by Nile perch and overfishing. Two hundred species have become extinct.
- The decline of perch prey forebodes the collapse of that fishery.
- Subsistence fishers are unable to capitalize to compete in the new fishery. Surviving fishers have adapted by using large-mesh nets to catch perch.
- The local population prefers the native species, as reflected in the low value of perch.
- Perch cannot be sun-dried and must be smoked, requiring extensive use of firewood and leading to deforestation of some islands.
- The most important freshwater fishes in East Africa have vanished from the marketplace.

Box 16-2. The Barents Sea

Luka *et al*. (1991) considered causes of depression of Barents Sea fish stocks and options for recovery. In the late 1970s, total catches reached 4.5 million tons. Then, due to a decreasing abundance of cod, catches dropped, especially sharply in the early 1980s. In the second half of the 1980s, after the fishery on capelin ended, the total catches were about 300,000 tons. The main cause was overfishing, but the unfavorable climatic regime (cooling in 1977–1982) led to poor year classes of all main species. Fishing was very heavy in the 1970s and the first half of the 1980s, despite a declining biomass (Kovtsova *et al*., 1991; Zilanov *et al*., 1991). By the second half of the 1980s, herring, capelin, and polar cod— the main food for cod and haddock—were very scarce. This led to slow growth, starvation, and increased mortality. Moreover, predation of cod and haddock on juveniles of deepwater redfish, plaice, and wolffish increased greatly, reducing some strong year classes before they entered the fishery (Kovtsova *et al*., 1991).

The total Soviet catch was unaffected by these depressed stocks. Fuel was inexpensive, and the fishing fleet moved to other regions [e.g., the Norwegian Sea (blue whiting), Irminger Sea (deepwater redfish), and Antarctica]; thus, there was little impact on the Soviet economy.

By the early 1990s, the Barents Sea spawning biomass was at its historically lowest level. However, there is now a sharp increase in the abundance of cod and capelin, perhaps associated with an observed warming of the northeast Atlantic and adjacent seas.

---

mostly of higher-valued products. Aquaculture contributes to the resiliency of the fisheries industry, tending to stabilize supply and prices.

Advancements are unevenly distributed across regions, farming systems, and communities. Growth is about 5% annually. The marine component is growing rapidly, but freshwater is still dominant. Aquaculture will not rapidly solve the scarcity of natural fish, and current industry growth will fulfill the demand only for certain commodities, regions, and consumer groups.

Large-scale systems specialize in a few high-value species (e.g., shrimp and salmon) and are developing wherever profitable. Small-scale systems (e.g., for freshwater finfish and shellfish) are restricted to regions where aquaculture and/or settled agriculture have existed for centuries (essentially in eastern and southern Asia and in Europe). This distribution reflects social and institutional factors (notably land and water property regimes) that change very slowly. The need for improved management is great. In Taiwan, for example, inadequate control of expansion of shrimp farming resulted in mass mortalities of stocks and the collapse of production in 1987–89 from 100,000 down to 20,000 tons.

Genetic engineering holds great promise to increase the production and efficiency of fish farming (Fischetti, 1991). However, fishers and resource managers are very concerned about accidental or intentional release of altered and introduced species that might harm natural stocks and gene pools. Around Scandinavia, escapees and nonindigenous reproduction may have reached or exceeded the recruitment of salmon wild stocks (Ackefors *et al*., 1991). Introduction of pathogenic organisms and antibiotic resistant pathogens is also of concern.

Ranching (in which young fish are released to feed and mature at sea) and fish farming, like their equivalents on land, have self-generated and imposed impediments to success. The activities can compete for coastal space with other uses, and continued expansion can jeopardize the quality and quantity of fish habitat [e.g., through loss of mangroves and wetlands, competition for food with wild stocks, or other factors (NCC, 1989)].

16.2.   Climate-Change Impacts

GCM results can be used to make some global inferences, but caution must be used in forecasting fisheries impacts until scientists are able to forecast regional and finer climate and ecosystem processes. Global warming will likely be accompanied by changes in water temperature, precipitation, winds, water and nutrient flows, water level, biogeochemistry, sedimentation, salinity, water mixing, upwelling, ice coverage, and UV-B radiation. Changes in amounts, structures, and timing will affect ecosystem components, including habitats, entire food webs, and species interactions. Chapters 8, 9, and 10 describe these changes and ecosystem impacts.

16.2.1.   *Freshwater Fisheries*

The first indications of reaction by fish species to climate change probably will be among those populations living at the extremes of their temperature tolerance ranges (Holmes, 1990) or residing in streams with high rates of heat transfer from the air. In freshwater, population migration may be limited by watershed constraints (Regier and Holmes, 1991; Shuter and Post, 1990). In large drainage systems, the flexibility for migratory shifts to compatible temperatures will be greater in north–south flowing systems (Meisner, 1990).

It is intuitive to expect poleward range movement for species with climate warming (Shuter and Post, 1990). However,

Box 16-3. Temperature Preferences

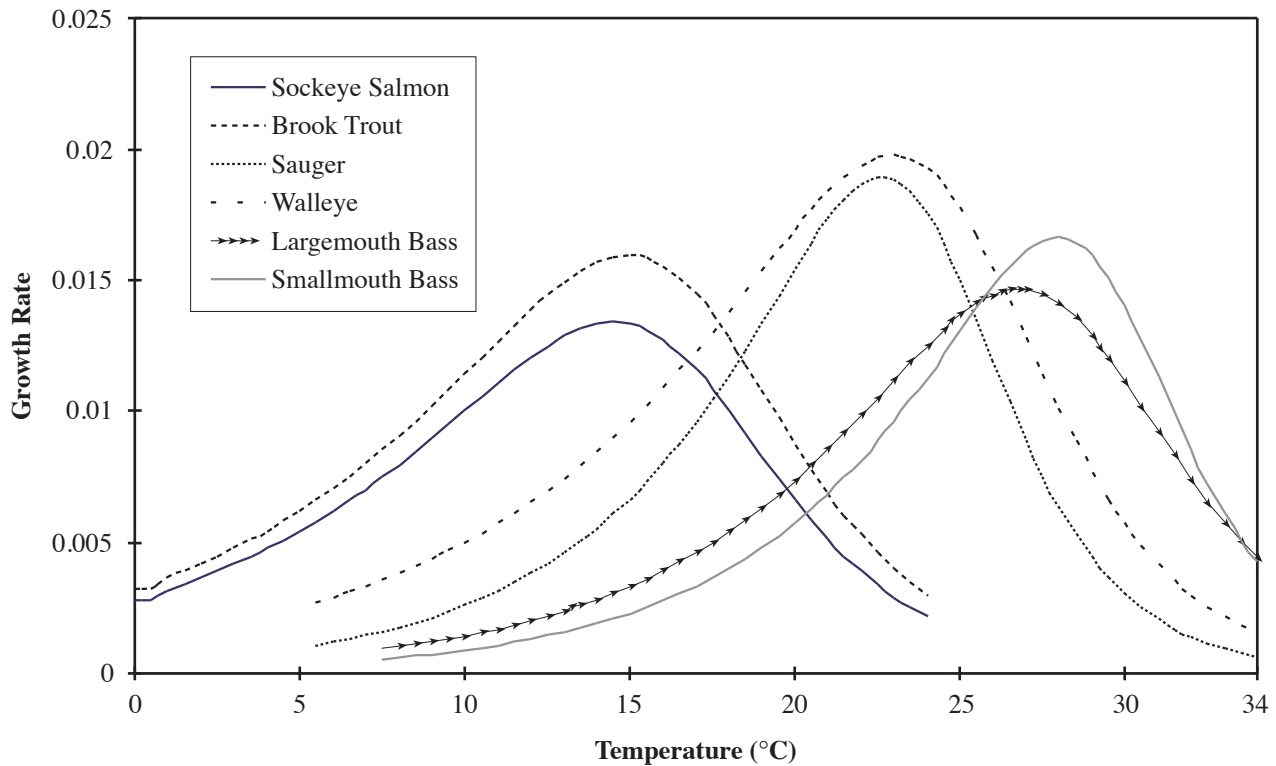
Fish cannot regulate their internal temperatures; they try to maintain preferred temperatures through behavior. They seek habitat close to the optimum temperature for growth, foraging success, and protection (Magnuson *et al*., 1979). Unless a water body has such temperatures for substantial space and time—with other factors also sufficient for well-being—a particular species will not likely thrive (Christie and Regier, 1988). Species have different preferred temperatures, with similarities between species within families. In the figure below (from Lin, 1994), with optimal food and other factors, two salmonid species prefer cold water at or below 25 °C; two percid species prefer cool waters; and two centrarchid species prefer warm waters and tend to "hibernate" in winter when water temperatures fall below 8°C.


Figure 16-1: Growth rates as a function of temperature.

habitat, food supply, predators, pathogens, and competitors must be within the species' ability to cope. Further, there must be a suitable dispersion route, not blocked by land or some property of the water such as temperature, salinity, structure, currents, or oxygen availability. Movement of animals without a natural dispersal path may require human intervention or hundreds or thousands of years (Kennedy, 1990).

Changes in the amount and timing of precipitation will affect freshwater fisheries production (Welcomme, 1985; Lowe-McConnell, 1987). Thus, expected precipitation increases in high northern latitudes—extending well into mid-latitudes in most cases—in winter (see the Working Group I volume) could provide largely positive benefits overall. However, if accompanied by higher evaporation in summer due to warmer temperatures or loss of habitat due to high flow rates in winter or spring, these benefits may not accrue. Species unable to move or adapt may suffer population declines or become extinct. Management to control critical temperatures of portions of

rivers and streams using impoundments, and timing of water releases and runoff may mitigate the impacts of climate change on some species.

Warming should produce a longer growing season for species that have not attained their maximum temperature limits (Shuter and Meisner, 1992), but warming also may lead to reduced productivity in species at or near their maximum limits (Mathews and Zimmerman, 1990). Greater fish production should occur in high-latitude lakes and reservoirs (Schlesinger and McCombie, 1983). Tropical lakes have longer growing seasons and shorter generational times and usually produce higher fish yields than temperate lakes because fish mature at earlier ages. Mean annual air temperature is the most important factor in predicting lake fish production across latitudes (Schlesinger and Regier, 1982), but changing rainfall patterns and flood regimes may have profound effects on river fish (Meisner and Shuter, 1992; McDowall, 1992). In rivers, low oxygen at low flows can severely limit fish production.

Alterations in seasonal climate patterns should change the population distributions in larger lakes. In a study using fish bioenergetics models, certain Great Lakes fisheries were found to have potentially greater yields, whereas others were predicted to collapse (Hill and Magnuson, 1990). White perch—a species of low value—might be among those with increased range and improved recruitment because of a longer growing season and shorter, milder winters (Johnson and Evans, 1990). Yields in southern Lake Michigan and central Lake Erie are projected to remain about the same for lake trout and lake whitefish but increase for walleye. Thermal habitats are expected to increase except for cold-water species in Lake Erie, where the deep water could become anoxic in summer (Magnuson *et al.*, 1990). Large lake fish production could increase about 6% with a 1°C rise in average annual air temperature (Meisner *et al.*, 1987).

Warm-water exotic species may invade large lakes where invasion routes are available (Mandrak, 1989). For example, Coutant (1990) speculates that, with warming, U.S. east coast populations of striped bass, *Morone saxatilis*, could move further north and perhaps enter the Great Lakes—where they might thrive in the lower lakes—and compete with salmonids; in the Gulf of Mexico, Florida coastal waters, and southern U.S. lakes and reservoirs, their existence could be threatened.

Changes in species dominance may occur. Each population has adapted to specific temporal and spatial features. For example, in New Zealand, native species occur throughout the nation, whereas introduced species seem to be temperature-limited in their distribution—suggesting that indigenous species may be more resilient than exotics in a warming climate (New Zealand, 1990). Species invasions and removals occur frequently, even without human causes, but climate and habitat change should accelerate them. Indigenous species will be subject to greater pressures from shifts in ecosystem structures and introductions of opportunistic exotics (Lodge, 1993).

Positive factors associated with greater warming and precipitation at higher latitudes include faster growth and maturation rates, lower winter mortality rates due to cold or anoxia, and expanded habitats with ice retreat. Offsetting negative factors include increased summer anoxia, increased demands for food to support higher metabolism, possible negative changes in lake thermal structures, and reduced thermal habitat for cold-water species. Individual effects are difficult to integrate. However, warm-water lakes generally have higher productivity than cold-water lakes, and existing warm-water lakes will be in areas with the least change in temperature. It is reasonable to expect higher overall productivity from freshwater systems. Most warming should occur during fall, winter, and nighttime during the summer, improving the survival of fish that are less tolerant of cold and having little effect on many species near their upper lethal temperature. Streams may be no more likely to reach high lethal temperatures. Lastly, fishery managers heavily manipulate freshwater fisheries in much of the world. If species mixes continue to be changed to support angler and market preferences and changing habitats, climate-change damages may dampen and benefits may heighten.

16.2.2. Saltwater Fisheries

The linkage between climate and marine fisheries is complex and poorly understood. Physical changes influence recruitment and abundance, the center of distribution and range, and availability by concentrating stocks in fishable locations. There are so many interacting variables (such as currents, upwelling, cloudiness, nutrient flows, salinity, temperature, and solar irradiance) that predictions of changes in primary production are not clear (Bernal, 1991; Mann and Lazier, 1991; see also the Working Group I volume). However, understanding is growing. For instance, in the Pacific, the intensity of the Aleutian low clearly affects primary production (Venrick *et al.*, 1987; Beamish and Bouillon, 1993) and ecosystem production (Polovina *et al.*, 1994).

16.2.2.1. Sea-Level Rise

About 70% of global fish resources depend on near-shore or estuarine habitats at some point in their life cycle (Chambers, 1991; IPCC, 1990). The growing rate of human occupation—with associated pollution—and the high property values of littoral areas, especially in Western countries, will severely constrain the inland displacement of wetlands and other habitats as sea level rises. Fish production will suffer when wetlands and other habitats that serve as nurseries are lost (Costa *et al.*, 1994). Chapter 9 discusses these issues, and Box 16-4 provides an example of the potential effects of sea-level rise on active fisheries.

If sea-level rise is too rapid, natural succession of coastal ecosystems cannot occur, harming many species. With a half-meter rise by 2100—and with protection of all developed areas—more than 10,360 km² of wetlands could be lost in the contiguous United States (Park *et al.*, 1989). In the near term, fish production could rise as marshes fragment, flood, die, and decompose, improving fisheries habitat in some cases as the protective land edge increases. More nutrients would become available from leaching of soils and flooded peat. The southeastern United States, where land subsidence compounds sea-level rise, may be in this phase of temporary improvement now (Zimmerman *et al.*, 1991). Eventually, detritus-based food webs would lose the protective habitat and nourishment, as well as wildlife nesting sites and refuge (Kennedy, 1990). In the longer term, by 2050 the overall impact on fisheries will probably be negative. The brown shrimp catch in the U.S. Gulf Coast could fall 25% with a 25-cm rise in sea level (Park, 1991). A 34-cm rise could cause the loss of 40% of the extensive Puget Sound tidal flats—an important habitat for shellfish and waterfowl (Park *et al.*, 1993). In certain areas, already nutrient-rich waters may become eutrophic (Caddy, 1993). Rising sea level may particularly affect coastal ponds as flooding septic systems increase nutrient loading, an important loading mechanism (Valiela and Costa, 1988).

Wetlands, coral reefs, mangroves, and sea grasses require a healthy environment to keep pace with a rising sea, to continue coastal protection benefits, and to serve as fisheries habitat.

Box 16-4. The Caspian Sea

Fluctuation of Caspian Sea water levels provides insight on interacting impacts. An increase in sea level could have a positive economic result for fisheries but a high cost to land-based industry and tourism.

The main species harvested from the Caspian are sturgeon, roach, bream, sander, sazan, herring, and kilkas (Anon., 1989). In the second half of the 1950s, diversion of river waters and unfavorable conditions resulted in a series of low-water years, with reduction of sea area and volume and higher salinities. Roach, bream, sander, and juveniles of all other species declined as their prey decreased in response to the water changes. At the same time, river fish (sheatfish, pike, redeye fish, tench, etc.) increased as suitable spawning habitat expanded.

In the late 1970s, the water level started rising, and bioproductivity increased. Plankton biomass increased threefold and shad—which spawns in the northeast shallow brackish area—recovered (Vodovskaya *et al*., 1978). By the mid-1980s, high natural reproduction and improvement of the hydrological regime in the northern Caspian resulted in strong year classes of roach, bream, and sander, and they increased to their highest level as favorable conditions stabilized.

As sea level continues to rise and inundate more developed areas, serious environmental implications confront productivity. The Caspian is heavily polluted with oil, phenol, and heavy metals from years of industrial dumping. As land is overwashed, additional oil and pollutants from industrial facilities will further threaten the sea's valuable stocks (Anon., 1994). If the shore is protected extensively, as is planned by Kazakhstan, there also could be significant losses of fish spawning habitat and production.

Sea-level rise with defense of properties, increased freshwater diversion, and human and industrial concentration in coastal areas would be detrimental to fisheries production.

16.2.2.2. Fishery Oceanography

Evidence in support of the view that environmental changes drive many changes in fish stocks has been accumulating in recent years (Mann and Lazier, 1991; Mann, 1992, 1993; Mann and Drinkwater, 1994; Polovina *et al*., 1995). The question of whether overfishing, environmental change, or a combination of the two is responsible for major declines in fish stocks is still a matter for debate and is situation-specific.

The literature is rich with studies relating historical changes in the abundance and distribution of aquatic organisms to climate changes. The studies show that relatively small changes in climate often produce dramatic changes in the abundance of species—sometimes of many orders of magnitude—because of impacts on water masses and hydrodynamics (e.g., Sharp and Csirke, 1983; Kawasaki *et al*., 1991; Beukema *et al*., 1990).

Changes in temperature, winds, currents, salinity, and other physical parameters affect life in the oceans. With warming waters, larger fish tend to move to cooler or more offshore and higher-latitude portions of their habitat, or suffer reproductive stress responses that debilitate individuals and lead to lower viability (Sharp, 1994). Water temperatures will increase least at the equator and more toward the poles. In contrast to tropical and mid-latitude regions, where productivity is mainly nutrient-limited, the basic limiting factors in polar and subpolar regions are light and temperature. Warming in high latitudes should lead to longer growing periods, increased growth rates,

and ultimately, perhaps, increases in the general productivity of these regions (Regier *et al*., 1990). Each species might be affected differently. For example, early research results for northern Pacific salmon indicate that ocean distribution in a warming climate would decline to half its present area by about 2070, and winter habitat could completely disappear for 3 months each year (Welch and Beamish, 1994).

The impacts of warming can be inferred from past displacements of transition zones—for example, the Russell cycle in the western English Channel (Southward, 1980) and the simultaneous discontinuities in the local occurrence of pilchard and herring (Cushing, 1957, 1982). Opposing fluctuations in these fisheries in the Channel and the Bay of Biscay have followed long-term changes in climate for three centuries (Binet, 1988b). Tropical Atlantic albacore recruitment is correlated with temperature anomalies during spawning (Leroy and Binet, 1986).

Warming would affect marine species in shallow, restricted impoundments long before deep oceanic species (Bernal, 1991). While fish can migrate, mollusks usually cannot move to favorable areas, although their progeny may develop and thrive in new locations—or be eliminated if suitable habitats do not develop. One example is the important fishery for soft-shelled clams in the Chesapeake Bay. These clams are essentially absent in warmer estuaries further to the south. They could disappear from the Chesapeake if there is substantial warming (Kennedy, 1990). Conversely, Dickie (1955) showed that Bay of Fundy scallop fluctuation from 1930–1953 followed water temperature but lagged by 6 years (i.e., the time for sea-scallop recruitment). Higher temperatures led to strong year classes (Frank *et al*., 1990).

Warming and wind changes would affect the distribution and characteristics of polynyas (ice-free areas) and ice edges that

are vital to polar ecosystems. Changes in the extent and duration of ice, combined with changes in the polar frontal zone and the circumpolar current in southern latitudes, also may affect the distribution, mass, and harvesting of krill. Krill is the fundamental link in the food web of the southern ocean; much of the fishery it supports is used as feed in aquaculture. Antarctic productivity also is closely related to spring retreat of pack ice. Warming could affect pack-ice movement and extent—in turn, affecting the distribution, abundance, and productivity of krill. However, little change is forecast in Antarctic ice for 100 years (see the Working Group I volume). Changes in wind strength also may affect productivity in the ice edge zone.

In the eastern Pacific, interdecadal natural variation resulted in warm periods of high sardine abundance during the 1940s and 1976–85, separated by cool periods of high anchovy abundance in between and in very recent years (Lluch-Belda *et al.*, 1992). While this suggests a direct correlation of high sardine abundance with warm temperatures, it is likely that there is a more complex relationship. At the time of these eastern Pacific warm periods, the western North Pacific has been generally cool, with very abundant Japanese sardines.

Major shifts in regional and global climate have major effects on the abundance and distribution of fish stocks. The 1976–77 climatic regime shift in the North Pacific Ocean (Beamish, 1995) was apparently the starting point for a high-sardine-abundance regime. Further, this period seems to be giving way to a new period of high anchovy abundance since 1985 (Lluch-Belda *et al.*, 1992). There is a long time lag before scientists recognize these events.

Warmer water and changes in circulation would substantially affect the structure and location of habitats. However, marine organisms as a rule have rather high genetic and behavioral plasticity, allowing them to adapt to constantly changing conditions. This property underlies the relative stability of zoogeographical patterns during natural climate variations (Odum, 1986). However, there may not be high plasticity with respect to temperature-dependent physiological and ecological rates and behavioral thresholds (Lin and Regier, 1995). While the mix of marine species constantly changes with naturally variable climates, the changes forecast by IPCC would happen relatively rapidly and be long-lasting. There will likely be food-chain disruptions that will destabilize certain marine populations (Kawasaki, 1991). Poleward shifts of some, but not all, elements of an ecosystem may result in discontinuous areas of high productivity (Lluch-Belda *et al.*, 1991).

Changes in currents could lead to changes in population location and abundance and the loss of certain populations—or the establishment of new ones—at the periphery of the present species distributions. Current GCMs do not adequately incorporate the ocean, and coupled physical/biological models are in their infancy. To date, only the Semtner-Chervin global ocean circulation model (Semtner and Chervin, 1988) has been generally used to provide information that is directly applicable to local and regional fisheries applications. If only the

direction of potential changes in ocean circulation could be known, useful assumptions could be made on the likely impacts on fisheries (Troadec, 1989b).

A general poleward extension of habitats and range of species is likely, but an extension toward the equator may occur in eastern boundary currents. For example, the range of *Sardina pilchardus* prior to World War II was from south Brittany to Morocco. In warm years following the war, sardines were fished up to the North Sea. During the 1970s, new fisheries developed off the Sahara and Mauritania, with small amounts landed as far south as Senegal—perhaps due to upwelling and ecological processes related to tradewind acceleration (Binet, 1988a). Changes in the circulation pattern are likely to induce changes in the larval advection/retention rates in and out of favorable areas and may explain changes in abundance and distribution (Binet, 1988a; Binet and Marchal, 1992). Areal overlaps in closely related species may change in unpredictable directions (Ntiba and Harding, 1993).

Even if the major currents are unchanged (see the Working Group I volume), winds can change local currents and upwelling dramatically. If upwelling-favorable winds intensify, as some authors suggest (Bakun, 1990, 1993a), the mixing of surface and subsurface waters will increase, improving their nutrient contents but perhaps delaying the phytoplankton spring outburst in some areas. The total production and species dominance of the whole food chain will be affected (Aebischer *et al.*, 1990). Conversely, some authors suggest that global warming will lead to a reduced temperature gradient between the poles and the equator—and therefore to decreased oceanic winds and decreased mixing of surface and subsurface waters (Wright *et al.*, 1986).

A physical forcing may have opposite effects in different areas because ecological relationships are not necessarily linear. The 1950–1980 northerly wind increase in western Europe enhanced the Iberian west coast upwelling and is associated with decreased sardine production (Dickson *et al.*, 1988), whereas wind acceleration along the Mauritania coast favored settlement of a new sardine population (Binet, 1988a), possibly illustrating a dome-shaped environment–resource relationship (Cury and Roy, 1989). A gentle breeze enhances the recirculation of nutrients in the euphotic layer and hence the biological production, whereas a strong wind mixes the water and causes phytoplankton to sink below the sunlit layer. Other examples of the influence of changes in upwelling systems and circulation are provided in Box 16-5.

Skud (1982) found that in both marine and freshwater systems, changes in environment can shift species dominance. Dickson and Brander (1993) describe how a change in the west winds resulted in a major influx of West Greenland cod larvae to the 1957 Labrador cod stock. Moreover, winds and warming can interact powerfully—as is demonstrated by the tale of the tilefish. In 1879, the tilefish, responding to a temporary warming of the Atlantic, appeared in large numbers off New England. Three years later, northern gales cooled the water below the

Box 16-5. Upwelling Systems

Changes in circulation and upwelling systems affect the distribution and abundance of pelagic species (Bakun, 1993b), often in interaction with fishing pressure:

- Long-term fluctuations in sardine stocks occur in apparent synchrony off Japan, California, and Chile/Peru (Kawasaki, 1983; Sharp, 1992a, 1992b; Sharp and McLain, 1993). These broad processes link through atmospheric and oceanographic patterns spanning a few decades. Transitions from one pattern to another involve massive declines in populations of coastal upwelling species and the emergence of more oceanic forms to recolonize large expanses of the near-shore environment (*c.f.*, Pauly *et al.*, 1987, 1989; Yañez, 1991).
- Recent changes in the distribution and abundance of west African pelagic stocks correlate with upwelling system modifications (Binet and Marchal, 1992, 1993; Binet and Servain, 1993; Cury and Roy, 1991):
  – A shortened food web resulted in more phytoplankton and fewer zooplankton, benefiting phytoplankton-feeders.
  – New concentrations of *Sardinia pilchardus* appeared off Mauritania and Senegal; pilchard catches declined off northern Morocco.
  – *Sardinella aurita* strongly expanded in the Ivory Coast.
- Similar stock changes are documented from Namibia and South Africa (Crawford *et al.*, 1991; Payne *et al.*, 1987), Argentina and Brazil (Bakun and Parrish, 1990, 1991), California (Parrish and McCall, 1978), Peru/Chile (Pauly and Tsukayama, 1987; Sharp and McLain, 1993), and the subarctic Pacific (Beamish and Bouillon, 1993).

---

lower thermal limit, causing mass mortality (Freeman and Turner, 1977).

Freshwater flows to the sea lower local salinity, bring nutrients to increase primary production, enhance turbidity, and impact coastal ecosystems. Salinity changes and warming of coastal waters may lead to a latitudinal redistribution of fish stocks, with changes in timing and pathways for migrating species. Increases are expected in evaporation in mid-latitudes and precipitation in low and high latitudes. The 1972–1985 west African drought led to a large-scale ecological change over the west African shelf (Caveriviére, 1991). The halving of river flows led to a small salinity increase along the coasts of Senegal and the northern Gulf of Guinea (Mahe, 1993) and greatly reduced sediment loading and turbidity.

In the Casamance—a long, narrow estuary in Senegal—a rainfall shortage that sharply raised salinity caused dramatic changes in fish populations. The total fish biomass remains the same but consists of small, low-priced species. High mortality can occur when the fish cannot escape the salt plug (Albaret, 1987). Shrimp production increased temporarily and then collapsed as salinity increased (Le Reste, 1992).

Higher temperatures and greater water-column stratification can result in less organic material reaching the bottom and thus favor pelagic over demersal fishes (Beamish and Bouillon, 1993). In addition, changes in phytoplankton production, such as shifting downward to smaller species, can lead to longer food webs or benefit smaller fish feeding at lower trophic levels (Frank *et al.*, 1990). Changes in wind, temperature, and precipitation can alter stratification processes and thereby affect the feeding and survival of larval fishes (Owen, 1981, 1989). Some species depend on turbulence at critical stages—for example, to oxygenate eggs or habitats—whereas others require stability to

allow surface-water stratification and the concentration of food organisms. Thus, changes in stratification of local water masses could disperse or concentrate food organisms of young fishes (Bernal, 1991). Lasker (1981) hypothesized, and Peterman and Bradford (1987) demonstrated, that the larval mortality of anchovy (*Engraulis mordax)* was negatively correlated to the number of calm periods. Rothschild and Osborn (1988) note that minimal turbulence is useful to enhance the encountering rate of particles and predators, whereas strong turbulence breaks up aggregations of particles on which feeding is possible. This apparent contradiction illustrates the complexity of ecological relationships and the difficulty of prediction.

The nature of climate-change impacts on fish can be inferred, in part, from an analysis of current interannual fluctuations of marine populations. Catch statistics and research surveys can yield information on stock fluctuations. Fish variability has been classified on the basis of taxonomic groups and environments (e.g., Kawasaki, 1980; Sharp, 1986) and by temporal variations (Caddy and Gulland, 1983). These categories describe:

- Highly unstable and unpredictable stocks varying by several orders of magnitude due to sporadic climatic shifts (e.g., capelin, sand eel, and saury)
- Unstable and partly predictable stocks varying by a few to several times due to cyclic climate and fishing variations (e.g., sardines, herrings, and mackerels; Sahelian freshwater fish)
- Stable and predictable stocks varying by tens of percent to a few times due to fishing and climate trends (e.g., bottomfish such as cods and flatfishes and large pelagics such as tunas).

In most cases, temperature increase is not the direct reason for change in aquatic ecosystems and fisheries, although fish may

react physiologically or behaviorally. The most crucial problems are associated with the whole complex of ecological changes. Fish have developed many patterns of behavior to deal with climate variability and migrating predators and prey. Some environments call for tightly constrained windows within which reproduction can succeed. Others require constant or prolonged spawning to cope with even finer-grained, less-certain opportunities. Because many fish early-life stages occur in shallow layers and estuaries where various climate components are important (Kawasaki, 1985), there is potential for significant effects on fisheries and dependent communities.

Individual species have adapted strategies to accommodate changes in their environment. Some even have fully diversified local population responses that would seem unlikely. Shad along the eastern United States spawn many batches of smaller eggs in their warmer southern range and, in the less variable north, produce larger eggs that they carry up rivers and spawn in single batches (Leggett and Carscadden, 1978). Thus, changes in patterns of climate variability can be as important as the magnitudes of the changes—and as much a source of uncertainty.

Descriptions of interrelated changes in oceanographic structures and bottomfish populations include: the 1962–1986 cod outburst in the North Sea and the Irish Sea (Hempel, 1978) and the rise and fall, with a maximum in 1945–1950, of Western Greenland cod stocks that were established from recruits of Icelandic stocks during the 1925–1960 North Atlantic warming (Cushing, 1982).

It is difficult to disentangle human and natural climate effects. For example, the environment adversely affected cod off eastern Canada, but the additional burden of heavy fishing probably caused the stock collapse—reducing the biomass, eliminating older year classes, and increasing stock vulnerability (Mann and Drinkwater, 1994).

There may be a synergistic effect between climate change and overfishing. With overfishing, the age composition of a stock becomes increasingly unbalanced: Fewer year classes and mature individuals are available, and fewer reproductive opportunities occur. Overfishing eliminates species characterized by low fecundity, slow growth, and late sexual maturation, while favoring species with opposite strategies, usually of less economic value. It introduces new trophic pathways, possibly produces empty ecological niches, and creates new competitive relationships. For example, there has been a change in fish sizes and species dominance in the Gulf of Biscay since 1800 (Quéro and Emmonet, 1993). Georges Bank also has been the scene of a "biomass flip," with skates and dogfish replacing cod, haddock, and flounder (Rothschild, 1991).

In the case of the Atlantic salmon (Pope *et al.*, 1961), the brown trout (Hardy, 1967), and the North Sea long rough dab (Ntiba, 1990), the larger, older fish lay larger eggs; Blaxter and Hempel (1963) showed that larger Atlantic herring eggs hatch into larger larvae. Larger eggs could influence survival and development and may have important ecological implications (Blaxter,

1988). Recruitment into the fishery is probably balanced on the number of larger and older fish in the population (Bagenal, 1970). Although some species can rebuild quickly (Beamish, 1993), most large species will have difficulty taking advantage of a favorable environmental episode that may come only once in several years. Overfishing also may reduce the genetic resilience of the population, with similar consequences. Climate changes may magnify the effects of overfishing at a time of an inherent instability in world fisheries (Stokes *et al.*, 1993).

Hydrodynamic structures are largely determined by wind fields, currents and fronts, temperature, salinity, and geographic topography. As new hydrographic structures stabilize, new populations may take advantage of the physical features. Colonization is determined by ecological constraints affecting reproduction (Sinclair, 1988). For species dependent on geographical features, there is less flexibility. For example, herring spawning in certain areas disappeared with the collapse of specific herring populations in the 1970s but reappeared in the same locations as the herring recovered (Daan *et al.*, 1990). Dislocations of and changes in density stratifications may affect the timing and location of fish availability for fishing and can be particularly significant in pelagic fisheries (e.g., tuna, salmon, herring, sardines):

- Most Peruvian anchovy concentrations moved into inshore waters after 1972: The percentage of catches made within 10 miles rose from 42% before 1970 to 91% after 1972 (Valdivia, 1978) as the areal extent of the upwelled water dwindled.
- The route by which sockeye salmon return to the Fraser River determines, in part, their availability to Canada and U.S. fisheries. In warm years—and especially in strong El Niño years (see Box 16-6)—80% of returning sockeye may use a cooler, northern route that favors Canadian fishing interests, compared to as little as 10% in some cold years (Miller and Fluharty, 1992).
- High salinity near the coast due to droughts can reduce the area of low-salinity waters, increasing the availability of some species to small-scale fisheries—for example, *Sardinella aurita* in the northern Gulf of Guinea, especially the Ghanaian canoe fishery (Binet, 1982), and *Sardina pilchardus* off northern Morocco (Belvèze and Erzini, 1983).
- Development of the Northeast Atlantic bluefin tuna fishery from 1920 to 1967, with a peak in the 1950s, has been related to the long-term warming of the North Atlantic until the late 1940s and subsequent cooling (Binet and Leroy, 1986).

16.2.2.3. Impacts on Fisheries

Global warming will likely cause collapses of some fisheries and expansions of others. It may be one of the most important factors affecting fisheries now and in the next few hundred years. The level of impact will vary widely and will depend on the complexity of each ecosystem, the attributes and adaptability of

Box 16-6. El Niño: How Short- and Long-Term Climate Events Can Affect Fisheries

Environmental processes, fisheries management, and population dynamics closely interact. The 1972 El Niño, coupled with anchovy overexploitation and resultant recruitment failure, led to a severe crisis in the following years. Although not the direct cause of the collapse (Sharp and McLain, 1993), the El Niño, nested within a much broader set of environmental changes, concentrated the anchovies—enabling the fishery to operate on the entire population, which previously was scattered over a broader area with some portions protected from continuous exploitation (Csirke, 1980). The anchovy collapse was an economic disaster for Peru. The production center for the Humboldt Current shifted southward, from north-central Peru to the Peru/Chile border, with sardines colonizing the coastlines from Ecuador to central Chile.

These short-term effects show how fish species react to some large environmental changes. They may be illustrative of effects from long-term changes. El Niño events, being anomalies riding on the long-term trend, may provide meaningful insights—particularly since some GCM results indicate reduced East–West temperature gradients similar to conditions found in El Niño events (see the Working Group I volume).

There also are less familiar El Niño impacts. Some can last for several years. For example, El Niño Southern Oscillation (ENSO) processes, combined with other natural variability, led to increased prices of salmon from 1980–1984, due to displacement of salmon migratory routes and complex ecological changes from warm-water intrusions along the Pacific coast of North America. Pacific gray whales moved far north of their usual locations, indicating that their habitat had moved northward and shoreward for the first time in decades (Sharp, 1994). The 1982–1983 El Niño led to increased stocks and catches of scallops and oceanic tunas and billfishes in Chile and Peru. The annual migration of whiting along the west coast of the United States and Canada is correlated with water temperature, especially with strong El Niño conditions. In warm years, more stock is available to Canadian fishers (Dorn and Methot, 1990). Temperate *Sardinops* populations in the Gulf of California are much less available during El Niños, whereas tropical thread herring are much more available (Lluch-Belda *et al.*, 1986).

---

each species, and the nature of the human communities that depend on them. Defining these contexts is the key to understanding and preparing for climate changes. If climate change occurs on the scale indicated by GCMs, we can expect significant effects, both beneficial and destructive, on the distributions and productivity of valuable regional fisheries and the local industries associated with them (Healey, 1990).

Over the long term, global changes in fish production may maintain some relative balance, but there could be important regional shifts in fishing areas and species compositions, with major socioeconomic impacts. These shifts may be in the relative abundance of particular species between contiguous EEZs or between EEZs and the high seas. Globally, fluctuations in fish abundances and distributions are expected to maintain similar ranges as previously documented due to natural variation (Sharp and Csirke, 1983; Sharp, 1987). In some cases, species may move poleward, but there may be little change evident to someone living in the middle range of a given ecosystem. However, significant differences may occur in habitat suitability and species dominances at the thermal limits of species ranges. Changes in climate near ecosystem borders could mask impacts from harvesting excesses and other anthropogenic changes, generating misguided international disputes. Local communities would be affected by changes in recruitment, distribution, and abundance.

Globally, overfishing and diverse human stresses on the environment will probably continue to outweigh climate-change

impacts for several decades. However, fishing impacts are usually reversible—whereas climate-change and habitat-loss impacts are not (at least within the IPCC scenario)—and the overfishing problem may well be solved within the time horizon of this IPCC assessment. For fish production, climate variability is not a new problem. Social policies and controls needed to adapt to global change and those required for managing high-sea stocks are of similar geopolitical magnitude.

In some cases, fisheries on the margin of profitability could prosper or decline. For example, if there is a rapid retreat of sea ice in Antarctica or if the ice has reduced extent, the krill fishery—which is regulated by the three months that the continental shelf is ice-free—could become more attractive to nations not already involved.

In developing countries, fishers can be expected to follow shifting fish distributions—comparable to what happens now within natural climate variability. New fishing sites often have poor or nonexistent provisions for freshwater supply, sanitation, and refrigeration. As a result, seafood handling may be less sanitary than is needed, and cholera or other diseases may occur. Where there are no cold storage facilities, fishers may have to resort to either salting or smoking as alternative means for preservation. Such change can, in turn, lead to local deforestation, increased soil erosion, or loss of mangroves and associated fish nursery habitat. Long-distance migrations of small-scale fishers can be constrained by newly established national frontiers or by confrontation between local fishers

and newcomers, as has already happened with west African small-scale fisheries.

In some communities—such as Fortaleza, Brazil—half or more of the fishing fleet may be dependent on wind and sails (Everett, 1994). Reductions in wind strength could cause significant costs to these small-scale fishers operating at the margin of profitability. Conversely, increased wind force in other regions will require more seaworthy vessels or other changes in fishing strategies. There are costs associated with these changes. Such costs are certainly less obvious, and may be less important, when they take place gradually over a longer time period than the life of the fishing vessels and other assets.

The ways in which societies have responded to past changes in the fisheries that support important components of their regional economies are instructive in guiding society toward developing better ways of adapting to the regional impacts of environmental change (Glantz, 1992). As an example, the industry collapses of the Chilean/Peruvian anchovy, the California sardine, and the Alaskan king crab led to varied socioeconomic responses. While the less industrially capitalized Chileans responded to perturbations in the anchovy catch with regulations and an adaptive restructuring of the industry to the more offshore jack mackerel (*Trachurus murphyi*) and secondarily the sardine (*Sardinops sagax*), the Peruvians continued peak extraction until the anchovy catch collapsed and only slowly shifted to alternative fisheries, with serious economic impacts (Caviedes and Fik, 1992). The California sardine bonanza, harvested at increasing levels for half a century, similarly collapsed—with perhaps even greater socioeconomic impacts on the region. When the industry collapsed in the 1960s, most of the fleet converted to less labor-intensive fisheries or was sold for pennies on the dollar; fishing and cannery crews, unneeded in the remaining fisheries, moved north to Alaskan waters, fished only seasonally, or left the industry; and much of the infrastructure was moved to South America, along with the expertise of many fishing captains and cannery operators (Ueber and MacCall, 1992). The 1981 collapse of the Alaskan king crab industry also resulted in economic disaster for the heavily overcapitalized industry, which was faced with foreclosure or diversification. The fleets that survived broadly expanded their fishing grounds, shifted to replacement species (other king crabs and Tanner crabs), or traded their former low-volume/high-value fishery for more high-volume/lower-value fisheries (e.g., pollock) (Wooster, 1992).

With the declaration of extended EEZs, long-range fishing industries have adjusted to the new access conditions through joint-venture agreements, further development of domestic fisheries and aquaculture, development of new processing methods to upgrade lower-value species (e.g., surimi), development of new fisheries within and outside the 200 miles, increased import and reduced consumption of fishery products, and the scrapping of long-distance vessels (Glantz, 1992; Yonesawa, 1981; Kaczynski, 1983a, 1983b). For long-distance fisheries, these adjustments often have entailed considerable costs. The new ocean regime has had more serious impacts on the fisheries sectors of long-distance fishing countries and on those of countries that extended their control over large resources (e.g., Iceland; Glantz, 1992) than would the effects of climate change.

Forecasting by analogy, therefore, can inform about the kind, but not the direction, magnitude, and geographic distribution, of economic and social effects of global change on fisheries. The lessons learned from experience include:

- The magnitude of effects depends on the importance of fisheries in an economy. Although all sectors may benefit from positive effects, the economies of traditional fishing groups and developing countries may be disproportionately impacted by negative effects. With little diversification, their means are limited and they are more vulnerable, particularly in developing countries bounded by major upwelling regions (e.g., Mauritania, Namibia, Peru, Somalia) (Troadec, 1989a).

- Small-scale fisheries, even in industrialized countries, maintain several characteristics of premercantile societies, such as autonomy, self-sufficiency, exploitation of local natural resources, self-limitation of demand, geographic mobility (to offset the law of diminishing returns), solidarity within family, and the original value systems. Industrialized, market societies are characterized by autonomy of individuals, professional specialization, mobility of production factors, development of new activities through technological innovations, and accumulation of profit. Because the economy of these organizations is different, it is difficult to compare their capacity to cope with variability and uncertainty; however, the former's frequent lack of means (poverty) is a major and new handicap.

- When climate change shifts the distribution of a fish stock within an EEZ, or between EEZs, or causes a stock to simply change in abundance within its previous distribution, the resulting mismatch between fish availability and fishing capacity will require greater management flexibility, both nationally and internationally. Because natural variability is so great relative to global change, and the time horizon on capital replacement (ships and plants) is so short, in most situations, there will likely be relatively small economic or food-supply consequences.

- There are three major institutional deficiencies: the allocation of access rights to fisheries and among competing uses of aquatic resources; regional fisheries bodies whose mandate and organization have not adjusted to the new requirements of shared and straddling stocks management; and international institutions whose development is lagging behind the globalization of the economy and uses of the ecosphere (Troadec, 1994).

- When fish stocks decline because of a combination of less favorable environmental conditions and overfishing—and even when there are initially abundant

stocks—industries often have continued heavy fishing pressure, leading to fishery collapse. With such complex relationships, scientists are often slow to recognize declining resources. Further, under most prevailing institutions, administrators and producers cannot take proper account of the value of use (harvest) rights resulting from resource scarcity when regulating access and planning investments. As a result, industries and governments have been unwilling or unable to accept the advice of scientists and take meaningful action to protect fish stocks and enhance harvest efficiency.

A number of reviews have appeared that attempt to predict the impact of climatic change, based on past events, but of necessity they are generalized and deal more with the direction of ecosystem and population changes than their magnitude (e.g., Costa, 1990; Siegfried *et al.*, 1990; Mann and Lazier, 1991; Carpenter *et al.*, 1992; Shuter and Meisner, 1992; Everett, 1995). They provide a strong foundation for understanding the likely impact of climate changes on future fish production.

The ineffectiveness of many management institutions (Anon., 1994; FAO, 1992b; Neher *et al.*, 1989; Parsons, 1993; Troadec, 1989a) will aggravate the likelihood of collapse. This ineffectiveness stems from insufficient authority, unwillingness to act, or incomplete knowledge about resources and their relationship to the environment (Everett, 1995; Talbot *et al.*, 1994). Because many institutions have not adjusted to new conditions of resource scarcity and have not developed means to value and price the rights to use resources, efficient use of resources will be difficult to achieve.

If future fish abundance becomes less certain, regulatory institutions will have even more difficulty in managing fisheries. Many stocks will risk continued overexploitation. This is already a major cause of variability. Institutional inadequacies may result first in greater difficulties in adapting exploitation and management to climate-induced changes. The current crisis may become worse at first. Then, the worsening of the fisheries crisis could make the need for institutional change more obvious and acceptable.

Gains and losses at all levels of social organization may result from climate-change impacts directly or from human responses to those changes. Some nations, sectors, and groups may have the ability to respond or adapt to climate change, turning it to their advantage (Glantz *et al.*, 1990). Others will not. In general, societies have not coped well with declines in biological productivity, regardless of cause (Glantz *et al.*, 1987; Glantz, 1992). Case studies of societal response provide insight into how people and their governments can better prepare for regional changes in distribution and abundance that might accompany global warming. If, in the face of climate change, leaders desire to maintain fisheries at levels matching society's needs, higher levels of international collaboration will be needed—for which there is no global analog from the past.

16.2.3. *Aquaculture*

The effects of climate change on aquaculture generally will be positive—through faster growth, lower winter mortality rates, and reduced energy costs in shore-based facilities (Smit, 1993). Nearshore warming could result in increased production in higher-latitude farming operations because of the prolonged availability of nearly optimum air and water temperatures (McCauley and Beitinger, 1992). With expanded regions of warmer water, the economic incentive to develop cultivation of temperate and subtropical species could develop. A decrease in ice cover could substantially relax the geographic limits for commercial operations for species such as salmonids, oysters, and scallops. Major areas with winter ice cover could become ice-free (Frank *et al.*, 1988). Winter temperatures could move above the lower lethal limit for salmonids and allow their aquaculture to expand into northern Nova Scotia, into the Gulf of St. Lawrence, and along Newfoundland's south coast. Oysters and other cultured species would likely increase in productivity with warmer temperatures, through greater spawning success and higher growth rates—if salinity regimes and disease agents do not become limiting (Frank *et al.*, 1990).

Climate warming may prove deleterious to existing aquaculture industries in some areas. A significant increase in summer water temperatures in the Marlborough Sound in New Zealand may have serious implications for the salmon farming industry there because temperatures are already near the maximum for successful cultivation (New Zealand, 1990). Elsewhere, increasing temperatures may augment the growth and spread of disease agents. The limited genetic variability of farm fish may decrease their adaptability and increase their susceptibility to pathogens.

Sea-level rise could damage aquaculture facilities and reduce areas suitable for aquaculture (e.g., for shrimp culture in mangroves in tropical countries or the Bangladesh floodplain, and for shellfish culture in western Europe). However, in some regions, increased areas will become available. For example, in New Zealand, a rising sea is expected to make more areas suitable for oyster farming because many mud flat areas are a little too shallow for intertidal rack cultivation of oysters. This positive benefit may be offset by a warmer sea that would trigger earlier spawning in the oysters, thus reducing their value for the very important Christmas market (New Zealand, 1990). Even in the mangrove situation, all is not clear because land may flood inland of the mangroves, where conditions could be better than the existing mangrove areas that have high-sulfur soils and very acidic conditions.

Culturing fish for release into the wild for augmentation of wild stocks (e.g., cod) or for capture upon return (e.g., salmon) can be affected by a changing climate at the rearing facilities, along the path to the open ocean or large lake, or in the water bodies where growth is to take place. This type of aquaculture may account for half of the global total for aquaculture. Its further growth is hampered by ecological, institutional (e.g., property regimes), and technological factors. Some scientists believe that many bodies of water may be at their biological

carrying capacity and cannot support more fish; others believe that there are great opportunities for expansion. In any case, fishery managers and hatchery operators need to consider possible interactive impacts of climate change and augmentation on wild stocks and other users of the ecosystem, such as marine mammals and birds.

New or stronger disease agents might flourish, while fish might have little time to build resistance. Farmed fish also may become increasingly susceptible to antibiotic-resistant strains of pathogens to which they had been accustomed, lowering or completely crippling aquaculture production, especially in developing countries.

In aquaculture facilities, fish often live in shallow structures at all life stages. Eggs and larvae near the surface and near-surface phytoplankton, zooplankton, corals, and wetland plants could be exposed to ultraviolet (UV) levels that could cause genetic abnormalities or death. In aquaculture, shallow ponds and unshielded egg and larval production facilities may be of particular concern; most eggs and larval stages of fish studied by Hunter *et al*. (1982) showed high sensitivity to UV radiation and often died if exposed in shallow containers.

16.2.4. Health Issues

One-fifth of global animal protein intake comes from fish, mostly marine species (Weber, 1994). Although there are large variations by country, fish is generally a much more important part of the diet in developing countries, where animal protein is relatively expensive, but per capita consumption is often highest in wealthier nations (Laureti, 1992). Even in the absence of climate change, fish production growth is not likely, and wealthy nations are importing more fish from developing nations that seek foreign exchange—with nutrition consequences for poor nations. With climate change, food production could change, affecting nutrition and health for societies highly dependent on fisheries.

There are natural toxins in ocean and freshwaters, as on land. The better-known toxins are "red tides"—found in both warm and tropical waters but also colder waters—and ciguatera, most often associated with warm or tropical waters. Red tides refer to high concentrations of toxic dinoflagellates that discolor the sea. Even when not abundant enough to discolor the water, they may toxify shellfish (Sampayo, 1989). Some researchers suggest that one red tide toxin, DSP, can cause liver cancer in humans. As plant toxins are concentrated through bioaccumulation at successive levels of predation, those fish at the top of food webs can contain lethal doses, particularly in fatty organs and tissues. Filter feeders such as mussels, clams, and oysters also concentrate toxins when they consume large quantities of these algae. Similarly, ciguatera poisoning occurs when algal grazers in tropical reefs consume toxin-bearing algae. Fish at the top of the food web, such as barracuda or grouper, can concentrate lethal toxin amounts. Cooking does not destroy these toxins. Ciguatera is usually kept in check by local fishing practices that avoid taking fish from affected areas. These areas usually occur in an erratic distribution. Climate change could alter the local habitats and change the areas where ciguatera toxin is produced, but the changes might be undetected by local fishermen or regulators. Warming would expand the range for ciguatera and other biotoxins and could lead to increased biotoxin poisoning.

A rising sea would lift the water table in low-lying land near the coast, releasing contaminants from dump sites and viruses and bacteria from septic systems into drainage systems and waterways. Such contaminants would enter estuarine and inshore food chains and pose a hazard for human consumers. Governments may close additional areas to the taking of fish and shellfish to protect citizens (IPCC, 1992). Also, some marine species may not have time to build resistance to disease agents that might come with a relatively rapid rise in temperatures. One example may be the susceptibility of North Atlantic green sea urchins to a waterborne disease to which they lack natural resistance at warm temperatures (Frank *et al*., 1990). It is not just the exposure of organisms to new pathogens that is a concern; there is also the possibility of increasing susceptibility to existing ones as a result of environmental stress.

Changes in precipitation patterns also are expected. Reduced water flows in streams and rivers will concentrate pollutants, rendering some fish unfit for consumption. Areas receiving higher flows may have lower concentrations of pollutants in fish whose use is now restricted (or should be). When increased precipitation comes in the form of pulses and leads to sudden surges of runoff, increased coliform bacteria counts will be reached more often, leading to closures of shellfish beds (New Zealand, 1990). When increased flows of pollutants enter lakes having a high rate of evaporation relative to water discharge, increasing concentrations of pollutants may occur.

Chapter 18 warns that cholera can be more easily transported in ship ballast water when there is a high density of marine algae and that warming could increase the amount and range of algal blooms. Ships often release ballast water in harbors or nearshore areas, thus transporting cholera throughout the world. This is a primary means for the introduction of new cholera strains. Clams, mussels, and oysters can be carriers of cholera, and—since they are often eaten raw—they can transmit cholera to humans. Ballast water seems to be the means of introduction of PSP algae into Tasmanian waters, and reproduction of the algae is helped by warmer, nutrient-rich waters (New Zealand, 1990).

When fishers pursue fish over longer distances and have inadequate infrastructure (e.g., refrigeration, potable water), opportunities for pathogens and spoilage increase. Health issues can cause great economic damage to fisheries because societies will act to keep contaminated food out of the marketplace. Stories about people becoming ill from eating problematic food receive a great deal of publicity, thus depressing markets.

16.2.5. Infrastructure Issues

Modern industrial fisheries require complex support, including electronic positioning, weather advisories, transportation, cold storage, ports, processing, markets, electricity, potable water, search and rescue, and provisioning. Any redistribution or increased variability of fishery resources, or of aquaculture production, adds strain on this sector. Natural variability is so great that the provision of these services is generally quite flexible. However, when long-term redistributions occur, economic efficiencies change as the distance between fish and home ports changes. Over time, ports nearer to new fishing areas will gain an advantage. Home ports will change, families will move, and there will be winners and losers. In some cases, the retail market may respond to long-term redistributions, if the predominant species change and the new species require different processing and marketing approaches. Rapid loss of shelf space in markets and absence from restaurant menu listings occurs when species are unavailable. It is difficult to regain these markets, further exacerbating variability in revenues.

A rise in sea level will adversely affect infrastructure that supports fisheries. In less-industrialized areas—where artisanal fishers land catches in numerous remote fishing villages and transport them, often by foot, to commercial centers and tourist motels for sale—a significant rise in sea level will drown much of the existing network of roads and footpaths used by many poor coastal people who financially and nutritionally depend on their daily catch. Sea-level rise also will impact industrialized countries, as implied in the Caspian Sea example (see Box 16-4). Reduction in fresh water supplies due to sea-level rise and increased evaporation—where not offset by increased precipitation—could have significant impacts on fish processing, which uses large amounts of potable water (Smit, 1993).

Some technical adaptations can ease the impacts on industrialized as well as developing countries—such as faster vessels, portable processing plants, alternative transportation infrastructure, and on-board processing. Nevertheless, costs will be incurred to finance the changes, and profitability will be reduced.

16.2.6. Recreational Fisheries Issues

There is no significant difference in the impacts of climate change on recreational species as opposed to commercial or subsistence species. Many species are pursued by multiple user groups. However, increased storminess or changes in weather patterns will affect the desirability and effort involved in recreational fishing more than other types of fishing. Changes might include shorter ice-fishing seasons and longer seasons for higher-latitude fisheries. On New Zealand's west coast, expected decreases in westerly winds, higher temperatures, and sea-level rise may lead to a decline in the distribution and abundance of toheroa, a popular shellfish species sought by aboriginal and recreational fishermen (New Zealand, 1990).

Many anglers prefer cold-water species, which are associated with higher expenditures. The ranges of such species can be expected to shift toward higher latitudes. However, if the daytime summer temperatures do not change significantly when compared to changes in nighttime temperatures, the ranges and production of such species may expand.

16.2.7. Sensitivities, Critical Rates, and Thresholds

Most fish species are sensitive to the expected climate-change effects. The individuals, or centers of production, can shift rapidly if suitable habitat and paths exist. Fish species are cold-blooded; life processes, such as growth, are faster when warmer (within limits). Many species have narrow ecological niches, but there are many species to fill niches. In a varying environment, species mixes will change. Examples of sensitivities are:

- Fish eggs that rely on a gyre to return them to their habitat on a certain day or week
- Fish eggs in streams or on the sea floor that require a minimum current speed for oxygenation
- Species that require a certain influx of freshwater to induce spawning or to kill predators
- Temperatures above or below the stock's lethal limit.

At the societal level, there are other sensitivities. Species in more stable environments often are more valuable. Fishing interests often can follow fish, but political boundaries or economics can stop pursuit. Even if fishing interests can follow, communities may not. Developing nations dependent on fish as food or export earnings are most sensitive. Examples of societal sensitivities are:

- Immobility of communities or industries dependent on one type of species
- Societies without the money needed to buy replacement foods
- Fishers without the ability to deal with increased storminess.

Information on critical rates, thresholds, and sensitivities exists for only a few important species. Available information includes:

- The relationship between fisheries production and the health or extent of corals, mangroves, and wetlands
- The temperatures governing some fish movements, migrations, reproduction, and mortality (in general, fish are much more sensitive to cooling rates than to warming; Brett, 1980)
- The optimum temperatures needed for certain aquaculture systems
- Freshwater flows required for stock movements, migrations, reproduction, and aquaculture operations
- Nonlinearities: As temperature rises and nutrients increase, eutrophication may suddenly produce critically low values of dissolved oxygen.

Additional responses that have some quantification are:

- The shift in production centers of some oceanic fish in response to temperature changes (e.g., Murawski, 1993)
- The distribution of some fish in relation to northern ice cover (Shuter and Post, 1990)
- Mortality-rate changes of some Antarctic krill and some eastern Pacific pelagic eggs and larvae in response to changes in UV-B radiation (Hunter *et al.*, 1979, 1981; Damkaer *et al.*, 1980, 1981; Damkaer and Dey, 1983; Dey *et al.*, 1988). For some species, the apparent thresholds for development and survival are at current incident UV-B levels (Damkaer *et al.*, 1980). Significant changes in ecosystem function and functioning could occur as species sensitive to UV-B radiation are replaced by more-resistant species (IGBP, 1990).

16.2.8. Storminess

Major storms such as cyclones have major consequences for ecosystems. They cause mixing of ocean waters and internal upwelling over the edges of shelf seas, moving nutrients and organisms into the photic zone—which then helps local food-web production and can be likened to terrestrial plowing (Sharp, 1994). Such mixing, though, can disturb the stratification of water masses and their biological components, on which many species depend as part of their reproductive strategies. Storms also can be disruptive to reefs, mangroves, and shoreline habitats and to egg masses laid on substrate. Storm paths are also important. Path changes can affect the density of plankton forage on which young fish depend, thus modifying the recruitment success of pelagic stocks (Lasker, 1981).

Changes in storm frequency and intensity could have subtle and easily missed impacts in the coastal zone. For example, in regions of small tidal range, such as the Gulf of Mexico, there are wetlands found above the high-tide line that get inundated by storms and weather fronts or distant oceanic events (Swenson and Chuang, 1983). These high super-tidal wetlands are important in supporting marine species. In some interior areas, near and distant storms are the dominant flooding mechanisms and affect the production of shrimp (Childers *et al.*, 1990).

Storms are also of major significance for the fisheries industry. Increased storminess can damage fishery and aquaculture infrastructure and lead to increased costs for the strengthening of facilities. In some cases, increased storminess can lead to longer fishing seasons if ice is broken up or cannot form. Storms are a major threat to the safety of fishers. Increases in intensity or frequency could lead to additional losses in the occupation, which is already among the most dangerous; the fatality rate of commercial fishing is seven times the U.S. industry average (Hart and Perrini, 1984).

16.3. Adaptation Options

Events influencing fisheries are accelerating. Adaptations must be matched with the concept of an already highly stressed ecology and the inherent volatility of fisheries. Further, coincident problems such as pollution, resource degradation, and sea-level rise (or subsidence) also must be addressed.

There is a danger that if climate-change alterations are slow, inexorable, and generally irreversible, impacts resulting from climate change will not be recognized in time. Alternatively, abrupt shifts in climate-influenced factors may be too limiting for species acclimation or management adjustment. Some fisheries involve high capital investment, and others are very important to whole coastal communities. To minimize economic and social disruption, the possibility of permanent long-term changes in the regional availability of traditional fish stocks must be anticipated and new management philosophies developed. Local fishery managers also need to anticipate and take advantage of short-lived benefits (Sharp, 1991). As in any stock management planning, managers must recognize the need for flexible approaches and for greater foresight when establishing policies.

The faster the rate of climate change, the more difficult will be adjustments in human systems. Surprises and divergences from the predicted scenarios are to be expected and must be anticipated by resource and community managers. Preparation for the unexpected is important (New Zealand, 1990). In general, technological innovations are developed faster than are those of a biological or societal nature. Cultural attitudes, which are critical for the adoption of institutional innovations, have the greatest inertia.

Fisheries strategies should concentrate on those that are compatible with sound conservation principles and—like the earlier IPCC response strategies—are beneficial for reasons other than climate change and make sense now in their own right; are economically efficient and cost-effective; serve multiple purposes; are flexible enough to change with new knowledge; are compatible with sustainable economic growth; and are administratively practical (IPCC, 1990).

Table 16-1 provides an overview of key fisheries impacts and whether there might be societal responses or adaptations. An I, P, or T indicates that an important response exists; the right-hand column indicates the type of adaptation or issue involved.

16.3.1. Fisheries

Adaptation to existing climate variability may demonstrate ways to deal with climate change. A Canadian report (Smit, 1993) offers insights. In the short term, the timing of fishing and tasks such as trip preparation and maintenance are adjusted to match the weather. Most full-time fishing interests also have several licenses and gear to allow flexibility in the species and locations fished. Others maintain work options in

activities such as construction, tourism, or other sectors, which reduces risk due to climate uncertainty. There also is risk-sharing within family businesses, extended families, and communities, which compensates for temporary setbacks in a particular fishery or enterprise. These may be formal or informal, involving cooperatives or financial institutions, based on a sense of mutual support. The vulnerability of communities to varying stocks, intense fishing pressure, and inappropriate government policies is graphically apparent with the current Canadian moratorium on northern cod, whose stock abundance and distribution may be partly related to water temperature and salinity (Smit, 1993; Mann and Drinkwater, 1994). The policy lesson here is that government fisheries managers should not lock fishing interests into narrow full-time activity within a single fishery. Flexibility in fishing, plus seasonal shifts to other sectors, will be a valuable approach to minimizing climate-change impacts, as long as fishing capacity is consistent with the resource base.

Climate change increases society's need to quickly adjust labor and capital to fish productivity. To have efficient fisheries, the capacity to control human inputs should precede and anticipate the development of technological intensification. This prescription is atypical of societal response. Overcapitalization problems are rooted in the uneven development of biotechnical, administrative, and regulatory systems.

Management systems developed when resources were not under intense fishing or environmental threat have become ill-adapted to resource scarcity. In traditional systems, resource access was regulated through the social structure of rural communities. These systems lose their effectiveness as population pressure and resource uses intensify. They are being supplemented by central legislation, with attendant lag times in addressing problems. These formal regulatory systems have also tended to become ineffective as the need for harvest rationing increases. As resources approach their production limits, administrators and producers have maintained the *status quo* even at the cost of greater economic inefficiency and overfishing. To function most effectively, economic systems need proper institutions (e.g., a market for pricing harvest rights), a property or ownership/stewardship regime for the functioning of that market, and an institutional context to administer the proper functioning of any allocation system based on such rights and markets.

There are several adaptation strategies:

- Develop international agreements for ecosystem research and management and for stock allocation before stocks of fish move due to climate changes. The dramatic decadal fluctuations in marine fisheries yields, considered in light of climate-change concerns,

Table 16-1: *Overview of key fisheries impacts.*

Global Change Impacts	Certainty	Adaptation Example Institutional/ Policy/Technical	Possible Adaptations
Redistribution of Living Resources	very likely		
– Increase inshore[1]	possible	I/T	– Fish management/industry expansion
– Decrease offshore[1]	possible	I	– Government welfare assistance
– Poleward migration[1]	likely	I/P/T	– Welfare/industry assistance/mobility
– EEZ jurisdiction changes	likely	I/P	– Negotiation/confrontation
Faster Fish Growth Rates	likely		
Extreme Events	possible	I/T	– Forecasts, rescue/hardier equipment
Precipitation Changes	likely	T	– Water desalination for processing
River Temperature Changes	likely	T	– Water release from dams
Aquaculture	possible		
– Sites (freshwater, sea-level rise, temperature)		P/T	– Regulations/species, location
– Growth rates		T	– Species, feed
– UV-B		T	– Shelter
– Diseases		T	– Hygiene, prophylactics
Reduced Ice Cover	likely		
– Freer navigation		T	– New fishing zones, routes, ports
– Less ice strengthening		T	– Ships, facilities
Seafood Health Issues[2]	possible	I/P/T	– Define responsibility, certify safety, establish monitoring system
Flooding from Sea-Level Rise	likely	T	– Build on higher ground, use water-control structures, allow procession
Increased UV-B	likely	T	– Shelter for aquaculture, crew

[1]Generalization difficult.

[2]Increased frequency.

should accelerate the adoption of large marine ecosystems as the appropriate units for fisheries research and management (Sherman and Gold, 1990; Talbot *et al*., 1994). Some post-United Nations Conference on Environment and Development (UNCED), ecosystem-scale research programs are being implemented (AAAS, 1993). These programs are designed to couple recent advances in ecological monitoring, management, and stress mitigation strategies with needs in developing countries (AAAS, 1990, 1991).

- Modify and strengthen fisheries management policies and institutions and associated fish population and catch-monitoring activities. In some areas, it takes many years to develop and implement changes in fisheries policies, even after the institutions are established.
- In coastal planning and environmental decisionmaking, consider that a healthy environment is a prerequisite for healthy ecosystems.
- Preserve and restore wetlands, estuaries, floodplains, and bottom lands—essential habitats for most fisheries. Cooperate more closely with forestry, water, and other resources managers because of the close interaction between land cover and maintenance of adequate fishery habitat. The adequacy of management practices in all sectors affecting fisheries (e.g., water resources, coastal management) needs to be examined to ensure that proper responses are made as climate changes.
- Monitor and ensure that the habitat needs of marine mammals (as they shift to remain in an optimum environment) are considered from the standpoints of coastal planning and ocean pollution control.
- Promote fisheries conservation and environmental education among fishermen worldwide.
- Be alert to possible increased health problems caused by biotoxins and the release of pollutants from a rising sea level; industry and seafood-safety agencies should take the lead. Take measures to prevent the introduction of undesirable organisms as climate changes.
- Tailor institutional innovations to ecological, technical, economic, and social features. Large-scale and small-scale production systems, in particular, require different regulatory arrangements. There is no standard institutional solution.
- Adapt to fish redistribution with faster vessels, portable processing plants and other onshore infrastructure, and on-board processing.
- Construct and maintain appropriate infrastructure for storm forecasting, signaling systems, and safe refuges for dealing with possible rising sea level and increased storminess.
- Take advantage of reduced need for ice strengthening of vessels and infrastructures in a warmer climate, except perhaps for areas with increased icebergs.
- Foster interdisciplinary research, with scientists meeting periodically to exchange information on observations and research results, and meeting with managers to ensure the proper interpretation of results and the relevance of research.

- In cases of species collapse and obvious ecosystem disequilibrium, restock with ecologically sound species and strains as habitat changes. Great care is needed to avoid long-term ecological damage.
- Consider, cautiously, the use of hatcheries to enhance natural recruitment when climate causes stocks to fall below the ecosystem carrying capacity for a given species. Such enhancement might increase stock productivity (per unit area), reduce recruitment variability (e.g., Héral *et al*., 1989), and enable the colonization or recolonization of new areas (e.g., Peterman, 1991). Conversely, injudicious use may alter or impoverish the biodiversity and genetic pool of resources and possibly transmit parasites and diseases (Barg, 1992). Research on identifying warm-water species with wide temperature tolerances also could be useful.

16.3.2. Aquaculture

Economic development of coastal communities beyond capture fisheries to tourism and other activities has long been a goal in many areas. Development of aquaculture and tourism will make coastal communities better able to deal with uncertainties of climate change (Smit, 1993). In adapting to climate change, aquaculturists should consider the following:

- Warming will mean generally longer growing seasons and increased rates of biological processes—and often of production.
- Warming will require greater attention to possible oxygen depletion.
- In some areas, the species grown may have to shift to those more tolerant of warmer and perhaps less-oxygenated waters.
- Coastal culture facilities may need to consider the impacts of sea-level rise on facilities and the freeing of contaminants from nearby waste sites.
- Competing wild fisheries production (and indeed, agriculture) may not vary much at the world level, but there could be significant regional changes in quantity and species mix.
- Precipitation, freshwater flows, and lake levels will likely change. Strong regional variations are likely.
- Warming waters could introduce disease organisms or exotic or undesired species before compensating mechanisms or intervention strategies have become established.
- Less ice cover and thinner ice will generally mean less ice damage to facilities and a longer season for production and maintenance.
- Covering culture tanks, or keeping them indoors under controlled light, may be needed more often to protect larvae from solar UV-B.
- Several of the above and other factors, such as competing demand for coastal areas, may argue for technological intensification in ponds and noncoastal facilities.

16.3.3. Adaptation Constraints

Technology, trade, and industry change rapidly to take advantage of new situations and adapt to those that are adverse. The success of many entrepreneurs derives from their abilities to adapt rapidly to opportunities and dangers, but those adversely affected by climate change may not be in a position to take advantage of opportunities. Many fish stocks are of supranational scope, but institutions to deal with them are not or lack sufficient authority. Changes in fisheries institutions generally result from crises, yet impacts from a changing climate may be too gradual to trigger needed responses from these institutions—as evidenced by the failure of most governments to respond to the profound impact of the 1976–77 climate change event on Pacific fisheries over the last 20 years (Beamish, 1993). Nations that do not strongly depend on fisheries may react slowly. Also, negative actions such as polluting and overfishing add stress to fish stocks and may reduce society's options.

16.4. Research and Monitoring Needs

Information is most valuable if there are institutions and management mechanisms to use it. Research on improved mechanisms is needed so that fisheries can operate more efficiently with global warming as well as in the naturally varying climate of today. There is relatively little research underway on such mechanisms. While useful inferences can be made about global-change impacts on fisheries, GCMs are inadequate to forecast changes at the regional scale—and even more so at the smaller scales of the spawning and nursery areas that are critical in the relationships between environment and fish populations (Sinclair, 1988).

Knowledge of the reproductive strategies of many species and links between recruitment and environment is poor, but interest has been growing rapidly. Several international, broad-scale research programs are in place, some of which are aimed at providing a scientific basis and linkage to ecosystem sustainability programs (IOC, 1993; Sherman *et al*., 1992; Wu and Qiu, 1993; Mee, 1992). The growing partnership among funding agencies, marine ecologists, and socioeconomic interests marks an important step toward realization of the UNCED declaration aimed at reversing the declining condition of coastal ecosystems and enhancing the long-term sustainability of marine resources.

The following lists focus on items needed specifically because of climate change. Other types of research, which are prerequisites for dealing with such concerns but which support the day-to-day needs of fisheries managers or relate more to understanding how ecosystems function, are not included.

16.4.1. Resource Research

- Determine how fish adapt to natural extreme environmental changes or latitudinal transitions, how fishing affects their ability to survive unfavorable conditions, and how reproduction strategies and environments are linked. Link fishery ecology and regional climate models to enable broader projections of climate-change impacts and improve fishery management strategies. Both of these model types are in their infancy for application to fisheries and require considerable additional specificity, in addition to linking with other models.

- Implement regional and multinational systems to detect and monitor climate change and its impacts—building on and integrating existing research programs. Fish can be indicators of climate change and ecological status and trends (Sharp, 1991). Assemble baseline data now so comparisons can be made later (Sharp, 1989).

- Develop ecological models to assess multiple impacts of human activities. Separate appraisal of individual impacts is no longer sufficient.

- Assess the effect of accrued global changes by compiling and analyzing regional data sources—globally containing information on fisheries distributions and the associated environment—to detect consistent trends over the last century and determine how societies have dealt with these changes.

- Determine the fisheries most likely to be impacted, and develop adaptation strategies.

- Assess the potential leaching of toxic chemicals, viruses, and bacteria due to sea-level rise and how they might affect both fish and the seafood supply.

16.4.2. Institutional Research

- Determine institutional changes needed to deal with a changing climate. Such changes are likely the same ones needed for mastering overfishing and coping with the variability and uncertainty of present conditions. Improved institutions would probably reduce stock variability more than climate change would increase it.

- Study the recorded ability of societies—including preindustrial ones, where fisheries are important—to understand how they have adapted their activities when their resources are impacted by climate changes (Glantz and Feingold, 1990).

CONTENTS

EXECUTIVE SUMMARY

Within financial services, the property insurance industry is most likely to be directly affected by climate change, since it is already vulnerable to variability in extreme weather events. The cost of weather-related disasters to insurers has risen rapidly since 1960. For example, the annual insured cost of major windstorms worldwide increased progressively from $0.5 billion in the 1960s to more than $11 billion (constant 1990 dollars) in the early 1990s. This trend has led to restrictions in coverage or steep price increases. Where insurance is unavailable or unaffordable, there are consequences for other economic activities, as well as for consumers and government. New enterprises may not start without insurance. Banks may be exposed to losses where financial transactions are backed by property.

There are several reasons for the escalation in the cost of severe weather. Developed countries have become wealthier. Many more people now live in coastal areas with costly infrastructures. Personal goods and business processes are generally more vulnerable to water damage. The built environment also contributes through inappropriate or incorrect design and construction. The insurance industry has compounded matters by extending the basis of coverage. It is a common perception in the insurance industry that there is a trend toward an increased frequency and severity of extreme climate events. The meteorological literature fails to substantiate this in the context of long-term change, though there may have been a shift within the limits of natural variability.

There is medium confidence that climate change will adversely affect property insurance. More frequent intensive rain events and sea-level rise are material to both storm and flood damage. The climatological literature does not supply sufficient information about future storms in relation to population centers or "combined events," like windstorms associated with heavy rain and storm surges. This could critically alter the pattern of insurance claims. Further, the industry is vulnerable to shifts in the variability as well as the scale of extreme events, and this is still obscure. Meteorological records are too short to calculate return periods of extreme events under current or changing climate conditions. The property insurance sector is very interested in the probability of events two to three years ahead, rather than the timescales associated with climate change. Research on teleconnections where there is a substantial lag between the event and its precursor offers the possibility of improved forward planning for the industry.

Through its experience, the insurance sector can help authorities to improve the response to property damage from extreme events. Control of land use, particularly in floodplains and coastal zones, is essential to prevent values at risk increasing. Information about hazards can be mapped and appropriate physical protections put in place. Necessary improvements to construction design and processes can be identified and incorporated into new building and, if possible, also retrofitted. Many countries now accept that it is not appropriate to account for insurance against extreme events on an annual basis, since funds need to be accumulated over a long period to meet infrequent but severe losses. Where it is not possible to provide private insurance, the industry can still assist with disaster-recovery services. This generally will prove to be a very efficient method compared to other *ad hoc* approaches.

The implications of climate change for financial services outside property insurance cannot be stated with any confidence. Few institutions, if any, were aware of the potential implications when this assessment began. Yet changes in human health may affect the life insurance and pension industries. Banking may be vulnerable to repercussions from property damage. Returns on long-term investments and capital projects may be affected by mitigation measures that alter the economics of whole industries—for example, shifting from carbon fuels to renewable resources. The economies of selected regions, such as coastal zones and islands, may be disadvantaged. Climate change might affect client behavior, or even alter the available portfolio of clients through the changing economics of different industries. Outsiders will be keen to know how the financial sector deploys its funds in the light of climate change. There is a need for increased recognition by the financial sector that climate change is an issue that could affect its future at the national and international level. This could require institutional change.

17.1. Introduction

This chapter commences with a brief overview of financial services. Property insurance is reviewed in more detail as the financial area most vulnerable to direct climatic effects, through multiple claims arising from extreme weather events. The study considers which extreme events are important for property and our limited knowledge of their past and future patterns. Because the future position is unclear, and the previous Assessment Report did not deal extensively with financial services, Section 17.5 discusses the recent upward trend in the cost of extreme events and the criticality of such shocks to the financial system. The techniques property insurers use to adapt to changes in risk also are described, before the chapter looks at how climate change will affect other financial services. Most likely it will be indirectly through the measures taken by other industries or policymakers to adapt to, or mitigate, climate change. Finally, the chapter summarizes cross-cutting implications for policymakers and indicates ways to make future assessments more effective. To the outsider, the discussion may seem biased toward property insurance. This reflects the reality of the direct impacts of climate and the available literature. The indirect impact of climate change outside property insurance is unclear and largely unresearched.

17.2. Financial Services

This section deals with external factors that affect the whole sector. The financial services sector falls into two broad clusters—insurance and banking, which will be described in Sections 17.3 and 17.7, respectively. It has evolved into a highly complex system that recycles "money" among other parts of the economy, including final consumption and capital investment. Governments participate to a varying degree through public debt issues and other investments, and the process operates on timescales from days to decades. The definition used here excludes foreign aid. Clearly, many countries have significant noncash economies; the discussion excludes those activities. Many of the costs of extreme events recorded by the financial sector reflect impacts in other sectors. Although this is in a sense "double-counting," the financial sector transmits these effects to other sectors and may indeed amplify them if it is unable to fulfill other services through lack of capital.

Projecting the impact of climate change strictly requires a view of future society at the relevant horizon. Given the unforeseen changes over the past 100 years, clearly such an attempt for the next 100 years would be highly inaccurate. The alternative adopted here is to identify current trends that may be relevant, without drawing up a coherent "worldview." Technological advances are accelerating, particularly in transportation, telecommunications, and information technology. This is leading to the globalization of society (Kennedy, 1993). Systems are becoming more complex and interconnected, with increases in the scale of operation and associated risk (Giarini and Stahel, 1994). Society is increasingly vulnerable to disruption because consumers are living on credit and businesses are

adopting "just in time" techniques. As society becomes more dependent on electricity, any supply disruptions from extreme events become potentially more catastrophic. Economic development has been rapid, bringing with it wealth but also pollution. In many cases, development has occurred in vulnerable locations (see Chapter 12). With the progression from primary to tertiary activities, the impact of climate change on many areas is likely to be indirect and thus more difficult to judge, particularly because social change also has been rapid. Population has burgeoned in many countries, and standards of behavior have altered regarding fundamental issues like the family, crime, and work (Kennedy, 1993). Consumerism and environmentalism have developed strongly as education has spread. Much financial services activity is "driven" by the private automobile, financing its purchase and use. Therefore, mitigating climate change by altering auto use would affect financial services. On the other hand, current trends in auto use cannot continue without putting enormous stress on society (Northcott, 1991). The answer may be to exploit telecommunications as a substitute, but this is not certain.

Trends to deregulate financial services nationally and internationally are putting traditional distribution methods under pressure. Tele-selling will be an increasingly important influence. It is likely that there will be fewer independent operators, often integrated either horizontally or vertically to provide benefits of scale or synergy (Swiss Re, 1992; Muth, 1993). It is possible that clients will key their own information (e.g., through the Internet). Data retrieval will become easier as paper files disappear. Information will become critical for management purposes, not just for recordkeeping. More powerful computers will facilitate the analysis of internal and external databases for sales and underwriting (Dlugolecki, 1995).

Many economies have been plagued by enormous surges in property values, followed by stagnation or even collapse. This makes it difficult to assess assets and liabilities. A second factor that complicates the valuation of property is the generally high rate of inflation between 1960 and 1990. A further difficulty is fluctuating exchange rates in economies with unstable currencies. Such instabilities have led to high interest rates and periods of rapid investment gains. These have diverted attention to "cash flow" strategies (Swiss Re, 1991) and also have created the possibility of insolvency through poor investments (Denlea, 1994). Another area of pressure on financial services is the need to fund environmental claims—seen at its most energetic in the United States, where the Superfund legislation has created huge liabilities for the property-casualty industry (Nutter, 1994). The banking industry also is threatened by "lender liability" as a consequence of repossessing or taking control of polluted land or a polluting operation (Vaughan, 1994).

17.3. The Property Insurance Market

The insurance industry serves to protect other activities from the financial consequences of unexpected events, including natural hazards; therefore, it is directly exposed to climate

change (Friedman, 1989; Roberts, 1990). Since 1987, fifteen extreme weather events have cost property insurers and reinsurers $50 billion (Leggett, 1994). In view of these impacts, Sections 17.3 through 17.6 consider property insurance and associated "interruption" coverage. "Property" is defined as buildings and their contents, business and personal goods, and plant and infrastructure; conveyances, livestock, crops, and humans are excluded.

The basic function of insurance is to transfer financial risk from an individual to a group; what is a disaster to the individual can often be managed by larger numbers. Typically, the individual proposes his risk to the underwriter, often with the assistance of an intermediary or broker. In some cases, the risk must be evaluated in great detail, and the insurer may stipulate certain actions (risk management) to reduce the likelihood and scope of potential loss. Finally, the insurer offers specific terms in a policy. The most important terms of the contract involve the price, or premium; any exclusions of events or property not covered by the contract; and limitations on the amount to be paid in a claim. Contracts of insurance are usually renewable. Usually the contract lasts for twelve months and is renegotiated with a

view to changes in circumstances, particularly claims experience. Following acceptance of the risk, the insurer must then decide whether to share it with reinsurers. The reinsurer may further spread the risk by "retrocession" to other reinsurers, but this has become less common. The other key activity is settling claims. After a loss, the policyholder reports it to his insurer, who will decide how much investigation is necessary. A loss adjuster is often retained for this purpose. Claims recovery often provides the occasion to implement risk-improvement measures. Policies have become more comprehensive over time, culminating in "all risks" coverage, where the policy stipulates what is excluded. Other significant changes have been to allow for inflation in property values by indexation, and to set aside the effect of depreciation by using replacement values. Finally, policies often allow for economic costs such as alternative accommodation if a claim results in temporary relocation.

17.3.1. Scale of Activities

The scale of the industry is measured either by premiums written or capital available. In 1992, the worldwide non-life insurance

---

Box 17-1. Examples of Property Insurance and Weather Cover

Property insurance is used to varying extents by different nations. Often, consumers are reluctant to purchase sufficient coverage. Lack of capital, culture, and consumer attitude to risk play their parts. In other cases, insurers are unwilling to provide affordable coverage because of an unduly high ratio of risk to return on capital. Lack of flood coverage is the most common absence of insurance. A selection of schemes for natural disasters is discussed briefly below.

Japan
Windstorm—Full coverage became generally available in 1984, with significant deductibles. In 1991, Typhoon Mireille consumed half of the tax-deductible catastrophe reserves insurers had accumulated (Horichi, 1993).

United Kingdom
Flood and subsidence—Coverage for these perils was added to virtually all domestic building policies in the 1960s and 1970s, respectively, at uniform rates. The market is now moving toward risk-based rating (Dlugolecki *et al*., 1994).

Netherlands
Flood risk—The government accepts responsibility for physical protection. Insurance against flood is not available.

United States
National Flood Insurance Program (NFIP)—Coverage is not privately available. Communities must qualify for the NFIP by undertaking a risk assessment and reduction program (FEMA, 1992a). Problems often arise with determining whether water damage stems from rain or storm surge (Kunreuther *et al*., 1993).

France
Natural catastrophe—A 1982 French law attached natural catastrophe to all property policies at a centrally determined set of surcharges on the basic premium. Claims are made only if the authorities declare a disaster. In 1990, the scheme was revised to exclude storm, but many practical problems remain, such as the difficulties of separating storm and flood damage and the issue of uninsured property owners (Florin, 1990).

Caribbean
As a result of heavy hurricane damage in the 1980s and 1990s, many insurers and reinsurers withdrew from the area. Remaining reinsurers insisted on separate, increased rates for windstorm, introduction of the "average" clause to eliminate the effects of underinsurance, and high deductibles for catastrophe losses (Murray, 1993; Saunders, 1993).

industry generated premiums of $700 billion. The United States accounts for 44% of the total, the European Union (EU) 29% and Japan 12%, leaving the rest of the world with 15% (Swiss Re, 1994b). These sums meet all claims: liability, accidental damage, fire, and natural hazards, as well as administration costs. Figures on capital are not readily available, but a commercial insurer would generally maintain capital at 40–50% of premiums, giving an equivalent of $280 to $350 billion. This capital provides a reserve to meet all unexpected costs, not just those from extreme weather events, and it is usually subject to a legal minimum requirement (e.g., 17% of premium in the EU). It is reinforced by reinsurers' capacity, but again the capital is required for various classes of claims. The scale of the commercial non-life reinsurance industry is hard to estimate. Based on estimates by Foreman (1989) for the United States, the net premium volume is probably about $100 billion, with capital reserves about the same size. Two-thirds of the capital is required to fund non-property business (Laderman, 1993), leaving approximately $35 billion for natural catastrophes.

17.3.2. Methods of Risk Assessment

Natural hazards are dangerous because of the likelihood of an accumulation of loss through damage to many individual properties (Nierhaus, 1986). Underwriters seek to estimate the maximum probable loss. In fact, any level of loss must have a finite chance of being exceeded; Tiedemann (1991) points out that under certain conditions, a 90% probability of being free from an event for 100 years implies that the event occurs once in 1,000 years. Four methods of a risk assessment are described by Friedman (1984): conventional pricing, two-tier pricing, stage-damage, and simulation.

Conventional pricing is experience-based but with a short "memory," giving a dubious allowance for disasters. Two-tier pricing has a first element based on experience, but also a second element specifically for disasters, set notionally. For stage-damage, the property at hazard is characterized by its key dimensions and vulnerability to different levels of event. Detailed knowledge of the local terrain is then used to model the likely impact on the property of a specific event. In simulation, the portfolio of property is treated at an aggregate level, and the likely damage is assessed by evaluating the damage over a large number of extreme events intended to be typical of the long-run distribution of severity and frequency. This approach overcomes two problems: first, that there are not many catastrophe events in practice, and second, that historic damage reflects very different portfolios (Clark, 1986). The third and fourth methods require considerable data. Topography can affect the damage potential by more than 100% (Georgiou, 1989). Other difficulties are that it may not be practical to keep a schedule of property; losses to production may be caused by events elsewhere; and one "event" may strike several "target" locations (Meek and Tattersall, 1989).

Two other methods are event prediction and parallelisms. As scientific knowledge grows about the conditions that produce hurricanes and other extremes—often months ahead of their occurrence—it is becoming possible to use specific probabilities rather than generalized ones as in simulation (North Atlantic storms: Tinsley, 1988; hurricanes: Clark, 1992; Landsea *et al.*, 1994). In fact, more and more disturbances can be associated with the El Niño Southern Oscillation (ENSO) phenomenon. Alternatively, where data on extremes is lacking, similar conditions may generate a similar distribution of extreme to normal frequency/severity, as for rivers (Meigh *et al.*, 1993).

There now are many applications of Friedman's techniques: storm surge (Stakhiv and Vallianos, 1993), flood (Smith, 1991), and European storms (Schraft *et al.*, 1993). The insurer can study the potential effect of historic events on today's exposure, model hypothetical events, assess the expected cost of natural hazards for a portfolio, and estimate the probability of exceeding some loss level. The financial effects of deductibles or reinsurance can be measured (Boissonade and Dong, 1993). An Applied Insurance Research study of hurricanes gave $53 billion for a class 5 hurricane hitting Miami and $52 billion for a class 4 hitting New York (IRC, 1995). The expected severity of the hazard often is codified by zoning territory to control the amount of risk in any event (Nierhaus, 1986). The CRESTA (Catastrophe Risk Evaluating and Standardized Target Accumulations) system for earthquakes was invented by reinsurers (Foreman, 1989). A multi-peril approach for Australia uses 52 zones for cyclone, thunderstorm, wildfire, and earthquake (Flitcroft, 1989).

17.3.3. Socioeconomic Factors

World population is increasingly concentrated in urban areas, coastal regions, and river valleys (Marco and Cayuela, 1992). The concentration of property in such areas exposes insurers to potentially large losses from extreme events. Already, two-thirds of the world population live within 60 km of the coast; this is expected to rise to 75% by 2010 (IPCC, 1994). The total amount of property assets is not well recorded. Hohmeyer and Gartner (1992) updated a 1971 estimate to give $22 trillion, but, allowing for economic growth, this must be at least $50 trillion by now. In 1988, insured property values were $2 trillion on the Gulf and Atlantic coasts of the United States (IRC, 1995). Most of the insured cost of storms relates to domestic property. This is explained by the sector's greater size and the greater likelihood that industry and government will self-insure their risks from weather. Prosperity has resulted in an increasing stock of personal property, often vulnerable to water, salt, and smoke damage. Parallel changes have occurred in commercial/industrial properties. Changes in organization and practice, and the increased significance of services like tourism, make interruption to business from extreme events more important. See Chapters 11 and 12 for more detail.

Whenever a major flood or storm occurs and householders are uninsured, political pressures build up. Regulators are faced with irreconcilable duties: to make insurance affordable but also available. If premium levels are held down, an influx of

claims from high-hazard policies may make the insurer insolvent (Denlea, 1994). A similar dichotomy is evident in the taxation treatment of catastrophe-prone business. The noncatastrophe years are milked for tax revenue, as opposed to allowing the transfer of "profits" to capital reserves (ABI, 1993). In recent years, media attention has highlighted insurance issues (Winters, 1993). Insurers therefore have been forced to settle claims with a minimum of investigation. Independent research shows that many claims are now either exaggerated or totally false (Shearn, 1994).

17.4. Extreme Events and Property Insurance

Severe events are the source of the greatest damage (Olsthoorn and Tol, 1993). For example, floods with a return period greater than 100 years cause more than 50% of the property damage arising from all floods (Smith, 1991). The following climate extremes are of concern to the industry:

River basin and coastal floods: What constitutes a serious flood is in part culture-dependent (Gardiner, 1992). Marco (1992) states that 0.3 m is a "small disturbance," with 1 m causing "a major disaster." The speed of water movement is also important (Smith, 1991).

Drought: The impacts are direct on harvests (which may be insured, and form the basis for futures trading) and indirect through wildfire or building subsidence due to excessive extraction of groundwater (Hadfield, 1994) or drying clay soils (Freeman, 1992).

Windstorm: Maximum gust and storm duration are both important (Schraft *et al.*, 1993), as are gustiness (Muir-Wood, 1993) and the location of the storm track in relation to population centers (Swiss Re, 1994a). A critical determinant of losses is the nonlinear relationship of windspeed to damage (Munich Re, 1993; Schraft *et al.*, 1993). Figure 17-1 shows this for the October 1987 storm that devastated southeast England (Dlugolecki, 1992). Because there is a limit to the damage that can be suffered, the full response curve is sigmoid. Hurricanes produce much higher damage because they are more intense and often accompanied by storm surges, and standards of building control may be poor. "Rainy" storms are more costly than "dry" storms (Bryant, 1991). This may mean an increased storm cost in the future because the atmosphere will generally be more water-laden (see Chapter 6, *Climate Models—Projections of Future Climate*, in the IPCC Working Group I volume). Bryant (1991) also reports the possibility that cyclones can trigger earthquakes.

Convective events and precipitation extremes: Tornadoes, hailstorms, and thunderstorms are expensive despite their localized nature (Munich Re, 1984; Staveley, 1991). Heavy rainfall events can lead to landslides (Ahmad, 1991; Manning *et al.*, 1992).

Temperature extremes: Low temperatures can cause significant property damage due to burst pipes and subsequent escape of water. High- and low-temperature extremes can reduce agricultural and industrial production (Palutikof, 1983) and increase mortality rates.

17.4.1. Present-Day Trends in Extremes

Lengthy base periods and a stable climate are essential to assess return periods (Knox, 1993; Tol, 1993). Reilly (1984) suggests that using 30 years' data could underestimate the true risk by 50%. Marco (1992) notes that current data may not be adequate to assess 100-year flood levels, yet the latter is the design level used for the U.S. Flood Program (with a second, 500-year level). Return periods often are reevaluated in the light of new extremes (Wilkinson and Law, 1990; Tooley, 1992; Anderson and Black, 1993). Attempts to develop long climate time series can be beset by inhomogeneities in the underlying data (von Storch *et al.*, 1993a). The impact of what may be termed "combined events" is important for the industry. Windstorm damage will be greatly increased if there is associated heavy rain or a storm surge (Englefield *et al.*, 1990; Davis and Dolan, 1993). The need for appropriate information has led some insurers to seek solutions through in-house research (Munich Re, 1990, 1993).

There is a large literature on present-day trends in extremes, which is thoroughly reviewed in Chapter 3, *Observed Climate Variability and Change*, of the IPCC Working Group I volume.
Figure 17-1: Storm cost vs. windspeed (October 1987). Mean damage ratio is based on Association of British Insurers data at postcode-district level (claims cost as a ratio of total value of insured property) for domestic buildings. Windspeed is interpolated from maps in Buller (1988). Each observation represents a postcode sector.

Just as climate varies regionally, we must expect any trends toward changes, or variability, in climate also to vary regionally (Jones and Briffa, 1992). One of the best-studied areas is North Atlantic storms. A study of the literature indicates some of the problems in attempting to determine whether trends are present. Lamb (1991) and Diaz *et al*. (1992) compiled long series of storm and wind records, respectively, but inhomogeneities in data collection are obvious or have been detected (Isemer, 1992). In the absence of reliable long-term records of windspeeds, one approach is to use a proxy variable with a long homogeneous record—for example, trends in the geostrophic wind calculated from mean sea-level pressure data (Palutikof *et al*., 1992; Schmidt and von Storch, 1993; von Storch *et al*., 1993b). These authors failed to find any trend that could not be explained by data inhomogeneities. A related insurance study suggests no trend in UK storminess over 60 years (Christofides *et al*., 1992), but other studies show a correlation between winter storms and temperature (Doberitz, 1991; Dlugolecki, 1992) or a tendency to deeper depressions in the Atlantic in this century (Schinke, 1992). Again, it has been suggested that this is due to inhomogeneities in compiling weather maps (Schmidt and von Storch, 1993).

17.4.2. *Appropriate Information on Future Climate Change and Extreme Events*

The recognized source of information on future climate change is the general circulation model, or GCM (for a review, see Cohen, 1990; Giorgi and Mearns, 1991). Improvements in GCMs in the near future can be expected (e.g., Roeckner *et al*., 1992), but at present GCMs are of limited use to the financial sector, for the following reasons:

- The length of model run is generally too short for statistical analysis of extreme events. Longer model runs are becoming available (e.g., Manabe and Stouffer, 1993, 1994).
- For analysis of extreme events, model output may be required at the daily timescale. Validation of variables (e.g., daily temperature) generally demonstrates inadequacies (e.g., Palutikof *et al*., 1995). Statistical downscaling methods offer opportunities to overcome this problem (e.g., Karl *et al*., 1990; Winkler *et al*., 1995; Zorita *et al*., 1995).
- Current models cannot generate sufficient spatial detail. Higher-resolution output from nested Limited Area Models (e.g., Giorgi *et al*., 1994) needs much more computing.
- There may be a lack of consistency in model results—for example, for tropical and mid-latitude storms (Hewitson and Crane, 1992a, 1992b; von Storch *et al*., 1993a; von Storch, 1994).

Most literature on climate change at the regional level concentrates on changes in the mean climate and on temperature and precipitation (e.g., Grotch and MacCracken, 1991; Boer *et al*., 1992; Palutikof *et al*., 1992). This is of limited use—first, because it is extreme events that have the greater implications for insurance; second, because changes in variables such as

windspeed and soil moisture content may be as significant as changes in temperature and precipitation. Even if the mean of a climate variable changes and the variance remains constant, the impact on the frequency of occurrence of extreme events would be nonlinear (Mearns *et al*., 1984; Parry and Carter, 1985; Wigley, 1985). We cannot assume that the variance will remain the same in a warmer world. Katz and Brown (1992) have shown that the frequency of extreme events is more dependent on changes in the variance than in the mean.

Tropical and mid-latitude storms: GCM results indicate conflicting trends in tropical cyclone frequency and severity. Whereas Haarsma *et al*. (1993) found an increase in the number of tropical storms, Bengtsson *et al*. (1994a, 1994b) found a decrease. Similarly, there is a lack of consensus regarding future trends in mid-latitude storms (see Gates *et al*., 1992; Hall *et al*., 1994; Koenig *et al*., 1993).

Convective events and precipitation extremes: Experiments with GCMs indicate a tendency for increased convective activity in a high-CO_2 world (Hansen *et al*., 1989; Noda and Tokioka, 1989). This implies an increase in the number of more intense rainstorms and hence in runoff (Mitchell *et al*., 1990; Gordon *et al*., 1992; Whetton *et al*., 1993). An increased frequency of intense rainstorms could lead, in turn, to more landslides.

Droughts: Increases in potential evapotranspiration due to higher temperatures could increase drought potential even in regions where total rainfall increases (Whetton *et al*., 1993). Several studies project droughtiness in populated areas (Rind *et al*., 1990: United States; Whetton *et al*., 1993: South Australia; Palutikof *et al*., 1994: Mediterranean region).

Temperature extremes: GCM-based regional studies indicate that there will be an increase in high-temperature extremes (Whetton *et al*., 1993: Australia) and a decrease in low-temperature extremes (Wilson and Mitchell, 1987: Europe).

Coastal flooding: Coastal flooding may be expected to become more common as sea level rises. However, sea level will not rise uniformly around the world (Mikolajewicz *et al*., 1990; Gregory, 1993; Chapter 7, *Changes in Sea Level*, of the IPCC Working Group I volume). Catastrophic incursions are generally the result of a combined event, such as a high tide associated with onshore winds. In Working Group I's Chapter 7, however, authors indicate that they expect little change in tide and surge as a result of sea-level rise.

17.5. Impact of Extreme Events on Property Insurance

The impact of an extreme event varies depending on the type of insurance system in place and socioeconomic and technological factors. Damage often is uninsured. The most expensive claims have arisen from cyclonic storms. Generally, poorer countries suffer more from the effects of extreme events because their economies are based on primary, weather-vulnerable activities. Less than 0.1% of gross domestic product (GDP) is "burnt up" by catastrophes in United States

(Anderson, 1991), compared to 49% in Tanzania (Nanjira, 1991). Damage to infrastructure may significantly delay recovery (Marco and Cayuela, 1992). Repair costs are often surprisingly high, since the owners may not be in residence; building materials may be in short supply, giving rise to sharp inflationary rises in repair costs; and stricter standards may be enforced (Insurance Services Office, 1994). Increasingly, claims arise indirectly from the disruption caused (business interruption) as well as the direct property damage. Much equipment is vulnerable to water, salt, or smoke damage, and often stocks of goods are minimal, so production quickly ceases (Berz, 1988; Horichi, 1993). Services such as tourism are also prone to interruption from denial of access or from consumer anxiety.

Reinsurers have noted a fourfold increase in disasters since the 1960s (Berz and Conrad, 1993). This is not due merely to better recording, because the major disasters—which account for 90% of the losses and would always be recorded—have increased just as quickly (Swiss Re, 1994a). Much of the rise is due to socioeconomic factors, but many insurers feel that the frequency of extreme events also has increased (Mercantile and General Re, 1992; Berz and Conrad, 1993). At present, the cost of insured catastrophes amounts to about 2.5% of global non-life insurance premiums (Jakobi, 1994), but in Australia it reaches 12%, without allowing for associated administration (Brigstock and Minty, 1993). The UK used to be considered relatively hazard-free. Since 1987, the cost of a single day's storm has twice exceeded £1 billion. Subsidence losses exceeded £500 million in 1990 and 1991, from a base of under £100 million in previous years (Dlugolecki *et al.*, 1995).

17.5.1.   International Reinsurers and Storms

Coverage against windstorm is provided in most countries. They cause several types of harm to socioeconomic systems— property damage, lost production, macroeconomic disruption, and personal death, injury, or stress (Anderson, 1991; Smith, 1991). Table 17-1 contains information on the impact of major windstorms worldwide since 1960. To allow a valid comparison for the partial decade of the 1990s, the figures have been expressed as an annual rate in constant values. There is a very clear upward trend in the number and overall cost. In addition,

Table 17-1: *Major windstorms^a worldwide: Annual impact 1960–1992.*

	1960s	1970s	1980s	1990s
Number	0.8	1.3	2.9	5.0
Total Damage ($B)	2.0	2.9	3.4	20.2
Insured Cost ($B)	0.5	0.8	1.7	11.3

Notes: Valued at 1990 prices; data from Munich Re & Swiss Re; 1990s include only 1990, 1991, and 1992.
^a A major windstorm is defined as one costing more than $500M in total damage.

Table 17-2: *"Billion dollar" storms.*

Year	Event	Insured Cost ($B)
1987	"Hurricane" in SE England/NW France	2.5
1988	Hurricane Gilbert in Jamaica/Mexico	0.8
1989	Hurricane Hugo in Puerto Rico/S. Carolina	5.8
1990	European Storms—Four	10.4
1991	Typhoon Mireille in Japan	4.8
1992	Hurricane Andrew in Florida	16.5
1993	"Storm of the Century" in Eastern USA	1.7
1995	Hailstorms in Texas	1.1
1995	Hurricane Opal in Southern USA	2.1

Sources: Munich Re, 1990; Leggett, 1994; PCS, 1995.

the proportion of insured damage has risen to more than 50% in the 1990s.

Table 17-2 shows insurers had at least one "billion dollar" storm event every year from 1987 to 1993. With such an unexpectedly high frequency, some local insurance companies collapsed, and the international reinsurance market went into shock. These catastrophe losses were one of the reasons for the crisis at Lloyd's, where capacity for all types of insurance fell from £11.4 billion to £8.9 billion between 1991 and 1993 (Tillinghast, 1994). Following the initial reduction in reinsurance availability, there has been recovery as new capital takes advantage of the consequent rise in premium rates, often in offshore tax havens (Hindle, 1993). However, this only has happened by trebling the insurer's retention and increasing the reinsurance charge by a factor of four or five (Laderman, 1993). Reinsurance contracts now have far more restrictive conditions (Powers and Hearn, 1993; Jakobi, 1994). Some hazard-prone regions such as the Caribbean and Pacific now find insurance very expensive or even impossible to obtain (Murray, 1993).

17.5.2.   Operational Repercussions

The financial insurance market itself may be disrupted by the effects of storm or flood because of serious failures of power and communications. Companies are tending to focus operations at fewer sites; if any single site is affected, the total impact will be greater. Insurers and loss adjusters may find the increased volume of claims difficult to handle because they probably will be operating on much tighter margins, with fewer staff in reserve (Dlugolecki *et al.*, 1994).

17.5.3.   Criticality of Events

Given that it is never possible to guarantee security even with a known loss distribution, the pressure of a worsening loss distribution has serious consequences (Brigstock and Minty, 1993). In such circumstances, the large thrive and the small

---

Box 17-2. Jamaica and Hurricane Gilbert

On 12 September 1988, Hurricane Gilbert struck Jamaica with winds of 220 kph but no real storm surge. Total losses were about $1 billion, equivalent to about one-third of the annual gross national product (GNP). More than 40% of the housing stock was destroyed, with heavy losses in agriculture, industry, and public services (Siegel and Witham, 1991). Indirect losses were estimated to be up to twice the direct damage, owing to lost production and reduced tourism. The recovery process was hampered by lack of records (Siegel and Witham, 1991), damage to public infrastructure (Alexander, 1993), and scarcity of many goods. Clement (1990) noted that the damage was exacerbated by poor construction practice and breakdown of public order.

The financial consequences were serious. Inflation doubled, and the trade deficit widened from 7% to 39% of GDP (Commonwealth Secretariat, 1991). The currency was devalued (Clement, 1990). Insurance records indicate that 8% of the insured values were destroyed—by no means extreme compared to the 30% caused by Hurricane Iniki in the Pacific (Murray, 1993) but far more extreme than European values. There was a painful readjustment in premium levels, contract terms, and risk-management requirements (Murray, 1993; Saunders, 1993; Nesbeth, 1994), but only when Hurricane Hugo emphasized the loss potential. Jamaica, like the entire Hurricane Belt, had been fortunate for many years; the average recurrence since 1881 for hurricanes had been 5.1 years (Siegel and Witham, 1991).

The Commonwealth Secretariat (1991) noted the benefits of insurance to industry: 90% of plant and 75% of stock was insured. Owing to the heavy use of international reinsurance, only 2% of the insured damage was paid by the local market. This event is typical of the threat to economic development from cyclones (Granger, 1989). Even in Mexico it took twenty months to repair structural damage, with serious consequences for tourism (Clark, 1991b).

---

survive: The proportion of the U.S. reinsurance market held by the top ten companies rose from 44% in 1985 to 57% in 1992. Clearly, each country will have its own "critical event." At one time it was thought that two hurricane "hits" of $7 billion in one season would be critical to the insurance industry (AIRAC, 1986). However, the industry coped with Hurricane Andrew ($16 billion insured damage, $30 billion in total), although seven companies became insolvent and forty-four sought to reduce their exposure afterward (Insurance Services Office, 1994). Exercises to assess the impact of a major earthquake on the U.S. insurance industry provide some feel for the impact of a major hurricane. Doherty (1993) felt that a $50 billion event would seriously weaken the U.S. insurance industry with its capital base of about $160 billion and leave property owners less well-protected financially. A second study found that the system should be able to cope with an event up to $100 billion because of the immense size of the American economy (GDP in 1990 was $5.5 trillion) (Cochrane, 1993). This study assumed that new capital would enter the industry. It neglected the problems of regional blight and nonavailability of insurance, which would certainly follow. Potentially, as insurers liquidate investments to raise cash, there would be some impact on financial markets, despite reconstruction (Hofmann, 1990).

The global insurance system, of course, will be able to cope with a larger event. However, the global reinsurance industry is much smaller than the direct insurance industry and can only survive by carefully controlling its exposure to any one event or territory. This makes it likely that government would be required to back any scheme for truly catastrophic losses (Gallardo, 1984; Nutter, 1994). However, Cochrane (1993) disagrees, saying that public borrowing is now at its limit and that the emphasis should be on loss prevention. It seems most

likely that multiple events would be the cause of a global failure, since the industry has proven fairly robust in response to single catastrophes. Flohn (1981) notes such occurrences in historic times, particularly when climatic change is occurring.

17.6.   Adaptation to Climate Change by Property Insurers

Traditionally, insurers have dealt with changes in risk in four ways: restricting coverage so that the balance of risk-sharing shifts toward the insured; transferring risk; physical risk management (before and after the event); or raising premiums. However, in view of the increasing costs of weather claims, insurers now are considering a more fundamental approach—involving better ways of creating the funds required for irregular disasters, education of the affected parties, and cooperation with other functional or regulatory bodies in the property "system" (Horichi, 1993; Paish, 1993; Berz, 1994). Lack of information about extreme events hampers such activity and makes insurers wary of committing their capital.

17.6.1.   *Restricted Insurance Coverage*

Increasing the contribution from the insured encourages better risk management, with consequent administrative savings. This may overcome any "moral hazard" through being insured or defended (Grose, 1992). The drawback could be in fraudulently inflated claims and a potential reduction in the fund from which to meet other claims, should the rating levels be significantly lowered. The obvious method would be to impose significant deductibles (Munich Re, 1993). Alternatives would be the increased use of coinsurance, whereby policyholders share

each loss on a predetermined percentage, and reduced upper limits of liability. "Reinstatement as new" coverage needs to be questioned because settlement net of depreciation would more fairly distribute the losses; most consumers must bear depreciation themselves (Shearn, 1994). High-risk items such as satellite dishes could be excluded.

Theoretical studies of risk transfer have identified several conditions that might make insurance nonviable (Berliner and Buhlman, 1986; Peele, 1988; Henri, 1991). These include: inadequate spread of risk, undue influence on the event by the policyholder, insufficient knowledge of the likely loss distribution, inability to define when a loss has occurred and quantify it, and, finally, premiums that are not affordable. The most common areas of nonparticipation are flood damage and damage to growing crops. A change in perception of the risk can lead to withdrawal of participation—for example, following storms in Fiji, Jamaica, and Florida (Clement, 1990; Anderson, 1991; Murray, 1993).

If insurers collectively withdrew coverage entirely for some peril, this would affect financiers, occupiers, the construction industry, and local and national government. New enterprises might never start without being able to protect their capital through insurance. Recovery following a disaster also would be problematic without the influx of insurance funds (IRC, 1995). The authorities might react as happened in Hawaii and Florida in 1993 (Insurance Services Office, 1994) to enforce participation by insurers. Insurers might still participate in the administration of a funding scheme, without bearing the risk (e.g., NFIP in the United States).

Government may decide to become directly involved in important areas such as flood or agricultural insurance where commercial insurers are unwilling (Hueth and Furtan, 1994; Ericksen, 1995). In Bangladesh, farmers require income replacement and recapitalizing, and moneylenders charge high interest rates (Hodgson and Whaites, 1993). Government can also assist with grants and subsidies, and so forth (Foster, 1984). This has several advantages: greater financial strength, less requirement for supervision, mandatory powers to enforce compliance, and recognition of social and international issues such as income distribution and inward investment. There also can be significant disadvantages. Few countries can bear the cost of disaster alone (Mead, 1993). Many losses (e.g., tourism in East Africa; Nanjira, 1991) would not be eligible. Funds may be diverted from more desirable policies. It may encourage hazardous activities, be cumbersome to administer, and undermine the system for standard risks (Porter, 1994). Commercial insurers can help to keep such systems efficient (Dlugolecki, 1993).

Funding can be by disaster relief. This approach is limited in scope, slow to react, undignified, and fraught with abuse. If too generous, it will act as a disincentive to insurance. The goal should be to ensure that insurance coverage is affordable for property owners. Certain propertyowners may decide they have sufficient resources to deal with the hazards themselves (e.g., government and big business) and choose not to insure on a rational basis (Geneva Association, 1992).

17.6.2. Transfer of Risk

Insurers have traditionally shared major exposures to loss with reinsurers. The solvency of the reinsurer is critical (Porro, 1984). Reinsurers now assess whether a given territory will be able to "pay back" its losses within, say, 10 years and carefully control their exposure (Crowley, 1991). Clearly therefore, insurers can only insure great natural perils if they are themselves financially strong, they charge an economic rate to reflect the underlying risk and the partial availability of reinsurance, and they underwrite the risks by acquiring sufficient information and adapting the contract terms to fit the degree of hazard.

A new approach is "catastrophe futures"—contracts issued quarterly at a specific price and redeemable at a price based

---

Box 17-3. Example of Criticality and Reinsurance

Suppose an insurer covers a portfolio of one million domestic buildings (with contents) valued in total at $100 billion. At an average rate of $0.3%, this gives an annual total premium of $300 million. The rating allows for a catastrophe every 10 years at a claims cost of $100 million, or $10 million per year. The insurer holds free reserves equal to 40% of the premium, equivalent to $120 million. Clearly, the fund can cope with the average catastrophe cost of $10 million per year, but it would be virtually wiped out in the year of the disaster. This is why reinsurance is necessary.

In 1987, the typical excess-of-loss reinsurance protection was equivalent to 30% of the premium at risk (Laderman, 1993). In the above example, we assume that $90 million of the risk was transferred [remember, the risk is actually the value of the property at risk (i.e., $100 billion)]. For this the insurer would pay a reinsurance premium somewhat higher than the annualized catastrophe cost, say $12 million. In the year of a catastrophe, he would now suffer $10 million catastrophe (= $100–90 million), which his resources can accommodate. Clearly, if catastrophes become more frequent, the reinsurer suffers most. However, if catastrophes become larger, the insurer suffers because he faces all the incremental claims above the reinsurer's cutoff point. In fact by 1993, the insurer would have raised his protection to $200 million, but with a deductible of $30 million. At the same time, the reinsurer would have increased his charge to perhaps $75 million (Laderman, 1993)!

upon the actual cost of future catastrophe claims (Bannister, 1993; UNCTAD, 1994). The benefits to the risk bearers are obvious, but so far this approach has not taken off because it lacks an obvious seller to match the buyer (insurer) (Boose and Graham, 1993). Also, insurance regulators need to recognize these contracts as admissible assets (ISO, 1994).

17.6.3. Physical Risk Management

Risk management is "a discipline for living with the possibility that future events may cause harm" (Kloman, 1992). It embraces physical and monetary techniques; we deal with the latter under other headings. Traditionally it has been site-specific, but now there are national and international initiatives [e.g., International Decade for Natural Disaster Reduction (IDNDR)]. Because development has grown very rapidly, there often is no realization of the hazard potential. Also, insurance is not required by the ultimate property owner until later and is often just part of a financial deal. Effective risk management comprises understanding the hazard and eliminating it, if possible; if not, it plans how to modify the impact of an event or the property likely to be at hazard and how to mitigate the loss after the event (Foster, 1984). It involves such techniques as hazard mapping, improved design, simulations, and a full disaster plan including the warning system, emergency response, and recovery (Stone, 1992). Land-use control and information are also essential (Berz, 1994). The issue of coastal defense is considered in detail in Chapter 9.

Within the construction sector, it is essential to identify the standards required and adhere to them. Incorrect construction often is to blame for damage; indeed, one of the great future issues will be how to "retrofit" substandard buildings (Sparks, 1993). This is now done regularly in Fiji, with a scheme that features professional certification of the work and premium discounts (FBSC, 1985; Walker, 1989, 1992). Unless adequate checks and controls are maintained on reinstatement works, the reconstruction may be carried out in a shoddy way—leading to further problems for the future (Norton and Chantry, 1993). It may be necessary to rebuild to higher standards (Peele, 1988).

Storm: Most damage is roof-related or due to poor detailing or wind-blown debris (NCPI, 1992a, 1992b; FEMA, 1992b, 1993). There is always pressure to reduce building costs (Norton and Chantry, 1993). Meek and Tattersall (1989) estimate that higher building standards introduced after Cyclone Tracy in Darwin, Australia would reduce damage by a factor of five. Offshore exposures are an obvious concern. Hurricane Andrew damaged or destroyed 173 energy rigs (Leggett, 1993a).

Flood: This peril is very destructive and strongly localized (Cuny, 1991; Moser, 1992). Yevjevich (1992) lists thirty-three methods to cope with flood—divided into insurance, intensive physical and extensive physical flood-proofing, prediction, and prevention. Alternative accommodation is often required. More stringent planning controls on floodplain development must be adopted (Henri, 1991). Appropriate defense work must be given

---

Box 17-4. Risk Management in Tanzania

In recent years, Tanzania has experienced heavy rains and floods. Severe windstorms have been frequent in the lake zone. These have caused financial loss, death, injuries, and the spread of diseases. The government has issued several directives prohibiting construction in the lower lands and has allocated new sites on higher ground. Most of the people cannot afford insurance. The lake zone is the main cotton-growing area. Natural-perils damage to the stored crop and the silos in which they are stored can be covered. The Cotton Act strictly regulates storage construction, and the National Insurance Corporation sends surveyors to advise the cooperative unions on how to minimize loss occurrences. To date, the National Insurance Corporation does not provide growing-crop insurance due to the lack of reliable data.

---

higher priority in the known problem areas (Anderson, 1991; Shearn, 1994). Upgrading buildings during maintenance (Miller, 1989), reviewing drainage capacity (Robbins, 1993), and landscaping exposed sites (Bush, 1994) could be very effective.

Risk management involves issues that go beyond the purview of the insurance industry. However, insurers and reinsurers play a leading role in mapping hazards, promoting better design codes, and improving the quality of implementation through trade bodies like the Insurance Institute for Property Loss Reduction (IIPLR) in the United States. At the micro-level, insurers inspect many buildings, making insurance dependent on adopting the inspector's recommendations for risk mitigation. Loss control is generally efficient, with help lines, recommended tradesmen, the use of loss adjusters in emergency panels, instructions through the media, and specialist recovery agencies. However, with the wholesale reduction of staffing in the financial sector, future response may be less effective. It is important that insurers reflect varying degrees of protection in their premium levels, to encourage risk management (Foster, 1984; Natsios, 1991). Infrastructure work such as sea defenses should fall to the public purse. Much of the benefit might accrue to non-property owners, and many property owners do not purchase insurance.

17.6.4. Technical Pricing

The initial response to increased losses might be to increase premiums. However, the decision is not usually simple because the market is increasingly competitive. The buying of market share inevitably leads to adverse results (the "underwriting cycle") (Munkhammar and Themptander, 1984). Individual property rating is based on value at risk, with an assessment of such factors as location, construction, and, for large commercial risks, trade processes. The rate is derived from past losses and modified for irregular events, administration expenses, and

profit margin (Brigstock and Minty, 1993). This method is clearly flawed if the size and number of weather related incidents are rising. Reinsurance pricing can modify the direct insurer's strategy significantly (Laderman, 1993). Recent experience will strongly color the consumer's expectations and willingness to pay (Changnon and Changnon, 1990). Owners tend to understate property values, which makes it difficult to ensure that an adequate fund is built up and also makes restitution contentious.

The general principle of insurance is to "share the risk." Henri (1993) points out that using a rate that does not reflect the degree of hazard will result in economically inefficient behavior (adverse selection). Below-average risks will be reluctant to insure, while insurers will shy away from the increasingly heavy pool of risks. A rate varying to reflect the individual exposure to hazard encourages risk management but can result in standard insurance becoming too expensive for some. It is desirable for insurance to be a prerequisite of property purchase/ownership; otherwise damage may not be repaired, leading to a downward spiral of decay. It is easier to achieve tradeoffs with a multi-peril policy (Anderson, 1976), and it has practical benefits in claim handling.

17.6.5. Funding over Time

Retrofunding is sometimes used commercially, similar to a banker's line of credit (Jakobi, 1994), but generally it is a government tool, taking the form of relief payments. These payments often do not provide sufficient or efficient assistance (Anderson, 1991; Kunreuther, 1984). The alternative of pre-funding (insurance) is therefore coming to the fore. It is important that natural-hazard insurance be treated as a long-term business rather than being accounted and taxed annually. The premiums must provide sufficient surplus to give a reserve for disasters through the troughs of the underwriting cycle. Catastrophe reserves should be accumulated over years, to reduce reliance upon reinsurance arrangements or shareholders' funds and to allow the accumulation of investment gains (Porro, 1984). The build-up of such reserve funds often is exempt from taxation (ABI, 1993; Candel, 1993). Insurers will still require reinsurance to cope with "super-catastrophes" or "multiple hits."

17.6.6. Improving the Knowledge Base

The collection and dissemination of information—including education and vocational training—is critical to the success of risk management (Foster, 1984; Ward, 1991). However, there is a serious lack of knowledge everywhere on weather patterns; the effects of climate change on these patterns; the effects of these changes on the potential for property loss and associated consequential costs to society and individuals; the value and specific locations and types of property at risk; and, lastly, a detailed record of the actual losses sustained (insured and uninsured). Insurers will not underwrite climate risks without adequate information on their variability and magnitude. Almost all countries have some form of natural-hazards risk analysis in hand, often prompted by UN initiatives such as IDNDR. Probably the only viable way is to rely on each country to carry out the work for its own hazards but to use common standards—and with central funding for less-developed nations, possibly using the IDNDR as a body to coordinate databases, not just for commercial needs but for the public good (McCulloch and Etkin, 1995). The basic climate data are increasingly costly but are essential both for projecting models of future trends and for claims verification.

17.6.7. Cooperation

Instead of dealing with problems piecemeal, financial industries need to influence the decisions of a wide variety of bodies and policymakers at the strategic level:

- The construction industry: regarding methods, standards, and regulation of construction
- Government and its various departments:
  - To resist new development in high risk areas
  - To protect existing developments in high risk areas
  - To plan how insurance can help society cope with extreme events.
- International bodies (e.g., United Nations): Many issues now are transnational (e.g., pollution, competition, communication, climate change). The insurance industry has no international underwriting organization, and this now seems an important gap. Such a body also could coordinate the industry's research work.

17.7. Impacts and Adaptation in Other Financial Services

The bulk of this chapter has dealt with the effects of weather and climate change on the insurance of property. However, other financial services may be affected. Many of the processes involved are similar to property insurance underwriting in that risks are assessed before a financial commitment is made.

17.7.1. Likely Impacts in Other Non-Life Insurance Activities

Transportation: This sector is an integral part of modern society. In addition to providing the means for our lifestyles and economies to function, transport goods and services are products in themselves, and the organizations supplying them are major employers. Sensitivity to weather and climate change is considered fully in Chapter 11. Extreme conditions can be very disruptive, causing damage and delay, often compounded by human error in these conditions. There has not been a major published study in this respect. Damage to infrastructure is generally not insured. Damage and particularly injury caused to other users is often insured. Hail damage to vehicles was a particular concern in the Munich hailstorm of 1984 (Munich Re, 1984). However, compensation for delays is not

generally covered because of the practical difficulties in proving losses. Travel insurance is an exception, but the sums insured are small.

Liability insurance: Liability insurance has become a rather difficult sector, with the over-use of tort law and increasing emphasis on strict liability combined with environmental degradation claims (Winters, 1993; Nutter, 1994). In dealing with impacts of weather, it is often difficult to prove negligence or to identify a currently pursuable person or organization. There has been some litigation in this field—for example, control of tree-root invasion into neighboring buildings (Institution of Structural Engineers, 1994); control of undergrowth following bush fires in Australia costing over $100 million (Alexander, 1993); limitation of beach erosion, which is often initiated by human action (Bryant, 1991); and even the accuracy of weather forecasts and flood control (Kusler, 1985). At a strategic level, there has even been discussion of national liability for climate change (Stone, 1992; Leggett, 1994), but this does not seem likely to become a commercially insurable risk. An interesting case cited by Changnon and Changnon (1990) involved liability for overselling drought policies, resulting in underwriting losses of $8 million.

Crop insurance: Agriculture is a key sector in many nations, though often it is not a part of the market economy. In most countries, insurers do not offer coverage for growing crops because of the possibility of catastrophic loss and the difficulties of loss control and evaluation. However, schemes do exist. Durham (1994) describes the use of crop insurance in the United States, where a multi-peril-crop insurance policy is sponsored by the federal government, with varying participation by private insurers. Hueth and Furtan (1994) coordinated a detailed investigation of such schemes in the United States, Canada, and other developed economies. They came to the conclusion that crop insurance was not the best way to address farmers' yield uncertainty because of moral hazard (the temptation not to mitigate losses because they will be met by insurance) and adverse selection (the tendency for farmers with worse-than-average risks to insure, knowing that they will make a "profit," while the better risks will not insure). The situation is further complicated by the relatively liberal granting of disaster relief in times of hardship, which discourages the prudent farmer from buying insurance at all. Sugar-crop insurance in Mauritius has been compulsory since 1946 and is government-administered. The scheme was discussed for Tanzania but not adopted (Putty, 1984). Similar schemes exist elsewhere (e.g., Costa Rica), with support from the banking sector (Gallardo, 1984). Climate change is expected to have significant impacts on agriculture (see Chapter 13), so it may be expected that interest in this area will increase.

The various considerations in Section 17.6 apply here. In transportation, weather-related hazards are likely to remain subordinate. There will be more attention to risk management in specific circumstances (e.g., tree owners, coastal property owners) to minimize liability. With regard to crops, private insurers are unlikely to take on large commitments.

17.7.2. Life Insurance and Pensions

By contrast with general insurance, these industries are long-term, highly actuarial in nature, and often linked with savings plans. The contracts are underwritten less rigorously than many general policies, are unusually nonrenewable, and last for many years, until terminated by death of the insured. Investment of the premiums is a major activity, with the emphasis on security over many years. A range of instruments is used, from government bonds to corporate stock, real estate, and fine art. The industry generated $770 billion in premiums in 1992 and is highly influenced by changes in government policy on social insurance and fiscal matters (Swiss Re, 1994b). As with general business, about 85% of the market lies in the United States, EU, and Japan. Although the volume of business is comparable to general insurance, the investible funds are much greater ($3,075 billion in 1989, as against $832 billion for non-life business).

Likely Impacts: The impact of climate change is likely to come in two ways. The first is through changes in morbidity or mortality. Such changes are associated with extremes of heat and cold. Potentially, shifts in mean conditions could lead to the introduction of new pests and diseases or, occasionally, the elimination of old ones (Epstein and Sharp, 1994). There have been many weather-related deaths in developing countries but, in general, without any significant involvement of life insurers. Indirect effects might include food and water shortages (see Chapter 18). The second major impact is in the potential impact on investments. Long-term decisions really need to include climate change as a factor, but this is definitely not happening yet. This will be discussed more fully in Section 17.7.3.

Adaptation: Given that there are many other imponderables such as drugs or crime-related influences on human well-being, it is unlikely that meaningful adjustments to mortality tables can be made. However, investment strategy can be adapted over a shorter period and therefore should be updated periodically to recognize the current views on the impact of climate change (Porro, 1984).

17.7.3. Banking

The other major industry is "banking," which also covers a wide range of activities. Liquid assets (e.g., savings and profits) are invested, either short term to finance debt (e.g., overdrafts) or long-term to finance assets (e.g., mortgages) and provide pensions. This requires banks to provide treasury and investment-management services. Some investments are speculative, with an uncertain return, but often loans are provided in return for fixed interest. This requires similar skills to insurance underwriting, in order to assess the riskiness of the venture or the likelihood of repayment. Loans often are secured on assets such as property (which is itself insured against damage) in order to provide some guarantee of repayment. The majority of loans are short-term (less than five years). Finally, the sector may act to organize the raising of capital for a project or to

strengthen the capital base of a company by finding new share-holders. A large and increasing range of financial instruments is used to manage the inherent financial risks (hedging, etc.) (Thompson, 1995).

In relation to this topic, banks fall into three types: international banks (i.e., economically involved all over the world); regional banks; and specialist banks, including building societies, "thrifts," and similar institutions. There has been much talk of product integration between banks and insurers (still forbidden in some countries). However, the cultural differences in treating claims versus bad debts, for example, make this unlikely for the mass consumer market. At corporate level, "risk" and "finance" are almost interchangeable (Seebauer, 1992).

17.7.3.1. Likely Impacts

Banking will be affected indirectly as its customers find their operations, consumption, and/or financial circumstances affected by climate change. Specifically, the banking industry and any investment activity could be affected if property insurers withdraw coverage from property that was the subject for some long-term financial transaction. This already has happened in some small island states, and any coastal site must be challengable (Leggett, 1993a; Dlugolecki *et al*., 1995). Indeed, the burden of uninsured catastrophe losses could cause loan defaults (Vaughan, 1994). Sectors that may be adversely affected, such as tourism and agriculture in certain regions, may find it difficult to raise finance if uninsured losses are perceived to be a real threat to viability. Moreover, a fall in property values precipitated by a loss of confidence in the local economy could itself trigger a "credit famine," because property is often used as security for loans (Medioli, 1989; Bender, 1991; Thompson, 1995).

If a financial center is unexpectedly exposed to extreme weather events, the added effect associated with being disrupted or even cut off from the nonstop global financial markets could be significant.

It can be argued that for the world banking system there is no critical threshold of climate change because banks would cooperate to reestablish a new basis, as happened after the Third-World debt crisis. The huge scale of global financial flows would outweigh the likely cost of even a series of catastrophes (Dlugolecki and Klein, 1994). At the national level, the banking system could be reestablished with external assistance, but of course this would result in a permanent weakening of the local economy though adjustments in the exchange rate and interest rates. As with insurance, the scale of event will vary from one country to another. For Jamaica, Hurricane Gilbert was extreme enough to cause lasting financial damage (Commonwealth Secretariat, 1991). Cochrane (1993) reports that the U.S. banking system has withstood two shocks of around $300 billion due to rapid changes in oil prices. He concludes that the effect of $100 billion natural catastrophe (in this case, earthquake) could be absorbed. While this might be true

at the scale of the U.S. economy, there is no doubt that major local disruption would result, with failures at the micro-level.

Investment activities can be affected indirectly by climate change through the actions of other sectors. In particular, mitigation policies to alter the production and use of energy may have a strong effect on the transport and energy sectors. This may alter the economics of specific technologies and entire nations or regions, with implications for rates of return on investment. Without coherent early guidance, changes in policy may result in suboptimal investment decisions. A more subtle effect on banking may stem from the changing mix of consumption and business activities brought about by climate change (Vaughan, 1994). This will surely affect the requirements for financial services, but no study has been made of this yet.

17.7.3.2. Adaptation

In banking, the key issues will be to anticipate the growing risk exposure of lenders by reduced insurance coverage, to include climate change as one of the factors in assessing the risk in investment and lending opportunities (past and future), to plan for changes in client portfolio, caused by global warming, and to anticipate operational impacts of climate change as outlined in Section 17.5.2.

It will be important to ensure that insurance coverage is available throughout the lifetime of loans. This will mean more stringent lending conditions. Environmentally integrated assessment, with regard to the direct impact on assets and the indirect effect on the borrower's business, will be required. Closer cooperation with insurers, to the extent of partnership or even ownership, is a possibility. Alternatively, it may require government intervention to ensure that alternative protection is available (Britton, 1989; Kunreuther, 1993).

It should be evident that some activities or projects are more likely to be affected by climate change than others. Therefore, this should be taken into account when appraising any investment. In particular, assets with long life spans situated in coastal zones or river basins may be sensitive, and there may be certain stages of construction that are more vulnerable (Anderson, 1991; Bender, 1991). The classic banking solutions to increased risk are similar to those of property insurers: restricted involvement (with consequent difficulties for economic activity) and higher prices, including an environmental risk premium—often not easy to achieve in a competitive environment. More radical approaches are necessary for a fundamental issue like climate change, and enlightened bankers are already exploring such avenues in the light of sustainable development initiatives (Vaughan, 1994). This will initially require a substantial effort to understand the problems and may generate new services to assist those clients most affected, once they have been identified through improved screening. A suitable starting place for such studies will be comprehensive national and international assessments of climate change impact, which allow an integrated appraisal of the many activities supported by financial services

(e.g., IPCC, 1990; CCIRG, 1991). Outsiders will be keen to see how the financial sector deploys its funds in the light of climate change. Shareholders and employees will be concerned about "their" capital and how it may be affected by mitigation policies or whether it is being used "responsibly" (ACBE, 1994).

17.7.4. Brokering

"Brokering," or arbitrage, provides the link between buyers and sellers of financial instruments, including foreign currency. As financial markets have become more turbulent, the use of "hedging" instruments has increased. This has been accelerated by the trend toward global markets with more deregulation (Swiss Re, 1992).

Likely impacts: A really major catastrophe could affect stock market valuations and the propensity to save. Such impacts currently are largely confined to the impact on insurers' share values and the construction sector.

Adaptation: The role of financial markets is to reallocate risk and to process and disseminate information, and this will be even more necessary with climate change. Research into areas of uncertainty and policymaking will be important to improve the efficiency of resource allocation. Financial rating agencies will devote more attention to this aspect, in particular seeking to quantify company performance on "green" issues (Mueller *et al.*, 1994).

17.8. Implications for Policymakers

One of government's roles is to provide leadership in the management of natural hazards (Towfighi, 1991; Britton and Oliver, 1993). This entails research into occurrence and impacts, followed by implementation of preventative measures. Key hazards are drought, flood, and storm, which often are not insured. Key vulnerable areas are developing countries (Stone, 1992), small island states and coastal zones (IPCC, 1990), cities (Cohen, 1991), and agriculture (IPCC, 1990). The public infrastructure is vital to recovery, but it is often exposed to natural hazards and may require retrofitting for robustness (Kreimer and Munasinghe, 1991; Minnery and Smith, 1995). Much of the cost of climate change will not be insurable [e.g., damage to ecosystems, gradual degradation, loss of economic value of coastal property (Stone, 1992)].

National planning: Short- and long-term objectives are required. Short-term objectives are principally in the area of "good housekeeping" and tightening of existing arrangements to minimize the effects of damage from extreme events. Long-term planning should consider particularly the risk of major inundation (Beatley, 1994). This is an increasing risk as population and investment move to coastal areas or river plains and will be compounded by sea-level rise. The question of how to treat property built on land to be redesignated as hazardous will be contentious (Minnery and Smith, 1995).

Education: All parties in the property market must be fully aware of the potential effects of climate change and fully educated in the means available to combat these impacts so that disaster plans can be prepared at all levels. These parties include property owners and occupiers, architects and builders, insurers, and regulatory authorities.

Integrating financial mechanisms: If the probability of an event is very low, consumers act as if it will never happen, even if the probable maximum loss is very high. It will therefore be necessary to offer incentives (or disincentives) to promote sound risk management by consumers and to introduce mandatory policies for risk-prone locations, backed by appropriate resources for regulation. In many cases, affordability will be an issue.

With better information, it will be possible to assess the risk exposure of individual entities and the nation as a whole. This will serve as a basis for discussion about which risks can be borne by the private sector. Where the risk is too hazardous for private insurance companies, there still are many advantages in involving the private insurance sector in planning for disaster mitigation. Their practical knowledge of marketing a financial product, tariff structures, access to international resources, damage recovery, avoidance of duplicate administration, and fraud control would prove invaluable (Leggett, 1993b; Vellinga and Tol, 1994). Similarly, because of the large-scale financial implications of adaptation or mitigation strategies, it will be important to consider whether and how the financial sector can contribute.

New cooperative institutions are required to draw together the many disciplines needed to tackle the implications of global warming (Kunreuther, 1994; Natsios, 1991; Sykes, 1991). The United Nations' IDNDR and Coastal Zone Management (CZM) provide excellent platforms to begin consultation on information and mitigation strategies (Bender, 1991; Berz, 1994; Clark, 1991a). Even cautious observers support the principle of collaboration for information-gathering in the context of the potential threat of climate change (Ausubel, 1991).

Climate data: The availability and affordability of climate data for research and commercial decisionmaking is critical.

Construction industry: The authorities must work with trade associations to improve building quality and design and consider how to "retrofit" structures if necessary.

Finally, in view of the long-term nature of much financial activity, particularly pension-funding, it would be valuable for governments to give an early indication of how they might modify policy on industries that contribute to, or counter, global warming and then act consistently so that investment can be channeled efficiently (Leggett, 1994). Initially, subsidies may be important for research and development in novel technologies.

17.9.   Requirements for Future Assessments

There are several key issues for property insurance and related activities. Better information is required on the past and future location, severity, and frequency of extreme events, especially storms and precipitation. The areas most vulnerable to extreme events need to be identified. Better information is required on the damage-response curve for the various hazards. A standardized database on the cost of extreme events would be extremely useful. Improved techniques are required for applying knowledge of actual events to hypothetical situations to evaluate risks (i.e., simulation).

For other areas of financial services, better information on the likely changes in morbidity or mortality is needed, as is a clearer exposition of how policymakers are likely to seek to adapt to or mitigate climate change.

Finally, it must be said that the current assessment was hampered by the lack of a substantial literature base and lack of awareness on the part of many financial services, organizations, and individuals. Therefore, a program of attention-raising is important.

CONTENTS

EXECUTIVE SUMMARY

The sustained health of human populations requires the continued integrity of Earth's natural systems. The disturbance, by climate change, of physical systems (e.g., weather patterns, sea-level, water supplies) and of ecosystems (e.g., agroecosystems, disease-vector habitats) would therefore pose risks to human health. The scale of the anticipated health impacts is that of whole communities or populations (i.e., it is a public health, not a personal health, issue). These health impacts would occur in various ways, via pathways of varying directness and complexity, including disturbance of natural and managed ecosystems. With some exceptions, relatively little research has yet been done that enables quantitative description of these probable health impacts.

It is anticipated that most of the impacts would be adverse. Some would occur via relatively direct pathways (e.g., deaths from heat waves and from extreme weather events); others would occur via indirect pathways (e.g., changes in the range of vector-borne diseases). Some impacts would be deferred in time and would occur on a larger scale than most other environmental health impacts with which we are familiar. If long-term climate change ensues, indirect impacts probably would predominate.

Populations with different levels of natural, technical, and social resources would differ in their vulnerability to climate-induced health impacts. Such vulnerability, due to crowding, food insecurity, local environmental degradation, and perturbed ecosystems, already exists in many communities in developing countries. Hence, because of both the geography of climate change and these variations in population vulnerability, climate change would impinge differently on different populations.

- An increased frequency or severity of heat waves would cause an increase in (predominantly cardiorespiratory) mortality and illness (High Confidence). Studies in selected urban populations in North America, North Africa, and East Asia indicate that the number of heat-related deaths would increase several-fold in response to two general circulation model (GCM)–modeled climate change scenarios for 2050. In very large cities, this would represent several thousand extra deaths annually. Although this heat-related increase in deaths would be partially offset by fewer cold-related deaths, there are insufficient data to quantify this tradeoff; further, this balance would vary by location and according to adaptive responses (Medium Confidence).

- If extreme weather events (droughts, floods, storms, etc.) were to occur more often, increases in rates of death, injury, infectious diseases, and psychological disorders would result (High Confidence).

- Net climate change-related increases in the geographic distribution (altitude and latitude) of the vector organisms of infectious diseases (e.g., malarial mosquitoes, schistosome-spreading snails) and changes in the life-cycle dynamics of both vector and infective parasites would, in aggregate, increase the potential transmission of many vector-borne diseases (High Confidence). Malaria, of which there are currently around 350 million new cases per year (including two million deaths), provides a central example. Simulations with first-generation mathematical models (based on standard climate-change scenarios and incorporating information about the basic dynamics of climatic influences on malaria transmission) predict an increase in malaria incidence in Indonesia by 2070 and—with a highly aggregated model—an increase from around 45% to around 60% in the proportion of the world population living within the *potential* malaria transmission zone by the latter half of the next century. Although this predicted increase in *potential* transmission encroaches mostly into temperate regions, actual climate-related increases in malaria incidence (estimated by one model to be of the order of 50–80 million additional cases annually, relative to an assumed global background total of 500 million by 2100) would occur primarily in tropical, subtropical, and less well protected temperate-zone populations currently at the margins of endemically infected areas. Some localized decreases may also occur (Medium Confidence).

- Increases in non-vector-borne infectious diseases such as cholera, salmonellosis, and other food- and water-related infections also could occur, particularly in tropical and subtropical regions, because of climatic impacts on water distribution, temperature, and microorganism proliferation (Medium confidence).

- The effects of climate change on agricultural, animal, and fisheries productivity, while still uncertain, could increase the prevalence of malnutrition and hunger and their long-term health impairments, especially in children. This would most probably occur regionally, with some regions likely to experience gains, and others losses, in food production (Medium Confidence).

- There would also be many health impacts of the physical, social, and demographic disruptions caused by

rising sea levels and by climate-related shortages in natural resources (especially fresh water) (Medium Confidence).

- Because fossil-fuel combustion produces both carbon dioxide and various primary air pollutants, the climate change process would be associated with increased levels of urban air pollution. Not only is air pollution itself an important health hazard, but hotter temperatures, in urban environments, would enhance both the formation of secondary pollutants (e.g., ozone) and the health impact of certain air pollutants. There would be increases in the frequency of allergic disorders and of cardiorespiratory disorders and deaths caused by various air pollutants (e.g., ozone and particulates) (High Confidence).

- A potentially important category of health impact would result from the deterioration in social and economic circumstances that might arise from adverse impacts of climate change on patterns of employment, wealth distribution, and population mobility and settlement. Conflicts might arise over dwindling environmental resources (Medium Confidence).

- Stratospheric ozone is being depleted concurrently with greenhouse gas accumulation in the troposphere. Although there are some shared and interactive atmospheric processes between disturbances of the stratosphere and troposphere, both they and their health impacts arise via quite distinct pathways. A sustained 10–15% depletion of stratospheric ozone over several decades would cause increased exposure to ultraviolet radiation and an estimated 15–20% increase in the incidence of skin cancer in fair-skinned populations (High Confidence). Lesions of the eye (e.g., cataracts) also may increase in frequency, as might vulnerability to some infectious diseases via adverse effects on immune function (Medium Confidence).

Adaptive options to minimize health impacts include improved and extended medical care services; environmental management; disaster preparedness; protective technology (housing, air conditioning, water purification, vaccination, etc.); public education directed at personal behaviors; and appropriate professional and research training. It also will be important to assess in advance any risks to health from proposed technological adaptations (e.g., exposures that could result from using certain alternative energy sources and replacement chemicals for chlorofluorocarbons; effects of pesticide use on resistance of vector organisms and their predator populations).

There is immediate need for improved and internationalized monitoring of health-risk indicators in relation to climate change. Existing global monitoring activities should encompass health-related environmental and bioindicator-species measurements and, where appropriate, direct measures of human population health status. To assist the evolution of public understanding and social policy, the health sciences must develop improved methods, including integrated predictive models, to better assess how climate change (and other global environmental changes) would influence human health.

In conclusion, the impacts of global climate change, particularly if sustained in the longer term, could include a multitude of serious—but thus far underrecognized—impacts on human health. Human population health is an outcome that integrates many other inputs, and it depends substantially on the stability and productivity of many of Earth's natural systems. Therefore, human health is likely to be predominantly adversely affected by climate change and its effects upon those systems.

18.1. Introduction

18.1.1. Climate Change and Human Population Health: The Nature of the Relationship

Global climate change over the coming decades would have various effects upon the health of human populations (WHO, 1990; Haines and Fuchs, 1991; McMichael, 1993; Last, 1993; *Lancet*, 1994). Because of the nature of the exposures involved, the scale of these climate-related changes would, in general, apply to whole populations or communities, rather than to small groups or individuals. The assessment of health impacts therefore focuses on changes in rates of death or disease in populations.

Many of the health impacts of climate change would occur via processes that are relatively unfamiliar to public-health science. They would not occur via the familiar toxicological mechanisms of localized exposure to environmental contaminants, nor via locally determined influences on the spread of infectious diseases. Instead, many of the impacts would arise via the indirect and often delayed effects of disturbances to natural systems and their associated ecological relationships. For example, changes in background climate may alter the abundance, distribution, and behavior of mosquitoes and the life cycle of the malarial parasite, such that patterns of malaria would change. Climate change also would have varied regional effects on agricultural productivity, so that some vulnerable populations may experience nutritional deprivation. There also would be some rather more readily predictable health impacts, arising, for example, from more frequent or severe heatwaves.

On a wider canvas, several of the world's ecosystems that are important in sustaining human health already have been weakened by damage, habitat loss, and species/genetic depletion. These include agricultural lands and ocean fisheries and the terrestrial ecosystems that influence the transmission of infectious diseases. Climate change may, via various processes, exacerbate those ecosystem disturbances. Because an ecosystem comprises a suite of interacting components, in which member organisms relate to the whole suite rather than to individual parts, the uncoupling of relationships by climate change could initiate a cascade of disturbances that might jeopardize human population health.

The range of potential major types of health impact is shown in Figure 18-1. For simplicity, they have been classified as "direct" and "indirect," according to whether they occur predominantly via the direct impact of a climate variable (temperature, weather variability, etc.) upon the human organism or are mediated by climate-induced changes in complex biological and geochemical systems or by climatic influences on other environmental health hazards.

18.1.2. Forecasting Health Impacts: The Challenge to Health Science

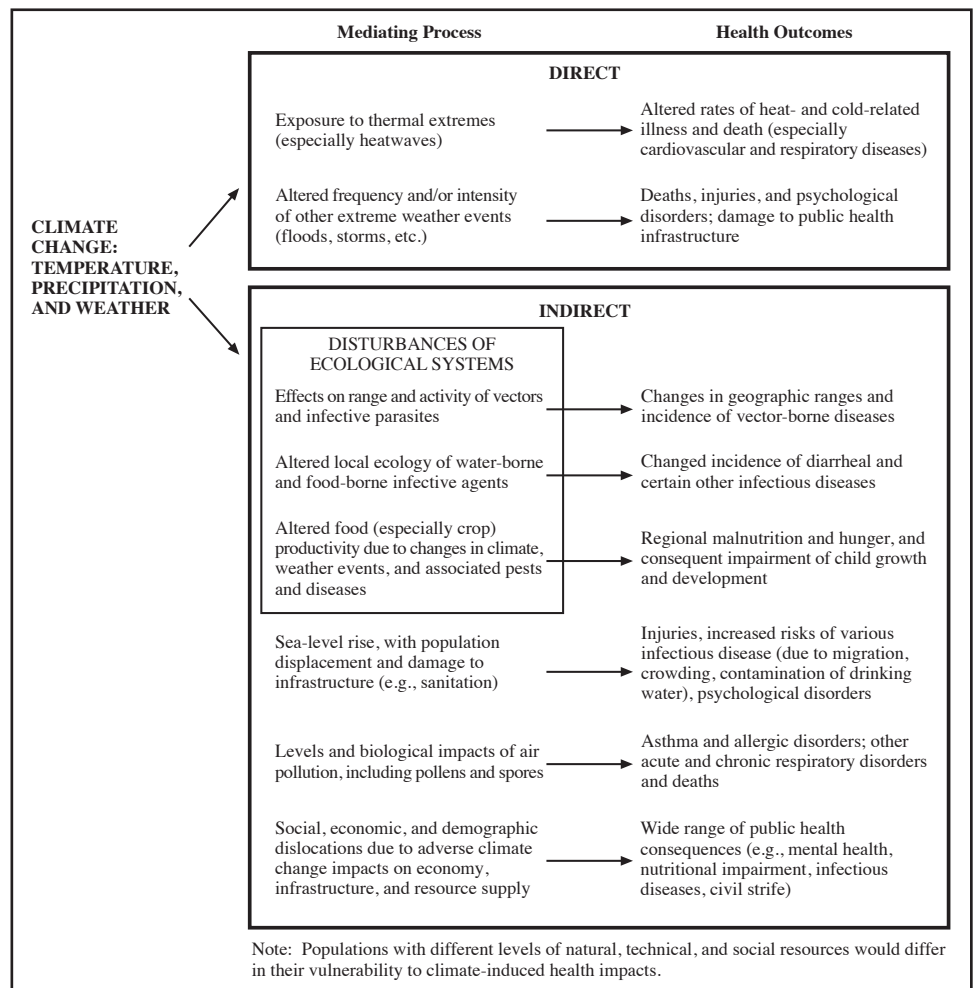
Predictions of future trends in population health are readily made in relation to actual current exposures—for example, future lung cancer rates can be predicted as a function of a population's current cigarette smoking habits (Peto *et al.*, 1994). It is unusual to make predictions on the basis of some anticipated future profile of exposure (e.g., smoking habits in the year 2020), yet this is the nature of the present exercise: Potential health impacts are being assessed in relation to future scenarios of climate change. There are inevitable, multiple uncertainties in such an approach (McMichael and Martens, 1995).


Figure 18-1: Ways in which climate change can affect human health.

Some aspects of climate change and its first-level impacts (on sea level, coastal ecosystems, forests, agriculture, fisheries, etc.), as projected by IPCC Working Group I, would lie outside the range of recorded human health experience. Hence, the forecasting of human health impacts must rely principally upon reference to historical analogy (where available) and reasonable extrapolation, judgment, and the use of integrated mathematical models (Niessen and Rotmans, 1993; McMichael and Martens, 1995). Most of the health impact modeling to date has been at a highly aggregated global or regional level, with no capacity to make finer-grained predictions. Ongoing developments in modeling techniques include the incorporation of complex nonlinear relationships and feedback processes, dealing with uncertainty, and richer use of local detail (Alcamo *et al*., 1994a, 1994b).

Some health impacts can be forecast by relatively simple extrapolation from empirical epidemiological dose-response data. For example, models to predict the mortality impacts of an increase in heatwaves can be based on existing empirical data. However, predicting the health impact of climate-induced shifts in ecological relationships and habitat boundaries (e.g., malarial mosquitoes, agricultural crops) poses a more complex challenge. Equally complex is the task of predicting the various indirect health impacts of such things as sea-level rise or of civil disruption and enforced migration because of deteriorating environments and dwindling resources.

A further difficulty arises with regional predictions. Not only is the ability to predict regional differences in climate change still limited, but human populations differ greatly in their environmental circumstances, social resources, and preexisting health status. They therefore differ in their vulnerability to climate-induced stresses. Although there is generally insufficient information available to make differentiated assessments of health impacts in different populations, the balance of the assessments published to date is that, because of the geography of the impacts of climate change (particularly in relation to infectious disease transmission and food production) and of population vulnerability, many of the anticipated adverse health impacts would be greater in the world's less-developed regions. Nevertheless, in developed countries, demographic trends including population aging and increasing levels of disability, chronic illness, and coastal retirement may increase the vulnerability of populations.

Although it is tempting to compile a list of discrete health impacts, it is important that the systemic quality of the impact of climate change be understood. There would be many cross-links, including interactions of climate change with other, coexisting environmental changes. Further, the attempts of society to mitigate the health effects of climate change may actually exacerbate some of them. For example, increased use of fertilizers to compensate for a decline in local agricultural production can increase algal blooms and hence the risk of cholera or shellfish poisoning; or the relocation of populations from drought-stricken areas might introduce them to unfamiliar pathogens (or introduce their unfamiliar pathogens).

Neither the scope of this chapter nor available scientific knowledge allows comprehensive consideration of these issues.

18.1.3. *Sensitivities and Thresholds*

Forecasting health impacts requires knowledge of, first, the sensitivity of change in population health status in response to climate change and, second, of any associated thresholds. "Sensitivity" refers to the rate of change in health outcome per unit change in climate (however defined), whereas "threshold" refers to a sudden change in slope or curvature in that dose-response graph (e.g., a certain amount of climate change may be tolerated before an impact on some particular health outcome occurs).

Although there is only limited information on the sensitivities and thresholds of human health response to climate change, some illustrative comments can be made:

*   The impact of thermal stress depends on physiological tolerance thresholds being exceeded (see Section 18.2.1). For example, most studies of heat-related mortality show that increased mortality occurs only after a critical temperature has been exceeded for a certain duration. This critical temperature varies geographically, reflecting socioeconomic differences, physiological acclimatization, and cultural-technical adaptation.
*   Infectious disease pathogens and insect pests are normally constrained by bioclimatic thresholds. That is, there is a range of climatic conditions with upper and lower thresholds within which a population of organisms is viable (Dobson and Carper, 1993). These thresholds account for seasonal and longer-term fluctuations in the distribution and abundance of most organisms. The uncoupling, by climate change, of previously stable ecological relationships between species would reveal other thresholds as population imbalances pass critical points.
*   Changes in the distribution of organisms (e.g., mosquitoes) that spread vector-borne diseases (e.g., malaria) would occur if climate change causes their geographic range to shift. This shift would reflect the critical thresholds of temperature, precipitation, and humidity (i.e., the bioclimatograph) for vector maturation and persistence. For example, the range of *Plasmodium vivax* malaria is limited because the parasite cannot develop inside its mosquito host at temperatures below 14–16°C (Gilles, 1993). Further, blood-feeding arthropods feed and reproduce only above certain temperatures and need less time to complete their life cycle as temperatures increase above that threshold (Curto de Casas and Carcavallo, 1984; Burgos *et al*., 1994). Threshold effects also apply to the life cycle of the infecting parasite.
*   Some animal and plant populations would be unable to migrate or adapt behaviorally to climate change, in part because of constraints imposed by non-climate

variables such as day-length and soil type. Other species with either migratory or dispersive activity (particularly arthropod and weed pests in agriculture and disease vectors that affect human health) would cope with the shifts in climate zones. Humans generally would be less sensitive to changes in background climate because of their capacity to adapt via culture, technology, migration, and behavior.

- The sensitivity of health-outcome response depends on population susceptibility. For example, the impact of a climate-related increase in exposure to infectious agents would depend on prior contact (i.e., herd immunity), on general biological resilience (especially nutritional and immune status), and on population density and patterns of interpersonal contact. Social infrastructure and health-care resources also would condition the impact. In general, the most vulnerable populations or communities would be those living in poverty, with a high prevalence of undernutrition, chronic exposure to infectious disease agents, and inadequate access to social and physical infrastructure.

Table 18-1 lists illustrative examples of the relative sensitivity of selected human health responses to key aspects of climate change. It also summarizes what is known about thresholds in those responses. Further, the "conditionality" of response (i.e., the extent to which it is modulated by other influences) is indicated. This latter criterion is important: Many factors (including the intrinsic vulnerability of the local population) influence the determination of health status, and many of these would condition the health impact of climate change.

Further, many of the impacts of climate change would depend on parameters other than the central changes in mean values.

For example, weather variability would be important for extreme events; rates of change would influence the production in ecosystems (e.g., agriculture and fisheries); and the ecology of infectious disease vectors is sensitive to many aspects of climate, including changes in the day-night differential in temperature. These aspects of climate change would vary in their relative importance for different health impacts, as illustrated in Table 18-2. However, information on such details is still rather incomplete.

18.1.4. Major Trends in World Health: Backdrop to Climate Change Impacts

Information about levels and time trends in specific health outcomes facilitates both the prediction and the appraisal of the health impacts of climate change. For example, patterns of malaria and malnutrition are changing around the world in response to various other changes in social, biological, and ecological circumstances. Any predicted impact of climate change upon such health outcomes should be assessed either by differentiating that impact from those of other independent background trends or, if appropriate, by assessing its interactive impact with those other, coexisting influences.

The main contemporary features of world health (World Bank, 1993; Murray and Lopez, 1994) are as follows: (1) near-worldwide increases in life expectancy [with the ex-Eastern Bloc countries standing in sharp recent contrast (Feachem, 1994)], (2) a decline in infant and child mortality in most developing countries, (3) persistent gradients in health status between rich and poor (within and between populations), (4) reductions in certain vaccine-preventable diseases (e.g., polio and measles), (5) increases in the chronic noninfectious diseases of adult life

Table 18-1: *Examples of important aspects of the relationship of selected health outcomes to climate change.*

Health Outcome	Sensitivity[a]	Conditionality[b]	Thresholds
Climate Stress/Mortality	+++	++	Temperature 33°C[c]
Climate Stress/Morbidity	+

Demographic Disruption	++	+	+	

Notes: ++++ = great effect, + = small effect; empty cells indicate no known relationship.

(especially heart disease, diabetes, and certain cancers) in urban middle classes in rapidly developing countries, and (6) widespread increases in HIV infection. Rates of disease and death from cigarette smoking are likely to escalate markedly in many countries over the coming decades, as the tobacco industry takes advantage of freer trade and market-based economies (Peto *et al*., 1994). In many urban populations, drug abuse and violence are increasing.

There appears to be a widespread increase in the tempo of new and resurgent infectious diseases (Levins *et al*., 1994). This primarily reflects the combination of environmental and demographic changes in the world, plus increases in antibiotic and drug resistance, pesticide resistance, and decreased surveillance (Morse, 1991; CDC, 1994a). The interaction of local climate change with other disruptions of ecosystems may have facilitated various infectious disease outbreaks: the emergence of rodent-borne hantavirus pulmonary syndrome in the United States during 1992–3; various rodent-borne arenaviruses in Africa and South America; the spread of harmful algal blooms—and its association with cholera (which is now affecting more nations worldwide than at any earlier time this century); the rapid resurgence of dengue in the Americas since 1981; and the occurrence of dengue and malaria at higher altitudes than previously recorded (Levins *et al*., 1994).

Many other important influences on population health are changing over time. For example, new vaccines are being developed, and existing ones are being used more widely; contraception is becoming more widely used, with benefits to maternal and child health; and safe drinking water is becoming available, albeit slowly, to an increasing proportion of householders in poorer countries. Other adverse effects (from cigarettes, drugs, urban traffic, social breakdown, violence, etc.) are increasing widely, and persistent widespread poverty remains a major structural impediment to improved health (WHO, 1995a). Against this complex balance sheet, it is inevitably difficult to estimate the likely net impact on population health status after the additional inclusion of climate change.

18.2. Potential Direct Health Impacts of Climate Change

The direct effects of climate change upon health result from changes in climate characteristics or short-term weather extremes that impinge directly on human biology. The following subsections deal with the health impacts of thermal stress and extreme weather events.

18.2.1. Health Impacts of Altered Patterns of Thermal Stress

Many studies, particularly in temperate countries, have observed a J-shaped relationship (often more generally referred to as a U-shaped relationship) between daily outdoor temperature and daily death rate: Mortality is lowest within an intermediate comfortable temperature range. The graph is not symmetrical; the death rate increases much more steeply with rising temperatures, above this comfort zone, than it does with falling temperatures below that zone (Longstreth, 1989; Kalkstein, 1993; Kunst *et al*., 1993; Touloumi *et al.,* 1994). Relatedly, death rates in temperate countries appear to be affected across a wider band of decreasing, cold, temperatures than that for increasing, hot, temperatures (Kilbourne, 1992; Kunst *et al*., 1993). Because death rates in temperate and subtropical zones are higher in winter than in summer (Kilbourne, 1992), it is a reasonable expectation that milder winters in such countries would entail a reduction in cold-related deaths and illnesses. However, since summer-related deaths appear to be more related to temperature extremes than are winter-related deaths, this reduction may not fully offset the heat-related increases. Further, this balance of gains and losses would vary among geographic regions and different populations. The issue of balance is examined further later in this section.

Quantitative interpretation of the impacts of altered daily-temperature distribution also is hampered by the fact that, for both heat-related and cold-related deaths, many of the apparent excess deaths occur in already-vulnerable persons (especially the elderly and the sick). Some analyses indicate that, in the absence of extreme temperatures, many of those persons would

have died in the near future. This "mortality displacement" issue also will be considered further.

Global warming is predicted to increase the frequency of very hot days (see Chapter 6, *Climate Models–Projections of Future Climate*, of the IPCC Working Group I volume). The frequency of such days in temperate climates (e.g., USA, UK, Australia) would approximately double for an increase of 2–3°C in the average summer temperature (e.g., CDC, 1989; Climate Change Impacts Review Group UK, 1991). Extensive research has shown that heat waves cause excess deaths (Weihe, 1986; Kilbourne, 1992). Recent analyses of concurrent meteorological and mortality data in cities in the United States, Canada, the Netherlands, China, and the Middle East provide confirmatory evidence that overall death rates rise during heat waves (Kalkstein and Smoyer, 1993; Kunst *et al.*, 1993), particularly when the temperature rises above the local population's threshold value. Therefore, it can be predicted confidently that climate change would, via increased exposure to heat waves, cause additional heat-related deaths and illnesses (Kalkstein, 1993; Haines *et al.*, 1993).

The effect of extreme heat on mortality is exacerbated by low wind, high humidity, and intense solar radiation (Kilbourne, 1992). Indeed, these meteorological elements can be treated synoptically, to evaluate the net impact of weather on human health. For example, recent studies in the United States have described "oppressive" air masses (analogous to the meteorologist's "stagnating" air masses), which represent synoptic meteorological situations that exceed physiological tolerance levels. This approach recognizes that humans principally respond to the umbrella of air that surrounds them rather than to individual meteorological elements (Kalkstein, 1993). It also should be noted that concurrent hot weather and air pollution have interactive impacts on health (Katsouyanni *et al.*, 1993; see also Section 18.3.5).

Healthy persons have efficient heat regulatory mechanisms that cope with increases in temperature up to a particular threshold. The body can increase radiant, convective, and evaporative heat loss by vasodilation (enlargement of blood vessels in the skin) and perspiration (Horowitz and Samueloff, 1987; Diamond, 1991). Further, some acclimatization to persistent oppressive weather conditions can occur within several days (Kilbourne, 1992). Nevertheless, the risk of death increases substantially when thermal stress persists for several consecutive days (Kalkstein and Smoyer, 1993). The elderly and very young are disproportionately affected because of their limited physiological capacity to adapt. Although some individuals die from heat exhaustion or heatstroke, the deaths associated with very hot weather are predominantly associated with preexisting cardiovascular and respiratory disorders, as well as accidents (Larsen, 1990a, 1990b). Although there is less evidence on nonfatal illness episodes, it is a reasonable general assumption that thermal stress also increases rates of morbidity.

Socioeconomic factors may have important modulating effects on thermal stress-related mortality. From studies in the United

States, the extent of protection from air conditioning remains unclear (Ellis and Nelson, 1978; Larsen, 1990a; Rogot *et al.*, 1992; Kalkstein, 1993). Of more general importance, people living in poverty, including segments of many urban populations in developing countries, are particularly vulnerable to heat stress. Poor housing, the urban heat island effect, and lack of air conditioning are among the primary causes (Kilbourne, 1989). Complete acclimatization may take up to several years (Babeyev, 1986), rendering immigrants (e.g., rural-to-urban) vulnerable to weather extremes for a considerable time. Ongoing rapid increases in urbanization (see Chapter 12) will increase the number of vulnerable persons.

The question in relation to the abovementioned notion of "mortality displacement" is: Would some of those who die during heat waves have succumbed soon afterward from preexisting frailty or disease (Kalkstein, 1993; U.S. EPA, in press)? Various time-series analyses indicate a "deficit" in daily deaths for up to a month after heat waves (e.g., Figure 18-2), and U.S.-based research suggests that 20–40% of the deaths occurring during heat waves would have occurred within the next few weeks (Kalkstein, 1993). A related uncertainty is whether, as the frequency of heat waves increases, the mortality excess remains constant or whether, as some research suggests, successive heat waves entail a progressive lessening of the associated mortality peak.

Kalkstein (1993) made predictions of heat-related mortality for selected urban populations in North America, North Africa, and East Asia in relation to IPCC-specified climate-change scenarios. This entailed, first, identifying for each population
Figure 18-2: Daily summer mortality during a New York heatwave, 1966 (Kalkstein, 1993).

setting the synoptic weather situations that are "oppressive" (i.e., exceed physiological tolerance levels). The annual number of oppressive synoptic situation days was then predicted for the climate-change scenarios, and the annual total of associated excess deaths was estimated. Model-based predictions of the numbers of additional deaths attributable to heat during a typical summer in a future warmer world were thus obtained. Two sets of predicted mortality increases were made: one assuming that the population does not acclimatize and the other assuming partial acclimatization (i.e., complete physiological acclimatization but without improved socioeconomic conditions such as the development of more protective housing).

Consider the population of Atlanta, for example. Presently, Atlanta experiences an average of 78 heat-related deaths each summer. Under the climate projections of the Geophysical Fluid Dynamics Laboratory (GFDL) 1989 (transient) climate-change model, and assuming no change in population size or age profile, this number would increase to 191 in the year 2020 and to 293 in the year 2050. If population acclimatization occurs, the annual total would increase less, to 96 and 147 in those two years. Under the UKTR (transient) model run, the corresponding four projections of heat-related mortality are 20–40% higher than for the GFDL model run: 247 and 436 deaths (unacclimatized, 2020 and 2050) and 124 and 218 deaths (acclimatized, 2020 and 2050). These and other results for selected North American cities, Shanghai, and Cairo indicate that the annual number of heat-related deaths would, very approximately, double by 2020 and would increase several-fold by 2050. Thus, in very large cities with populations displaying this type of sensitivity to heat stress, climate change would cause several thousand extra heat-related deaths annually.

As mentioned earlier, the seasonal death rates in developed countries are highest in winter (Kilbourne, 1992; Tan, 1994). In temperate-zone countries, death rates increase particularly during periods of severe winter weather. However, no single study has yet been published that allows a direct comparison of the anticipated winter gains and summer losses that would accompany global warming. A substantial proportion of winter-related deaths are from cardiovascular disease (Kunst *et al.*, 1993; Langford and Bentham, 1995). It is likely that this increased risk of cardiovascular disease reflects an increased cold-induced tendency for blood to clot (Keatinge *et al.*, 1989), perhaps exacerbated by the fibrinogen-enhancing effect of winter respiratory infections (Woodhouse *et al.,* 1994). The relative importance of respiratory infections and cardiovascular diseases to anticipated reductions in mortality, and how these would vary geographically, remains uncertain. One recent British study has forecast that approximately 9,000 fewer winter-related deaths (estimated to represent a reduction of 2–3%) would occur annually by the year 2050 in England and Wales, under typical climate-change scenarios that entail 2–2.5°C wintertime increases (Langford and Bentham, 1995). Just over half the avoided deaths would be from ischaemic heart disease and stroke, with chronic bronchitis and pneumonia each contributing 5–10%. Other researchers have concluded that a significant portion of the overall winter-related mortality is due to respiratory infections such as

influenza (Curwen, 1991). Since these respiratory infections depend upon aerosol transmission—usually in confined, poorly ventilated places—a small rise in winter temperatures should reduce this risk if it encouraged outdoor activities and improved ventilation. However, annual influenza outbreaks do not appear to correlate with mean winter or monthly temperature (CDC, 1994b; Langford and Bentham, 1995).

Overall, the sensitivity of death rates to hotter summers is likely to be greater than to the accompanying increase in average winter temperature. The overall balance is difficult to quantify, and also would depend on the population's capacity for adaptive responses. However, research to date suggests that global warming would, via an increased frequency of heat waves, cause a net increase in mortality and associated morbidity. This conclusion must be qualified by noting that there is an imbalance in the published research—most of which refers to developed, non-tropical, countries.

18.2.2. Health Impacts of Weather Variability and Extreme Events

Global warming may affect ocean currents, air currents, and atmospheric humidity (see Chapter 6, *Climate Models– Projections of Future Climate*, of the IPCC Working Group I volume). Any consequent changes in weather variability may alter the frequency and severity of extreme weather events: bushfires, droughts, floods, storms, and landslides (Gordon *et al.*, 1992; Meehl *et al.*, 1992). However, some of these relationships remain uncertain (e.g., for tropical cyclones; see Lighthill *et al.,* 1994) and have proven difficult to model with GCMs. Such events increase deaths, injuries, infectious diseases, stress-related disorders, and the many adverse health effects associated with social disruption, environmentally enforced migration (Myers, 1993), and settlement in urban slums. Health impacts would be greatest on those communities that are most exposed and have the fewest technical and social resources.

Low-lying, poorly resourced populations would be particularly vulnerable to an increase in frequency of storms and storm surges. In the 1970 Bangladesh cyclone, mortality varied from around 5% inland to almost 50% in coastal communities. Widespread destruction of food supplies may also occur; in 1970, two-thirds of fishing activities along the coasts and plains in Bangladesh were destroyed, along with 125,000 animals (Alexander, 1993). In Andhra Pradhesh, India, in 1970, many victims died when wind and rain caused the collapse of houses (Sommer and Mosely, 1972).

Flash floods and landslides (see Chapter 12) would increase in frequency in regions experiencing increased torrential rainfall. Heavy rains can erode soil, thereby impairing agricultural productivity. Flooding also can affect the incidence of vector-borne diseases. On the one hand, flood waters may wash away mosquito eggs/larvae; on the other hand, residual water may increase mosquito populations and consequent infectious diseases. In southeastern Australia, epidemics of Ross River virus

infection follow heavy rains in the Murray-Darling basin (Nicholls, 1993). Flooding also may affect the transmission of diarrheal diseases: In Bolivia, for example, flooding associated with El Niño in 1983 led to a 70% increase in salmonella infections, particularly in children (Telleria, 1986).

Flash flooding is a leading cause of weather-related mortality in the United States (French and Holt, 1989). Damage to homes and displacement of residents may facilitate the spread of infectious diseases because of crowded living conditions. Flooding can contaminate water sources with fecal material or toxic chemicals. Flooding also increases runoff from agricultural lands and urban stormwater systems (Thurman *et al.*, 1991, 1992). Water resources thus are contaminated by toxic chemical wastes, agricultural chemicals, and pathogens (e.g., *Cryptosporidium*). Hazardous exposure may arise from contaminated drinking water and from edible fish that bioaccumulate contaminants.

The many psychosocial effects of natural disasters have been studied in survivors of storms, floods, earthquakes, and fires (e.g., Gregg, 1989). Severe disturbance (including "post-traumatic stress disorder") usually affects only a minority, many of whom recover (de Girolamo and McFarlane, 1994)—although children in affected families may show developmental problems over the ensuing years (Titchener and Frederic, 1976). The level of psychological impact may depend upon the suddenness and unexpectedness of the impact, the intensity of the experience, the degree of personal and community disruption, and long-term exposure to the visual signs of the disaster (Green, 1982; Green *et al.*, 1991). Data from disasters in developing countries are sparse, but a follow-up study after the disastrous 1988 floods in Bangladesh showed increased behavioral disorders in young children (Durkin *et al.*, 1993).

Two final comments on extreme events are appropriate here. First, a major effect of extreme climatic events on human health has been malnutrition and starvation due to severe drought and its consequences (Escudero, 1985). This, in turn, causes increased susceptibility to infection (Tomkins, 1986). Second, there is evidence that environmental degradation, unequal access to resources, and population growth may be potent factors in provoking conflict (Homer-Dixon *et al.*, 1993). By affecting water and food supply, climate change could increase the possibility of violent conflicts in a number of regions.

18.3. Potential Indirect Health Impacts of Climate Change

The indirect effects of climate change upon health are those that do not entail a direct causal connection between a climatic factor (such as heat, humidity, or extreme weather event) and human biology.

18.3.1. Vector-Borne Diseases

The transmission of many infectious diseases is affected by climatic factors. Infective agents and their vector organisms are sensitive to factors such as temperature, surface water, humidity, wind, soil moisture, and changes in forest distribution (Bradley, 1993). This applies particularly to vector-borne diseases (VBDs) like malaria, which require an intermediate organism such as the mosquito to transmit the infective agent. It is therefore projected that climate change and altered weather patterns would affect the range (both latitude and altitude), intensity, and seasonality of many vector-borne and other infectious diseases. In general, increased warmth and moisture would enhance transmission of these diseases. However, any such climate-related redistribution of disease may also entail—perhaps in conjunction with other environmental stresses—some localized reductions in rates of infection.

The sustained (or endemic) transmission of VBDs requires favorable climatic-environmental conditions for the vector, the parasite, and, if applicable, the intermediate host species. For vectors with long life spans (e.g., tsetse flies, bugs, ticks), vector abundance is a major determinant of disease distribution; arthropods that transmit VBDs generally thrive in warmth and moisture. For vectors with short life spans (e.g., mosquitoes, sandflies, blackflies), the temperature-sensitive extrinsic maturation period of the parasite is of critical importance. The geographic distributions of many of the parasites, both unicellular (protozoa) and multicellular (e.g., flukes and worms), correlate closely with temperature (Gillet, 1974; Shope, 1991). The geographic distributions of vector-borne viral infections, such as dengue and yellow fever, are affected by temperature and surface water distribution. For many VBDs, such as plague and hantavirus, rodents act as intermediate infected hosts or as hosts for the arthropod vector (Wenzel, 1994); rodent activity would also tend to increase in a warmer world (Shope, 1991).

In tropical countries, VBDs are a major cause of illness and death. For the major VBDs, estimates of numbers of people at risk and infected, and of VBD sensitivity to climate change, are shown in Table 18-3. While the potential transmission of many such diseases would increase (geographically or from seasonal to year-round) in response to climate change, the capacity to control these diseases also will change. New or improved vaccines can be expected; some vector species can be constrained by use of pesticides. Nevertheless, there are uncertainties and risks here, too: for example, long-term pesticide use breeds resistant strains and kills many predators of pests.

18.3.1.1. Malaria

Malaria remains a huge global public-health problem, currently causing around 350 million new infections annually, predominantly in tropical countries. Malaria is caused by an infective parasite (plasmodium) transmitted between humans by a mosquito vector. Its incidence is affected by temperature, surface water, and humidity (Gill, 1920a, 1920b; Sutherst, 1983). Although anopheline mosquito species that transmit malaria do not usually survive where the mean winter temperature drops below 16–18°C, some higher-latitude species are able to hibernate in sheltered sites. Sporogonic development (i.e., the extrinsic incubation phase of

Table 18-3: *Major tropical vector-borne diseases and the likelihood of change of their distribution with climate change.*

Disease	Vector	Population at Risk (million)[a]	Number of People Currently Infected or New Cases per Year	Present Distribution	Likelihood of Altered Distribution with Climate Change
Malaria	Mosquito	2,400[b]	300–500 million	Tropics/Subtropics	+++
Schistosomiasis	Water Snail	600	200 million	Tropics/Subtropics	++
Lymphatic Filariasis	Mosquito	1,094[c]	117 million	Tropics/Subtropics	+
African Trypanosomiasis (Sleeping Sickness)	Tsetse Fly	55[d]	250,000–300,000 cases per year	Tropical Africa	+
Dracunculiasis (Guinea Worm)	Crustacean (Copepod)	100[e]	100,000 per year	South Asia/ Arabian Peninsula/ Central-West Africa	?
Leishmaniasis	Phlebotomine Sand Fly	350	12 million infected, 500,000 new cases per year[f]	Asia/Southern Europe/Africa/ Americas	+

the plasmodium within the mosquito) ceases below around 18°C for *Plasmodium falciparum* and below 14°C for *P. vivax*. Above those temperatures, a small increase in average temperature accelerates the parasite's extrinsic incubation (Miller and Warrell, 1990). Temperatures of 20–30°C and humidity above 60% are optimal for the anopheline mosquito to survive long enough to incubate and transmit the parasite.

Until recent decades, parts of today's developed world were malarious. These included the United States, southern Europe, and northern Australia. In the last century, outbreaks of *P. vivax* malaria occurred in Scandinavia and North America. Although climate change would increase the potential transmission of malaria in some temperate areas, the existing public-health resources in those countries—disease surveillance, surface-water management, and treatment of cases—would make reemergent malaria unlikely. Indeed, malaria is most likely to extend its spread (both latitude and altitude) and undergo changes in seasonality in tropical countries, particularly in populations currently at the fringe of established endemic areas (Martens *et al.*, 1994). Newly affected populations would initially experience high case fatality rates because of their lack of natural acquired immunity.

Box 18-1. Examples of Modeling the Future Impact of Climate Change upon Malaria

Mathematical models have been recently developed for the quantitative prediction of climate-related changes in the potential transmission of malaria (e.g., Sutherst, 1993; Matsuoka and Kai, 1994; Martin and Lefebvre, 1995). Note the use of the important word "potential" here; the models are primarily predicting where malaria could occur as a function of climate and associated environment, irrespective of the influence of local demographic, socioeconomic, and technical circumstances.

A simple model has been used for Indonesia, based on empirical historical data from selected provinces on the relationship of annual average temperature and total rainfall to the incidence of malaria (and dengue and diarrhea) (Asian Development Bank, 1994). The model forecasts that annual malaria incidence (currently 2,705 per 10,000 persons) would, in response to the median climate-change scenario, increase marginally by 2010 and by approximately 25% by 2070. Because of the limited technical information, it is not easy to appraise these particular forecasts.

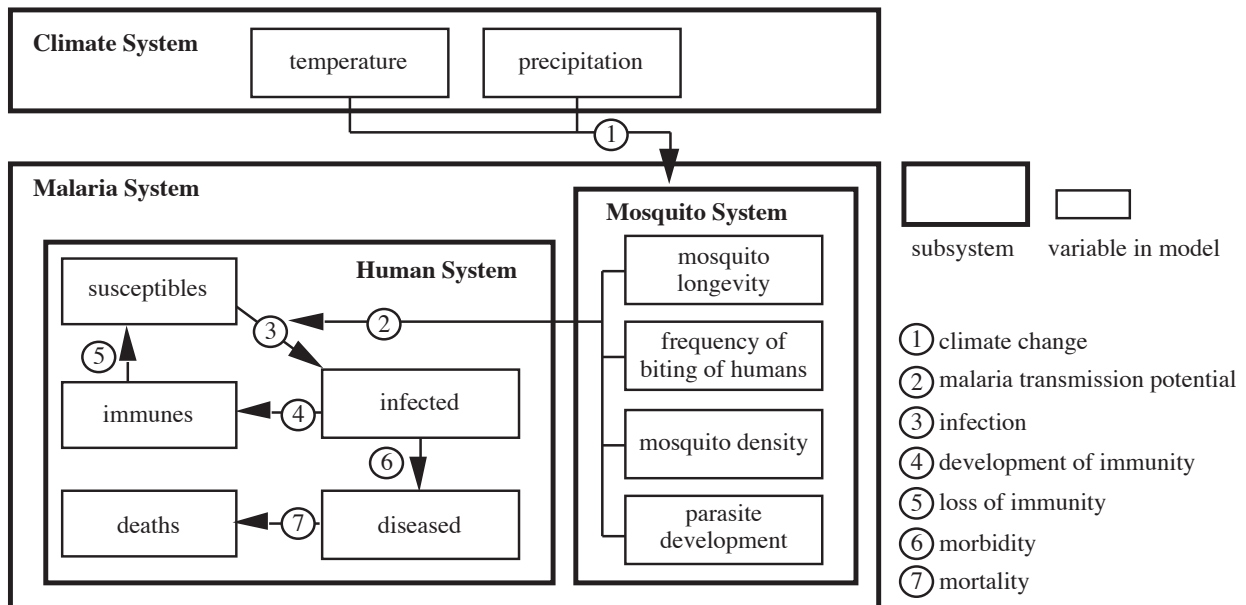
A more complex integrated global model has been developed by Martens *et al*. (1994). This model takes account of how climate change would affect the mosquito population directly—i.e., mosquito development, feeding frequency, and longevity—and the incubation period of the parasite inside the mosquito (see Figure 18-3). As a highly aggregated model, it does not take account of local environmental-ecological factors, and it therefore cannot be regarded as a source of precise projections. The model's output refers to geographic changes in *potential* transmission (i.e., the range within which both the mosquito and parasite could survive with sufficient abundance for sustained transmission of malaria). This is not, therefore, a projection of actual disease incidence, and it must be interpreted in relation to local control measures, health services, parasite reservoir, and mosquito densities. Further, until such models have been validated against historical data sets, their predictions must be viewed cautiously.


Figure 18-3: Systems diagram of a model designed to assess the impact of climate change on the potential transmission of malaria (adapted from Martens *et al*., 1994).

 This particular model predicts widespread increases in the potential habitat range and the "vectorial capacity" of the mosquito, and therefore potential malaria transmission, in response to climate change. For example, using GCM predictions of 3–5°C increases in global mean temperature by the year 2100, the malaria epidemic potential of the mosquito population is estimated to increase twofold in tropical regions and substantially more than tenfold in temperate climates (Martens *et al*., 1995a). Overall, there is an increase from around 45% to around 60% of the world population living within the potential malaria transmission zone by the latter half of the next century. However, most of the developed countries have effective control and surveillance measures that should preclude reintroduction of endemic malaria. In the already endemic areas, especially in the subtropics, malaria may increase (although in some hot climates, further temperature increases may shorten the life span of mosquitoes, and local malaria transmission would then decrease). In particular, in adjoining areas of lower endemicity or unstable malaria, the occurrence of infection is far more sensitive

---

Box 18-1 (continued)

to climate variation, so climate change may have a marked effect on its incidence and stability. Simulations with this model, using several different GCMs, predict a climate-induced increase in the incidence of annual malaria cases of approximately 50–80 million in response to a temperature rise of around 3°C by the year 2100, relative to an assumed approximate base of 500 million annual cases in a 2100 world without climate change (Martens *et al*., 1995b).

Another recent attempt at aggregated global modeling (Martin and Lefebvre, 1995) has predicted that potential malaria transmission would spread to higher latitudes, while some currently stable endemic areas near the equator would become unstable, leading to reductions in population immunity levels.

Such models, despite their highly aggregated predictions and simplifying assumptions, provide indicative information about the likely impact of climate change on the potential transmission of vector-borne diseases (assuming that other relevant factors remain constant). There is a clear need for validation of these models and for incorporating more extensive detail into them. Meanwhile, this line of research has begun to elucidate the interdependent relationships among climate change, vector population dynamics, and human disease dynamics.

Recent evidence of the responsiveness of malaria incidence to local climate change comes from observations of marked increases in malaria incidence in Rwanda in 1987, when atypically hot and wet weather occurred (Loevinsohn, 1994), and annual fluctuations in falciparum malaria intensity in northeast Pakistan that correlated with annual temperature variations during the 1980s (Bouma *et al*., 1994). Hence, it is a reasonable prediction that, in eastern Africa, a relatively small increase in winter temperature could extend the mosquito habitat and thus enable falciparum malaria to reach beyond the usual altitude limit of around 2,500 m to the large, malaria-free, urban highland populations, e.g., Nairobi in Kenya and Harare in Zimbabwe. Indeed, the monitoring of such populations around the world, currently just beyond the boundaries of stable endemic malaria, could provide early evidence of climate-related shifts in malaria distribution (Haines *et al*.,1993).

18.3.1.2. African Trypanosomiasis

African trypanosomiasis, or "sleeping sickness," is transmitted by tsetse flies. The disease is a serious health problem in tropical Africa, being generally fatal if untreated. Research in Kenya and Tanzania shows only a very small difference in mean temperature between areas where the vector, *Glossina morsitans,* does and does not occur. This indicates that a small change in temperature may significantly affect the limits of the vector's distribution (Rogers and Packer, 1993).

18.3.1.3. American Trypanosomiasis (Chagas' Disease)

American trypanosomiasis is transmitted by insects of the subfamily *Triatominae*. It is a major problem in Latin America, with 100 million people at risk and 18 million infected (WHO, 1995c). An estimated 15–20% of infected people develop clinical Chagas' disease. Most of the triatomine vector species need a minimum temperature of 20°C for feeding and reproduction (Curto de Casas and Carcavallo, 1984), but at higher

temperatures (28–30°C) they feed more frequently, have a shortened life cycle, and an increased population density (Carcavallo and Martinez, 1972, 1985). At even higher temperatures, the most important vector species, *Triatoma infestans*, doubles its reproductive rate (Hack, 1955).

18.3.1.4. Schistosomiasis

Schistosomiasis is a water-based disease caused by five species of schistosomal flukes. Water snails act as the intermediate host (and, strictly speaking, are not active "vectors"). The infection has increased in worldwide prevalence since mid-century, perhaps largely because of the expansion of irrigation systems in hot climates, where viable snail host populations interact with infected humans (White *et al*., 1972; Grosse, 1993; Hunter *et al*., 1993).

Data from both the field and the laboratory indicate that temperature influences snail reproduction and growth, schistosome mortality, infectivity and development in the snail, and human-water contact (Martens *et al*., 1995b). In Egypt, for example, water snails tend to lose their schistosome infections during winter, but if temperatures increase, snails may mediate schistosomiasis transmission throughout the year (Gillet, 1974; WHO, 1990). Predictive modeling indicates that a change in background temperatures may cause the infection to extend to currently unaffected regions. Fluctuations in temperature may also play an important role in optimizing conditions for the several life-cycle stages of schistosomiasis (Hairston, 1973).

18.3.1.5. Onchocerciasis (River Blindness)

Onchocerciasis, or "river blindness," is a VBD affecting approximately 17.5 million people—some in Latin America, most in West Africa. The vector is a small blackfly of the genus *Simulium*, and the infectious agent is the larva of the *Onchocerca volvulus* parasite. This threadlike worm damages the skin, the

lymphatic system, and, in the most extreme cases, the eye. Climate affects the occurrence of onchocerciasis because the vector requires fast-flowing water for successful reproduction (WHO, 1985), and the adult vector can be spread by wind.

A recent simulation study on the potential impact of climate change on blackfly populations in West Africa showed that if temperature and precipitation were to change across parts of the sub-Sahel, as predicted by the Goddard Institute for Space Studies (GISS) GCM (Hansen *et al.,* 1988), blackfly populations may increase by as much as 25% at current breeding sites (Mills, 1995). Since these vectors can travel hundreds of kilometers on wind currents, new habitats in previously unsuitable areas could be quickly colonized by blackflies, introducing onchocerciasis into new areas (Garms *et al.*, 1979; Walsh *et al.*, 1981; WHO, 1985).

18.3.1.6. Trematode Infections

Some trematode infections, such as fascioliasis (a liver fluke that currently affects around 2.4 million persons), would be affected by climate changes because the life cycle and population size of the snail host are very sensitive to temperature. Similarly, the incidence of cercarial dermatitis (skin inflammation) would be increased at higher temperatures. This infection is currently found in Europe (Beer and German, 1994) and the United States (CDC, 1992), where it causes "swimmer's itch"; its incidence has recently increased in Russia (Beer and German, 1993) and in very poor rural communities in developing countries.

18.3.1.7. Vector-Borne Viral Infections

Many vector-borne infective agents are viruses. The human-infecting arboviruses (i.e., arthropod-borne viruses) generally have a mosquito vector. Arboviral infections span a wide clinical spectrum, from those that cause mild feverish illness or subclinical infections to those causing severe and often fatal encephalitis (brain inflammation) or hemorrhagic fever. Under favorable environmental conditions, an arboviral disease can become epidemic (population-wide), from a local endemic base or by its introduction to a previously unaffected area. The distribution and abundance of vectors are influenced by various physical factors (temperature, rainfall, humidity, and wind) and biological factors (vegetation, host species, predators, parasites, and human interventions) (WHO, 1990). Temperature also affects the rapidity of the virus' life cycle—e.g., the extrinsic incubation period for the mosquito-hosted stage of the yellow fever virus varies from several weeks to 8–10 days, depending on temperature.

Increased temperature and rainfall in Australia would influence the range and intensity of various vector-borne viral infections. For example, certain arthropod vectors and natural vertebrate hosts would spread southward and proliferate in response to warming and increased rain, resulting in increased incidence of arboviral infections such as Murray Valley encephalitis (which

can cause serious brain damage), Ross River virus (which causes multiple, often long-lasting joint inflammation), and dengue (e.g., Sutherst, 1993; Nicholls, 1993).

Dengue is a severe influenza-like disease, which in some cases may take the form of a hemorrhagic fever, which can cause an average of 15% mortality without proper medical attention. Dengue is transmitted by the *Aedes aegypti* mosquito, as is urban yellow fever. In parts of Asia, dengue also is transmitted by *Ae. albopictus,* which now is colonizing North and South America. Research in Mexico has shown that an increase of 3–4°C in average temperature doubles the rate of transmission of the dengue virus (Koopman *et al.*, 1991). Although there is no clear evidence of regional climatic influence, annual epidemics of dengue have returned to Central America over the past decade (as they did about twenty years ago in Asia), and, in Mexico, dengue has recently spread to previously unaffected higher altitudes (Herrera-Basto *et al.*, 1992). *Ae. aegypti* mosquitoes, once limited to 1,000 meters altitude by temperature in Colombia, have been recently reported above 2,200 meters. The habitat of the mosquito is restricted to areas with a mean midwinter temperature of more than 10°C. Epidemic transmission of dengue is seldom sustained at temperatures below 20°C (Halstead, 1990).

18.3.1.8. Other Vector-Borne Diseases

VBDs are now relatively rare in most developed countries; however, it has been predicted that various VBDs might enter or increase in incidence in the United States because of higher temperatures (Longstreth, 1989; Freier, 1993; Martens *et al.*, 1994); Venezuelan equine encephalitis, dengue, and leishmaniasis could extend into the southern United States; Western equine encephalitis might move further north within the United States (Reeves *et al.,* 1994). The dengue-transmitting *Ae. albopictus* mosquito, which is more cold-hardy than *Ae. aegypti,* is now well established in the United States and may extend toward Canada if temperatures increase.

Climate change would influence the global pattern of VBDs via other disturbances of ecological relationships. For example, it would bring together vertebrate animals of different species and would thereby expose animals to new arthropod vectors. Warming (and rising sea levels) would displace some human populations, perhaps resulting in migration into wilderness areas where zoonotic infectious agents are being transmitted in silent wildlife cycles. Migratory humans would thus be at risk of infection with enzootic (i.e., locally prevalent animal-infecting) agents. Climate-induced changes in ecology also could force the rapid evolution of infectious agents, with newly emergent strains of altered virulence or pathogenicity. Additionally, changes in climate means and variability can disrupt predator/prey ratios, thus loosening natural controls on pests and pathogens.

Two other general points should be noted. First, because vector control methods exist for many of these diseases, developed

countries should be able to minimize their impact. Second, however, the quicker "turnover" of the life cycle of parasites at higher temperatures will increase their likelihood of evolving greater resistance to drugs and other control methods. This would pose a particular problem to those tropical countries with high infection rates and limited socioeconomic resources.

18.3.2. Water-Borne and Food-Borne Infectious Diseases

Climatic effects on the distribution and quality of surface water—including increases in flooding and water shortages that concentrate organisms, impede personal hygiene, and impair local sewerage—would influence the risks of diarrheal (including cholera) and dysentery epidemics, particularly in developing countries. Diarrheal diseases can be caused by a large variety of bacteria (e.g., *Salmonella*, *Shigella*, and *Campylobacter*), viruses (e.g., *Rotavirus*), and protozoa (e.g., *Giardia lamblia*, amoebas, and *Cryptosporidium*). Many of these organisms can survive in water for months, especially at warmer temperatures, and increased rainfall therefore could enhance their transport between groups of people. An increased frequency of diarrheal disease is most likely to occur within impoverished communities with poor sanitation. There have been outbreaks of diarrheal disease after flooding in many such settings. If flooding increased, there also would be risks of outbreaks of infection in developed countries within temporary settlements of displaced communities.

The cholera organism, *Vibrio cholerae*, can survive in the environment by sheltering beneath the mucous outer coat of various algae and zooplankton—which are themselves responsive to climatic conditions and to nutrients from wastewater and fertilizers (Epstein, 1992; Smayda, 1990; Anderson, 1992). Increases in coastal algal blooms may therefore amplify *V. cholerae* proliferation and transmission. This might also assist the emergence of new genetic strains of vibrios. Algal blooms also are associated with biotoxin contamination of fish and shellfish (Epstein *et al*., 1993). With ocean warming, toxins produced by phytoplankton, which are temperature-sensitive, could cause contamination of seafood more often (see also Chapter 16), resulting in increased frequencies of amnesic, diarrheic and paralytic shellfish poisoning and ciguatera poisoning from reef fish. Thus, climate-induced changes in the production of both aquatic pathogens and biotoxins may jeopardize seafood safety for humans, sea mammals, seabirds, and finfish.

Climate change also could create a problem via the warming of aboveground piped-water supplies. In parts of Australia, for example, there has been a seasonal problem of meningoencephalitis caused by the *Naegleria fowleri* amoeba, which proliferates in overland water pipes in summer (NHMRC, 1991). Soil-based pathogens (e.g., the tetanus bacterium and various fungi) would tend to proliferate more rapidly with higher temperature and humidity, depending on the effectiveness of microclimatic homeostatic mechanisms. Higher temperatures would also increase the problem of food poisoning by enhancing the

survival and proliferation of bacteria, flies, cockroaches, and so forth in foodstuffs.

18.3.3. Agricultural Productivity and Food Supplies: Effects upon Nutrition and Health

Food, as energy and nutrients, is fundamentally important to health. Malnutrition is a major cause of infant mortality, physical and intellectual stunting in childhood, and immune impairment (thus increasing susceptibility to infections). Currently, around one-tenth of the world's population may be hungry (Parry and Rosenzweig, 1993) and a larger proportion malnourished—although estimates differ according to definition.

Human societies have evolved farming methods to counter various local climatic and environmental constraints on agriculture, especially via irrigation, fertilization, mechanization, and the breeding of better-adapted varieties. Today, as gains in per capita agricultural productivity appear to be diminishing, widespread land degradation accrues, and access to new arable land is declining, the further possibility exists of adverse effects of climate change upon aspects of world food production (Houghton *et al*., 1990; Kendall and Pimentel, 1994). The impacts of climate change upon crop and livestock yield would be realized within a complex setting that encompasses climate change scenarios, crop yield response, pest population response, demographic trends, patterns of land use and management, and social and economic responses.

18.3.3.1. Modes of Climatic Impact upon Agricultural Productivity

Global warming would alter regional temperature and rainfall. Changes in these two major influences on agriculture, and consequent reductions in soil moisture, could impair the growth of many crops. Increases in the intensity of rainfall in some regions would exacerbate soil erosion. The net global impact of these climate-related changes upon food production is highly uncertain (Reilly, 1994). Although the IPCC assessment is uncertain about the overall impact, it foresees productivity gains and losses in different regions of the world (see Chapter 13). While productivity may increase initially, longer-term adaptations to sustained climate change would be less likely because of the limitations of plant physiology (Woodward, 1987).

Climate change also could affect agriculture by long-term changes in agroecosystems, by an increased frequency and severity of extreme events, and by altered patterns of plant diseases and pest infestations (e.g., Farrow, 1991; Sutherst, 1991). Debate persists over whether enrichment of the atmosphere with carbon dioxide will have a "fertilization effect" (Idso, 1990b; Bazzar and Fajer, 1992; Körner, 1993). Experiments consistently indicate that C_3 plants (e.g., wheat, soya beans, rice, and potatoes) would respond more positively than C_4 plants (e.g., millet, sorghum, and maize), which would be unaffected (see Chapter 13). This effect may be temperature-dependent (Vloedbeld and

Leemans, 1993). Such influences on the climatically optimal mix of crop species would disturb patterns of traditional agriculture in some regions.

18.3.3.2. Impacts upon Food Supplies, Costs, and the Risk of Hunger

Since climate change may threaten food security in poorer countries within the semi-arid and humid tropics (Rosenzweig *et al.*, 1993; see also Chapter 13), poorer countries, already struggling with large and growing populations and marginal climatic conditions, would be particularly vulnerable to food shortages, malnutrition, and demographic disruption. In such countries, there is minimal capacity for adaptive change (Leemans, 1992). Already in Africa, more than 100 million people are "food insecure," many of them in the arid Sahel region. The cost of food on world markets would increase if crop production declined in the world's mid-latitude breadbasket regions. The large minority of the world population that already suffers from malnutrition would then face an increased threat to health from agricultural failure and rising food costs. A recent analysis predicts an extra 40–300 million people at risk of hunger in the year 2060 because of the impact of climate change, on top of a predicted 640 million people at risk of hunger by that date in the absence of climate change (Rosenzweig *et al.*, 1993).

18.3.3.3. Impacts of Climate Change on Non-Cereal Food Production

Climate change may influence the production of noncrop food supplies, including animal productivity. For example, the U.S. Environmental Protection Agency has identified several infectious diseases—such as the horn fly in beef and dairy cattle and insect-borne anaplasmosis infection in sheep and cattle—that could increase in prevalence in response to climate changes (Rosenzweig and Daniel, 1989). An increase in temperature and temperature extremes also could affect the growth and health of farm animals (Furquay, 1989); young animals are much less tolerant of temperature variation than are adult animals (Bianca, 1976).

Changes in ocean temperatures and currents could affect the base of the marine food web and alter the distribution, migration, and productivity of fish species, a major source of protein for many human populations (Glantz, 1992). Increased soil erosion from intensified rainfall raises the turbidity of lakes and rivers, reducing photosynthesis and therefore fish nutrition. As in agriculture, climate change may contribute to the decline of some fisheries and the expansion of others (see Chapter 16).

18.3.4. Health Impacts of Sea-Level Rise

Each of the vast changes in sea level that have occurred during the past million years, before and after ice ages, typically took many thousands of years. The predicted rise of around half a meter over the next century (see Chapter 7, *Changes in Sea Level*, of the IPCC Working Group I volume) would be much faster than anything experienced by human populations since settled agrarian living began. Such a rise would inundate much of the world's lowlands, damage coastal cropland, and displace millions of persons from coastal and small island communities (see Chapter 12).

Much of coastal Bangladesh and Egypt's heavily populated Nile Delta would be flooded. Some low-lying, small island states such as the Maldives and Vanuatu would be at risk of partial immersion, and many other low-lying coastal regions (for example, eastern England, parts of Indonesia, the Florida Everglades, parts of the northeast coast of Latin America) would be vulnerable. The displacement of inundated communities—particularly those with limited economic, technical, and social resources—would greatly increase the risks of various infectious, psychological, and other adverse health consequences.

Sea-level rise could have a number of other effects, of varying directness, upon public health. In some locations, it could disrupt stormwater drainage and sewage disposal. Poverty and the absence of social infrastructure would compound the health consequences of storm damage, disruption of sanitation, and displacement of coastal dwellers. In many places, industrial and agricultural depletion of groundwater already are causing land subsidence, thus decreasing the threshold for impact. Meanwhile, widespread damage to coral reefs is reducing their capacity to buffer shorelines. Rising seas also would cause saltwater to encroach upon freshwater supplies from estuarine and tidal areas. Some changes in the distribution of infectious disease vectors could occur (e.g., *Anopheles sundaicus*, a saltwater vector of malaria).

18.3.5. Climate and Air Pollution: Impacts on Respiratory and Other Health Disorders

The incidence of respiratory disorders—many of which are caused primarily by dusts, noxious gases, allergic reactions, or infections—may be modulated by climate change. Some of these modulatory effects may occur via extreme temperatures or amplification of pollutant levels. Rapid changes in air masses associated with frontal passages may alter the intensity of respiratory illnesses (Ayres, 1990). People with chronic obstructive pulmonary disease (bronchitis and emphysema) often experience exacerbation during winter.

Seasonal allergic disorders would be affected by changes in the production of pollen and other biotic allergens; plant aeroallergens are very sensitive to climate (Emberlin, 1994). Changes in pollen production would principally reflect changes in the natural and agriculturally managed distribution of many plant species—for example, birch trees, grasses, various crops (e.g., oilseed rape, sunflowers), and ragweed species. Hay fever (allergic rhinitis) increases seasonally and may reflect the impact of pollen release. The seasonal distribution and the causation/exacerbation of asthma is more complex. It peaks in the pollen

season and increases again later in the year in temperate climates; in the tropics, asthma occurs more frequently in the wet season (LAIA, 1993; *Lancet*, 1985). In many asthmatic individuals, aspects of weather can exacerbate bronchial hyperresponsiveness. For example, the passage of a cold front followed by strong high pressure was found to be associated with unusually high number of asthma admission days in two U.S. cities (Goldstein, 1980). Sandstorms in Kansas (USA) and the Sudan have been accompanied by increases in bronchitis and asthma (Ayres, 1990).

It is well established that exposure to air pollutants, individually and in combinations, has serious public health consequences. For example, exposure to ozone has been shown to exacerbate asthma and impair lung function in children and the elderly (Beckett, 1991; Schwartz, 1994), and both chronic and acute exposures to fine particles are a cause of excess deaths (Dockery *et al.*, 1993; Pope *et al.*, 1995; Schwartz, 1994) even at exposures below prevailing air-quality standards. Since the combustion of fossil fuels is a major source of both carbon dioxide (a major greenhouse gas) and various air pollutants, climate change can be expected to entail more frequent occasions that combine very hot weather with increases in air-pollutant concentrations. In urban environments, the weather conditions that characterize oppressive air masses (see Section 18.2.1) also enhance the concentrations of air pollutants (Seinfeld, 1986); conditions of low wind speed and high humidity occur periodically in which neither heat nor air pollutants are rapidly dispersed. Further, increases in temperature or in ultraviolet irradiation of the lower atmosphere enhance the chemical reactions that produce secondary photochemical oxidant pollutants such as tropospheric ozone (Akimoto *et al.*, 1993; de Leeuw and Leyssius, 1991; Chamiedes *et al.*, 1994).

In many urban settings, studies have shown that daily mortality from cardiovascular and respiratory diseases is a combined function of temperature and air pollutant concentrations. This combination of exposures is also likely to have interactive impacts on health. Indeed, some epidemiological evidence indicates a synergy (a positive interaction) between stressful weather and various air pollutants, especially particulates, upon mortality (e.g., Shumway *et al.*, 1988; Katsouyanni *et al.*, 1993; Shumway and Azari, 1992). The net effect on morbidity/mortality therefore would be greater than anticipated from prior estimates of the separate effects of weather and pollutants.

18.4. Stratospheric Ozone Depletion and Ultraviolet Radiation: Impacts on Health

Stratospheric ozone depletion is a quite distinct process from accumulation of greenhouse gases in the lower atmosphere (troposphere). Depletion of stratospheric ozone has recently occurred in both hemispheres, from polar regions to mid-latitudes (Kerr and McElroy, 1993; see also IPCC Working Group I volume). The major cause of this ongoing depletion is human-made gases, especially the halocarbons (UNEP, 1994).

The problem can be considered alongside climate change for three reasons: (1) several of the greenhouse gases (especially the chlorofluorocarbons) also damage stratospheric ozone; (2) altered temperature in the troposphere may influence stratospheric temperature and chemistry (Rind and Lacis, 1993); and (3) absorption of solar radiation by stratospheric ozone influences the heat budget in the lower atmosphere (see also IPCC Working Group I volume).

Stratospheric ozone absorbs part of the sun's incoming ultraviolet radiation (UVR), including much of the UV-B and all of the highest-energy UV-C. Sustained exposure to UV-B radiation is harmful to humans and many other organisms (UNEP, 1994). It can damage the genetic (DNA) material of living cells and can induce skin cancers in experimental animals. UV-B is implicated in the causation of human skin cancer and lesions of the conjunctiva, cornea, and lens; it may also impair the body's immune system (Jeevan and Kripke, 1993; Armstrong, 1994; UNEP, 1994).

18.4.1. Skin Cancers

Solar radiation has been consistently implicated in the causation of nonmelanocytic and melanocytic skin cancers in fair-skinned humans (IARC, 1992; WHO, 1994b).

Nonmelanocytic skin cancers (NMSCs) comprise basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). The incidence rates, especially of squamous cell carcinoma, correlate with cumulative lifetime exposure to solar radiation (IARC, 1992; Kricker *et al.*, 1995). Studies of the action spectrum (i.e., the relative biological effect of different wavelengths) for skin carcinogenesis in mice indicate that the UV-B band is primarily responsible for NMSC (Tyrrell, 1994). Malignant melanoma arises from the pigment-producing cells (melanocytes) of the skin. Although solar radiation is substantially involved in melanoma causation (IARC, 1992; Armstrong and Kricker, 1993), the relationship is less straightforward than for NMSC; exposure in early life appears to be a major source of increased risk. The marked increases in incidence of melanoma in Western populations over the past two decades (Coleman *et al.*, 1993) probably reflect increases in personal exposure to solar radiation due to changes in patterns of recreation, clothing, and occupation (Armstrong and Kricker, 1994).

The UN Environment Programme predicts that an average 10% loss of ozone (such as occurred at middle-to-high latitudes over the past decade), if sustained globally over several decades, would cause approximately 250,000 additional cases of NMSC worldwide each year (UNEP, 1994). This prediction assumes that a 1% depletion of stratospheric ozone results in a 2.0% (±0.5%) increase in NMSC incidence (80% of which are BCC). Another estimation of this "amplification factor" gives a figure of 2.25% (Slaper *et al.*, 1992; den Elzen, 1994). At higher geographic resolution, Madronich and de Gruijl (1993) predict that persistence of the ozone losses of the 1979–92

period for several decades would cause the incidence of BCC to increase by 1–2% at low latitude (5°), 3–5% at 15–25°, 8–12% at 35–45°, and, at 55–65°, by 13–15% in the northern hemisphere and 20–30% in the south. They estimate that the percentage increases for SCC would be approximately double those for BCC.

18.4.2. Cataracts and Other Damage to the Eye

The external epithelial (keratotic) layer of the eye, comprising cornea and conjunctiva, absorbs virtually all UVR of less than 290 nm wavelength. Corneal photokeratitis, pterygium (a growth of the conjunctival epithelium), and climatic droplet keratopathy are thought to be UVR-related (Taylor *et al.*, 1989; Gray *et al.*, 1992; WHO, 1994b). Inside the eye, the lens absorbs much of the residual UVR, and this absorbed radiation may cause cataracts (Taylor *et al.*, 1988; Dahlback *et al.*, 1989; West *et al.*, 1989; WHO, 1994b).

Cataracts (lens opacities) are independent of skin pigmentation (unlike skin cancer). They occur predominantly in old age and cause more than half of the world's estimated 25–35 million cases of blindness (Harding, 1991). In Western countries, 5–10% of people aged over 65 have cataracts (Klein *et al.*, 1992). The prevalence often is much higher among elderly, malnourished persons in poor countries, where micronutrient deficiencies and the metabolic consequences of severe diarrheal episodes may contribute to cataract formation (Harding, 1992). Scientific debate persists over the extent of the influence of UV-B upon cataract formation (Dolin, 1994; WHO, 1994b); some epidemiological studies have found clear-cut positive results, but others have not. The relationship is most evident for cortical and posterior subcapsular cataracts but less so for the more commonly occurring nuclear cataracts.

Ocular photodamage by UVR is enhanced by certain clinical drugs used in photochemical therapy that can cause photosensitizing reactions (Lerman, 1988). Various other photosensitizing medications would render individuals generally more susceptible to adverse health effects from increased exposure to UVR; these medications include psoralens, thiazides, phenothiazines, barbiturates, allopurinol, and retinoic acid compounds (Lerman, 1986).

18.4.3. Alteration of Immune Function

Human and animal evidence indicates that UV-B irradiation of skin at quite modest levels causes local and, probably, systemic suppression of immunity (Morison, 1989; Noonan and DeFabo, 1990; Jeevan and Kripke, 1993). Most of the evidence is for local immunosuppression, in which the skin's contact hypersensitivity response is impaired (Giannini, 1986; Yoshikawa *et al.*, 1990; UNEP, 1994). UV-B exposure disturbs the function of the skin's Langerhan cells and stimulates the release of certain cytokines (messenger chemicals) that promote the activity of suppressor T lymphocytes, thus dampening the local immune system (UNEP, 1994).

Evidence for more generalized (i.e., systemic) suppression of immunity comes from studies in humans, which show that sunlight exposure increases the suppressor T cells in blood (Hersey *et al.*, 1983). Although there is evidence in humans of UV-induced changes in the profile of circulating immunologically active lymphocytes for several days to weeks, the extent of systemic immune suppression involved remains uncertain (de Gruijl and van der Leun, 1993). Systemic suppression also occurs in UV-irradiated mice (Kripke, 1981; Jeevan and Kripke, 1990).

Immune suppression would alter susceptibility to infectious diseases (Armstrong, 1994). Exposure to UV-B modifies various immunological reactions in mice that influence the pathogenesis of infectious diseases, such as those due to *Herpes simplex* viruses (Otani and Mori, 1987; Yasumoto *et al.*, 1987), leishmania (Gianinni, 1986; Giannini and DeFabo, 1989), candida (Denkins *et al.*, 1989), and mycobacteria (Jeevan and Kripke, 1989). The relevance of these findings for naturally occurring infectious diseases, and for vaccination efficacy, in humans remains unknown. UNEP (1994) concluded that: "It will be very difficult to assess the role of UV-B radiation on natural infections in human populations. Based on current knowledge, we would predict that an effect of UV-B radiation would manifest as an increase in the severity or duration of disease and not necessarily as an increase in disease incidence."

18.4.4. Indirect Effects of Ozone Depletion upon Human Health

An increase in UV-B irradiance is predicted to impair photosynthesis on land and sea (UNEP, 1994). Although the magnitude is uncertain, and may well not be large, there would be at least a marginal reduction in crop yields (Worrest and Grant, 1989) and in the photosynthetic production of biomass by marine phytoplankton, the basis of the aquatic food chain (Smith and Baker, 1989; Smith *et al.*, 1992). Thus, adverse effects of UV-B upon photosynthesis would, to some extent, reduce global food production.

18.5. Options for Adaptation

Various adaptation strategies are possible to reduce the impacts of climate change on human health. Such adaptation could be developed at the population or individual level. The feasibility of adaptation would be constrained for many of the world's populations by a lack of local resources.

At the population level, environmental management of ecosystems (e.g., freshwater resources, wetlands, and agricultural areas sensitive to invasion by vectors), public health surveillance and control programs (especially for infectious diseases), and introduction of protective technologies (e.g., insulated buildings, air conditioning, strengthened sea defences, disaster warning systems) would be important. Improved primary health care for vulnerable populations could play a significant

role in reducing a range of health impacts, including some vector-borne and other communicable diseases, and the effects of extreme events. One example is extension of vaccination coverage, although no suitable vaccines exist for some of the diseases most sensitive to climate change (e.g., dengue and schistosomiasis) or for many of the newly emerging infections.

At the individual level, people should be encouraged to refrain from or to limit dangerous exposures (e.g., by use of domestic cooling, protective clothing, mosquito nets). Such behavioral responses could complement any physiological adaptation that might occur spontaneously through acclimatization (to heat stress) or acquired immunity (to infectious diseases).

In view of limitations to the forecasting of health impacts at this stage of our knowledge, an important and practical form of adaptation would be to improve large-scale monitoring and surveillance systems, especially for vulnerable populations and areas. Recently initiated efforts to observe and monitor aspects of the Earth's environment and ecosystems in relation to climate change now should incorporate health-related monitoring (Haines *et al*., 1993). Advances in climate forecasting and in the regional integration of ecological and health monitoring (including local vulnerability factors) will facilitate development of early-warning systems.

Finally, if health impacts of climate change are probable and serious, then the only effective long-term basis for mitigation lies in primary prevention at the societal level. This would require acceptance of the Precautionary Principle as the foundation of policy response. This, in turn, would suggest some fundamental, and therefore difficult, reorientations of social, economic, and political priorities. Meanwhile, care must be taken that alternative technologies do not introduce new health hazards.

18.6.   Research Needs

- Development and validation of integrated mathematical models for the prediction of health impacts. Such models must draw on multiple scientific disciplines and should take maximal account of regional and local influences on the effects being modeled and on their interaction with other environmental stresses.
- Identification and analysis of current or recent settings in which the health impacts of local or regional climate changes (occurring for whatever reason) can be studied. The apparent recent changeable patterns of infectious diseases around the world may afford good opportunities for clarifying and quantifying the influences of climatic factors.
- Incorporation of health-related measurements in global, regional, and local monitoring activities. This would enhance the early detection of shifts in health

risks, the evaluation of alternative indices for monitoring health (including the use of sensitive species as bioindicators), and the opportunity to detect and/or examine previously unsuspected or undocumented environment–health relationships.

- Some specific research needs include:
  - Comparison of impacts of heat waves in urban and rural populations, to clarify the relative importance of thermal stress and air pollutants
  - Examination of the interplay between climatic impacts on forests and other terrestrial ecosystems on the range and dynamics of vector-borne disease
  - Study of factors influencing population vulnerability to climate change.

18.7.   Concluding Remarks

Forecasting the health impacts of global climate change entails unavoidable uncertainty and complexity. Human populations vary greatly in their vulnerability to climate changes and in their resources for protection and mitigation. Likewise, the responses of infectious disease vectors to changes in climate depend greatly on other concomitant environmental stresses and the adequacy of control measures and health care systems. Meanwhile, population health status continues to be influenced by a rich mix of cultural and socioeconomic factors. Hence, assessing the health impact of climate change requires a systems-based modeling approach that integrates information about climatic factors, other environmental stresses, ecological processes, and social-economic-political inputs and responses.

Alongside the need for improved health impact assessment capability is a precautionary need to develop global, regional, and local monitoring systems for the early detection of climate-induced changes in human health. There have, indeed, been various recent events that, plausibly, might be early signals of such change. The increased heat-related deaths in India in 1995; the changes in geographic range of some vector-borne diseases; the coastal spread of cholera: Could these be early indications of shifts in population health risk in response to aspects of climate change? Of course, it is not possible to attribute particular, isolated events to a change in climate or weather pattern; other plausible explanations exist for each of them, and a number of different factors may combine to produce each event. However, it is important that we begin to assess patterns of change in the various indices of human health that will provide early insight and will assist further the development of predictive modeling.

There is thus a clear need for enhanced research and monitoring activities. This need reflects the assessment that the potential health impacts of climate change, particularly if sustained in the longer term and if generally adverse, could be a serious consequence of the ongoing anthropogenic changes in the composition of Earth's atmosphere.

CONTENTS

EXECUTIVE SUMMARY

This review focuses on energy supply options that can sharply reduce greenhouse gas (GHG) emissions while providing needed energy services. By the year 2100, the world's commercial energy system will be replaced at least twice, which offers opportunities to change the present energy system in step with the normal timing of the corresponding investments, using emerging technologies in environmentally sound ways. Therefore, this assessment focuses on the performance of these emerging technologies.

Since the preparation of the IPCC 1990 Assessment Report, there have been some significant advances in the understanding of modern technology and technological innovations relating to energy systems that can reduce GHG emissions. Examples of such technologies are found, *inter alia*, in gas turbine technology; coal and biomass gasification technology; production of transportation fuels from biomass; wind energy utilization; electricity generation with photovoltaic and solar thermal electric technologies; approaches to handling intermittent generation of electricity; fuel cells for transportation and power generation; nuclear energy; carbon dioxide (CO_2) sequestering; and hydrogen as a major new energy carrier, produced first from natural gas and later from biomass, coal, and electrolysis.

In the energy supply sector, we conclude with a high degree of confidence that GHG emissions reductions can be achieved through technology options in the following areas (which have been ordered according to type of measure rather than priority):

- **More efficient conversion of fossil fuels**: New technology offers considerably increased conversion efficiencies. For example, the efficiency of power production can be increased from the present world average of about 30% to more than 60% in the longer term. Also, the use of combined heat and power production replacing separate production of power and heat—whether for process heat or space heating—offers a significant rise in fuel conversion efficiency.
- **Switching to low-carbon fossil fuels and suppressing emissions**: Switching from coal to oil or natural gas, and from oil to natural gas, can reduce emissions. Natural gas has the lowest CO_2 emissions per unit of energy of all fossil fuels at ~14 kg/GJ, compared to oil with ~20 kg/GJ and coal with ~25 kg/GJ. The lower carbon-containing fuels can, in general, be converted with higher efficiency than coal. Large resources of natural gas exist in many areas. New, low capital cost, highly efficient, combined-cycle technology has reduced electricity costs considerably in many areas. Natural gas could potentially replace oil in the transportation sector. Approaches exist to reduce emissions of methane from natural gas pipelines and emissions of methane and/or CO_2 from oil and gas wells and coal mines.

- **Decarbonization of flue gases and fuels, and CO_2 storage**: The removal and storage of CO_2 from fossil fuel power-station stack gases is feasible, but reduces the conversion efficiency and significantly increases the production cost of electricity. Another approach to decarbonization uses fossil fuel feedstocks to make hydrogen-rich fuels. Both approaches generate a byproduct stream of CO_2 that could be stored, for example, in depleted natural gas fields. The future availability of conversion technologies such as fuel cells that can efficiently use hydrogen would increase the relative attractiveness of the latter approach. For some longer-term CO_2 storage options, the costs and environmental effects and their efficacy remain largely unknown.
- **Increasing the use of nuclear energy**: Nuclear energy could replace baseload fossil fuel electricity generation in many parts of the world, if generally acceptable responses can be found to concerns such as reactor safety, radioactive-waste transport and disposal, and proliferation.
- **Increasing the use of renewable sources of energy**: Solar, biomass, wind, hydro, and geothermal technologies already are widely used. In 1990, renewable sources of energy contributed about 20% of the world's primary energy consumption, most of it fuelwood and hydropower. Technological advances offer new opportunities and declining costs for energy from these sources. In the longer term, renewable sources of energy could meet a major part of the world's demand for energy. Power systems can easily accommodate limited fractions of intermittent generation, and with the addition of fast-responding backup and storage units, also higher fractions. Where biomass is sustainably regrown and used to displace fossil fuels in energy production, net CO_2 emissions are avoided, as the CO_2 released in energy conversion is again fixed in biomass through photosynthesis. If the development of biomass energy can be carried out in ways that effectively address concerns about other environmental issues and competition with other land uses, biomass could make major contributions in both electricity and fuels markets.

In addition to climate change concerns, there are several concerns of an immediate nature that could be addressed by the energy supply options discussed here (except carbon sequestering); for example, modern renewable sources of energy are often beneficial for local and regional environmental problems (e.g., urban air pollution, indoor air pollution, and acid rain) and for some technologies (especially biomass), rural income and employment generation, and land restoration and preservation. These energy supply options can be pursued to varying degrees

within the limits of sustainable development criteria, which may however limit the exploitation of their full technical potential.

A wide range of modular renewable and other emission-reducing technologies are good candidates for cost-cutting through innovation and experience. For such technologies, the cost of the needed research, development, and demonstration (RD&D) and commercialization support is relatively modest (High Confidence).

Some technology options—for example, combined-cycle power generation—would penetrate the current marketplace. To realize other options, governments would have to take integrated action—by improving market efficiency (e.g., by eliminating permanent subsidies for energy), by finding new ways to internalize external costs, by accelerating RD&D on low- and zero-CO_2 emitting technologies, and by providing temporary incentives for early market development for these technologies as they approach commercial readiness. It is concluded with high confidence that the availability, cost, and penetration of technology options will strongly depend on such government action.

To assess the potential impact of combinations of individual measures at the energy system level, in contrast to the level of individual technologies, variants of a low CO_2-emitting energy supply system (LESS) are described. The LESS constructions are "thought experiments" exploring possible global energy systems.

The following assumptions were made: World population grows from 5.3 billion in 1990 to 9.5 billion by 2050 and 10.5 billion by 2100. GDP grows 7-fold by 2050 (5-fold and 14-fold in industrialized and developing countries, respectively) and 24-fold by 2100 (13-fold and 69-fold in industrialized and developing countries, respectively), relative to 1990. Because of emphasis on energy efficiency, primary energy rises much more slowly than GDP. The energy supply constructions were made to meet energy demand in (i) projections developed for the IPCC's First Assessment Report (1990) in a low energy demand variant, where global primary commercial energy use approximately doubles, with no net change for industrialized countries but a 4.4-fold increase for developing countries from 1990 to 2100; and (ii) a higher energy demand variant, based on the IPCC IS92a scenario where energy demand quadruples from 1990 to 2100. The energy demand levels of the LESS constructions are consistent with the energy demand mitigation chapters in this volume.

The analysis of the alternative LESS variants leads to the following conclusions:

- Deep reductions of CO_2 emissions from energy supply systems are technically possible within 50 to 100 years, using alternative strategies.
- Many combinations of the options identified in this assessment could reduce global CO_2 emissions from fossil fuels from about 6 Gt C in 1990 to about 4 Gt C per year by 2050, and to about 2 Gt C per year by 2100. Cumulative CO_2 emissions, from 1990 to 2100, would range from about 450 to about 470 Gt C in the alternative LESS constructions.

- Higher energy efficiency is underscored for achieving deep reductions in CO_2 emissions, for increasing the flexibility of supply-side combinations, and for reducing overall energy system costs.
- Interregional trade in energy grows in the LESS constructions compared to today's levels, expanding sustainable development options for Africa, Latin America, and the Middle East during the next century.

Costs for energy services in each LESS variant relative to costs for conventional energy depend on relative future energy prices, which are uncertain within a wide range, and on the performance and cost characteristics assumed for alternative technologies. However, within the wide range of future energy prices, one or more of the variants would plausibly be capable of providing the demanded energy services at estimated costs that are approximately the same as estimated future costs for current conventional energy. It is not possible to identify a least-cost future energy system for the longer term, as the relative costs of options depend on resource constraints and technological opportunities that are imperfectly known, and on actions by governments and the private sector.

The literature provides strong support for the feasibility of achieving the performance and cost characteristics assumed for energy technologies in the LESS constructions, within the next 1 or 2 decades, although it is impossible to be certain until the research and development is complete and the technologies have been tested in the market. Moreover, these performance and cost characteristics cannot be achieved without a strong and sustained investment in R&D. Many of the technologies being developed would need initial support to enter the market, and to reach sufficient volume to lower costs to become competitive.

Market penetration and continued acceptability of different technologies ultimately depend on their relative cost, performance (including environmental performance), institutional arrangements, and regulations and policies. Because costs vary by location and application, the wide variety of circumstances creates initial opportunities for new technologies to enter the market. Deeper understanding of the opportunities for emissions reductions would require more detailed analysis of promising clusters of options, taking into account local conditions.

Because of the large number of options, there is flexibility as to how the energy supply system could evolve, and paths of energy system development could be influenced by considerations other than climate change, including political, environmental (especially indoor and urban air pollution, acidification, and need for land restoration), and socioeconomic circumstances. Actual strategies for achieving deep reductions might combine elements from alternative LESS constructions. Moreover, there may well be other plausible technological paths that could lead to comparable reductions in emissions. More work is required to provide a comprehensive understanding of the prospects for and implications of alternative global energy supply systems that would lead to deep reductions in CO_2 emissions.

19.1. Introduction

The world energy supply system is huge, and many of the installations have economic lifetimes measured in decades. Annual worldwide investments are on the order of $150 billion. This means that changes will take considerable time to implement. However, within a period of 50–100 years, the entire energy supply system will be replaced at least twice. New investments to replace an old plant or to expand capacity are opportunities to adopt technologies that are more environmentally desirable at low incremental cost. Significant reductions in GHG emissions will not be achieved by a few scattered improvements. New technology must become characteristic for all new investments in order to reduce net carbon emissions significantly. The technologies discussed in this chapter are relevant worldwide and may be introduced more quickly in countries with rapid economic growth than in other countries.

This chapter identifies and assesses energy supply options that can reduce net GHG emissions. However, it does not attempt a comprehensive analysis of all options available for energy system development. There are many ways to reduce emissions. Some are cost-effective now; others will become cost-effective within the next decades; and some options may never be cost-effective, even with massive government support for RD&D and market introduction. Market penetration of different energy sources ultimately depends on the relative costs of fossil and alternative energy forms, as well as other attributes such as abundance, accessibility, institutional arrangements, and regulations and policies that address climate change and other issues. Because costs vary by location and application, the wide variety of circumstances creates initial opportunities for new technologies to enter the market. Deeper understanding of the opportunities for emissions reductions would require more detailed analysis of options, taking into account local conditions. Box 19-1 provides the conventions used throughout this chapter.

19.2. Options to Reduce Greenhouse Gas Emissions

Options to reduce GHG emissions from the energy supply system include improved efficiency in the use of fossil fuels; suppression of GHG emissions; switching to low-carbon fossil fuels; decarbonization of fuels and flue gases, and CO_2 storage and sequestering; and switching to nuclear energy and renewable sources of energy.

19.2.1. More Efficient Conversion of Fossil Fuels to Power and Heat

In this section, technologies for conversion of fossil fuels into heat and electricity—including advanced power-generation technologies, gasification, fuel cells, cogeneration, and the direct use of coal—are discussed.

19.2.1.1. Efficient Power Generation

Large-scale fossil fuel-fired power plants generate power in a steam turbine, a gas turbine, or a combination of the two as a combined cycle. The global average efficiency of fossil-fueled power generation is about 30%, and about 35% in the Organisation for Economic Cooperation and Development (OECD) countries (based on higher heating values, HHV). At a current efficiency of 40%, an increase of 1 percentage point in the efficiency of power generation results in a 2.5% reduction of CO_2 emissions. Figure 19-1 shows the impact of changes in technology and fuels on emissions (Mills *et al.*, 1991). The figure shows that changes in technology can reduce specific emissions by half and changes in fuel by another half, yielding emissions about one-quarter of initial levels.

Environmental and economic concerns have led to major development programs in various countries, in which state-of-the-art, higher-efficiency, combined-cycle, gas-fired stations and coal-fired units operating with supercritical steam cycles have been installed. Such considerations also have led to other major development programs—such as Pressurized Fluidized Bed Combustion (PFBC) and Integrated Gasification Combined Cycles (IGCC) for coal, residual oil, and biomass power generation, which should be commercially available

---

Box 19-1. Conventions Used

Unless otherwise stated:

Costs are presented in 1990 U.S. dollars and calculated as direct costs on a life-cycle basis, neglecting taxes and assuming a 6% discount rate. Wherever practical, costs are provided for alternative discount rates. Costs for mitigating external effects are included only to the extent required to satisfy existing regulations. There is wide variation in the extent to which external costs have been included in market prices through regulation and/or taxation.

Energy balances are calculated on a life-cycle basis.

Emissions of greenhouse gases [grams of carbon (C) in CO_2 or grams of methane (CH_4)] refer to emissions at the point of use (direct emissions).

The SI system of **units** is used. Weights also are given in metric tons (t).

Heating values. Energy contents of fuels are based on higher heating values (HHV).

before the year 2010 (Jansson, 1991; Menendez, 1992; Wolk *et al*., 1991). Characteristics of some of these technologies are indicated in Table 19-1. The information in Table 19-1 was compiled for the year 1992 on a consistent basis; however, recent market transactions suggest capital costs that are significantly lower (by 30% or more), especially for natural gas-fired

combined-cycle power plants, leading to lower electricity generation costs.

Considering the situation described above, it would be possible to reduce CO_2 emissions from fossil fuel-fired power plants by 25% or more compared to existing generating technology. This
aCogeneration.
[1]Average conventional steam turbine (coal, 34%).

[3]Pressurized fluidized bed combustion (coal, 42%).
[4]Average conventional steam turbine (oil, 38%).
[5]Best available combined-cycle gas turbine (oil, 48%).
[6]Cogeneration: Average conventional steam turbine (coal, 78%, 0.50).
[7]Average combined-cycle gas turbine (natural gas, 36%).
[8]Cogeneration: Best available steam turbine (coal, 83%, 0.60).
[9]Best available combined-cycle gas turbine (natural gas, 45%).
[10]Cogeneration: Pressurized fluidized bed combustion (coal, 86%, 0.65).
[11]Cogeneration: Best available steam turbine (oil, 81%, 0.60).
[12]Cogeneration: Steam-injected gas turbine (natural gas, 75%, 0.80).
[13]Cogeneration: Best available combined-cycle gas turbine (natural gas, 77%, 1.0).

Figure 19-1: Greenhouse gas emissions (in grams of C-equivalent per kWh$_e$) for commercially available alternative fossil fuels and conversion technologies (adapted from Mills *et al*., 1991). Central-station power plants are compared with cogeneration plants providing both useful heat and power. The energy requirements for electricity production using cogeneration technologies are taken as the total energy supplied minus that which would have been required to produce the heat independently (assuming a boiler efficiency of 90% on an LHV basis). Parenthetical data in the notes above are fuel, efficiency based on higher heating value in percent, and power-to-heat ratio.

reduction could be achieved with state-of-the-art or near-commercialized technology at little technical risk. Major developments in these areas are being actively pursued in a number of countries.

Further opportunities are provided by advanced gas turbines. Higher turbine inlet temperatures have become possible through the development of new materials and improved cooling systems, offering improved efficiency in power generation. Research efforts are concentrated mainly on improved air cooling of the hot gas path of the turbine; new materials (ceramics, composites, and superalloys); and more efficient air cooling systems (Williams and Larson, 1989).

Advanced cycles, in general, couple a higher-temperature thermodynamic cycle to a lower-temperature cycle to increase efficiency. The most important application is the use of the hot exhaust gases from a gas turbine to raise steam for a steam turbine. Major characteristics of the combined cycle are summarized as follows:

- **High efficiency**: The most efficient units now on the market achieve 52% efficiency (net, generator terminals), and 54–55% is expected in the next few years.
- **Low investment costs**: Approximately 30% less than for a conventional steam power plant
- **Good operating flexibility**: Power generation may be adjusted to demand changes relatively easily.
- **Short installation time**: Operation approximately one year after order, making capacity expansion in small steps possible
- **Low environmental impact**: In particular, very low emission levels of NO_x
- **High power-to-heat ratio in a combined heat and power production**: This means that a larger fraction of the energy is produced as more valuable electricity.

Table 19-1: *Characteristics of some systems for fossil fuel-based power generation under European conditions.*

Plant Type	Coal Typical with de-SO_x and de-NO_x	Coal Supercritical with de-SO_x and de-NO_x	Coal IGCC	Coal IGCC with CO_2 Capture	Natural Gas Combined Cycle	Natural Gas Combined Cycle with CO_2 Capture

[1] All component parts of the technology are available, but have not been demonstrated at scale in this application.

[2] These are typical values for the power production plant and, where relevant, CO_2 capture and disposal. Figures in brackets are LHV efficiencies on a full fuel-cycle basis.

[3] Higher figures in parentheses are for a well-documented, state-of-the-art advanced plant.

[4] For 500-MW net units in mainland northern Europe (overnight build).

[5] Fuel price level A based on gas at 2.2 US$/GJ and coal at 1.2 US$/GJ.

[6] Fuel price level B based on gas at 4.5 US$/GJ and coal at 2.0 US$/GJ.

[7] Fuel price level C based on gas at 5.5 US$/GJ and coal at 2.5 US$/GJ.

[8] On gas-to-gas and coal-to-coal basis (i.e., not including fuel switching gain of coal to gas), using price level B and 10% discount rate.

Because of such prospects, fossil fuel-based thermal power stations could have efficiencies of around 55% (HHV) on average before the middle of the 21st century.

These advanced cycles require clean gaseous fuels, which has stimulated interest in the production of such fuels from coal and oil.

19.2.1.2. *Gasification of Fossil Fuels for Power Generation*

Gasification of coal and other heavy fossil fuels may be used, for example, to substitute for natural gas, to produce medium calorific gas, or to produce synthetic gas for chemical production.

Fuel flexibility often is cited as a major advantage of gasifiers. Gasifiers can be either air- or oxygen-blown. In the context of power generation, the relative merits of air- and oxygen-blown systems are far from clear. The penalty for producing the required oxygen from air in an oxygen plant is severe because this consumes about 10% of the power produced. On the other hand, the use of oxygen offers the possibility of CO_2 sequestering and suppresses nitrogen oxides (NO_x) (see Section 19.2.3).

Although there are several proprietary gasifiers on the market that are well established in the chemical industry, they are only at the beginning of their development as far as power generation is concerned. Development programs in progress should ensure that, by the year 2000, IGCC systems will be available. Major gasification development programs are underway in Europe, the United States, and Japan.

To provide a sufficiently clean gas, a wide range of gas treatment processes are available from conventional chemical and gas-processing industries. Many of these clean-up processes are capable of delivering a fuel gas with very low levels of undesirable constituents such as sulfur. IGCC systems, therefore, offer great potential to meet strict air pollutant emission limits.

Maintaining the exit gases from the gasifier at their exit temperature—which is commonly in the range 800–1,000°C—during subsequent cleaning of the gas can contribute significantly to the increased efficiency of IGCC systems. This does not hold for systems in which CO_2 is captured because they are based on shift conversion of the gas CO content to CO_2, and this cannot be done at such high temperatures. Much technical effort is being applied in this area. Examples include the development of high-temperature dust-removal systems such as ceramic filters; dry desulfurization systems, such as zinc oxide-based adsorbents; and solid-based ammonia and alkali metal-removal systems. All of these systems have yet to be demonstrated on a significant scale, although recent PFBC work with demonstration-scale hot gas filters has been done in Sweden.

19.2.1.3. *Fuel Cells for Power Generation*

Fuel cells convert chemical energy into electricity without first burning the fuel to produce heat. Fuel cell power systems are characterized by high thermodynamic efficiency and low levels of pollutant emissions. Almost all fuel cells currently developed for commercialization use pure hydrogen as the fuel. Generally this implies that a primary fuel—for example, coal, natural gas, or biomass—first has to be converted to a hydrogen-rich gas. Fuel-cell systems offer the possibility of small-scale as well as large-scale electricity production at a conversion efficiency from hydrogen ranging from 40–70% (LHV) and more than 80% in cogeneration (de Beer and Nieuwlaar, 1991). Different types of fuel cells are currently being investigated: the alkaline fuel cell (AFC), phosphoric acid fuel cell (PAFC), molten carbonate fuel cell (MCFC), solid oxide fuel cell (SOFC), and solid polymer electrolyte fuel cell (SPEFC) (for an overview, see de Beer and Nieuwlaar, 1991).

Much attention is being given to the development of fuel cells for large-scale power production (more than 200 MW_e), integrating fuel cells with steam turbines or gas turbines. Key uncertainties are the limited fuel-cell lifetime and the relatively high cost of the high-temperature fuel-cell systems. The environmental performance of these systems probably is not much better than the performance of conventional power generation with additional cleaning technologies. Therefore, fuel-cell plants for large-scale power production will have severe competition from advanced IGCC and natural gas, combined-cycle power plants. This situation might change, however, when power production is combined with CO_2 removal; a combined coal-gasifier/fuel-cell system facilitates such removal (Jansen *et al*., 1994).

Small-scale combined heat and power (CHP) production is the first market segment in which significant market penetration of fuel cell systems is expected. Widespread use would reduce the emission of pollutants significantly.

In the longer term, one can envisage centralized energy systems in which fossil fuels are converted and separated into hydrogen and CO_2 (or carbon black). The latter could be stored; the former piped and utilized for a variety of applications. Low-temperature fuel cells—such as AFC, SPEFC, and PAFC—are especially well-suited for such configurations. Potential markets are CHP in residential and commercial buildings that need low-temperature heat (Ingersoll, 1991; A.D. Little, 1995; Dunnison and Wilson, 1994), as well as transportation applications (see Section 19.2.6.4).

19.2.1.4. *Combined Heat and Power Production*

CHP production offers a significant rise in fuel efficiency and therefore is of interest in connection with GHG mitigation. CHP has applications in the industrial, residential, and commercial sectors (IEA, 1993a).

Combined production of heat and electricity is possible with all heat machines and fuels (including biomass and solar thermal) from a few kW-rated to large steam-condensing power plants. Heat-plus-power (first-law) efficiencies are typically 80–90%. CHP plants may have an added heat storage that allows the production plant to operate at optimum economy while still covering heat needs. Table 19-2 lists four typical examples of

Table 19-2: *Energy balance and C emissions of CHP plants and separate power and heat production.*

Power and Heat Plant Technology	Energy Balance (GJ)		Fuel Reduction by Introducing CHP	CO$_2$ Emissions	
	Fuel Input[1]	Power/Heat Output		t C	Reduction by Introducing CHP[2]
Large Coal-Fired CHP Plant	100	36/56		2.4	
Large Coal-Fired Power Plant plus Residential Gas Burner	80/59	36/56	28%	2.7	11%
Large Coal-Fired Power Plant plus Residential Coal Burner	80/112	36/56	48%	3.5	31%

Large Coal-Fired Power Plant plus Residential Gas Burner	78/48	39/46	21%	2.5	45%

[1]Arbitrarily fixed reference level.
[2]Some of the percentage reductions show the combined effect of CHP and fuel switching.

CHP installations of various sizes, their power and heat production, and reductions in fuel use and CO$_2$ emissions relative to appropriate alternatives for separate supply of heat and power (Olsen, 1993). Combined-cycle power and heat production provides better thermodynamic performance than single cycles, even if first-law efficiencies are lower, because more electricity is produced. This electricity may in principle be used with heat pumps to generate more heat at a higher temperature.

The employment of CHP is closely linked with the availability or development of district heating (DH) and/or cooling networks and building heat and/or cooling distribution systems, as well as industrial heat loads. DH networks are energy transmission systems suited for the distribution of heat and/or cooling within areas with sufficiently high heat/cooling load densities (Kalkum *et al*., 1993; Rogner, 1993). Modern water-based heating and/or cooling transmission and distribution systems for cities have low losses, typically 10–15% (WEC, 1991).

A prerequisite for DH is central heating systems in buildings. These are customary in most temperate and some subtropical regions. Central heating is most easily achieved if considered at the planning stage, along with electricity, water and sewage, telephone, and optical fiber lines.

Today, widespread coverage by CHP exists in Denmark and Finland (WEC, 1991; Danish Energy Agency, 1993), and substantial DH exists in Austria, Germany, the Netherlands, Poland, Russia, Sweden, and other countries.

Fossil fuels, industrial wastes, and waste heat from processes are used widely in process industries to generate power and heat. The pulp and paper industry is the largest user of biomass energy through combustion of waste liquors and other wood waste. CHP has been utilized in other industries, but to much lesser extent. Now the situation is changing because of regulatory changes (like the Public Utilities Regulatory Policy Act in the United States) and the good economy of cogeneration. Industrial heat demand often has some special characteristics, such as large and fast load variations, intermittent need for heat and power (mechanical work), and extractions of heat (as steam) at different temperature and pressure levels. Otherwise, CHP technology is very similar to that in DH except for the use of special process and waste-heat boilers, where corrosion may limit the attainable pressure and temperature levels (Saviharju, 1995). Compared with DH plants, the temperature levels of the extracted heat are higher, which results in much lower power yields (lower power-to-heat ratio). These may be enhanced considerably, however, through the use of combined-cycle

technology, including IGCC technology. The heat distribution system may serve a single mill or a whole industrial city, ranging to hundreds of MW of heat.

19.2.1.5. Direct Coal Use in Developing Countries and Economies in Transition

Developing countries and economies in transition burn coal directly as fuel for cooking and space heating and fuel for small industries. For example, the direct use of coal accounts for about two-thirds of the coal used in China. Typically, conversion efficiencies are low for these applications, and—because of coal's high content of ash, sulfur, and other pollutants—direct coal use is a major source of local and regional air pollution. A substantial reduction in emissions, including CO_2, can be achieved by using coal in more efficient appliances or by converting coal into a synthetic fuel (or electricity and district heat) before distribution to final users.

Coal conversion to cleaner fuels—for example, town gas—essentially eliminates sulfur and particulate emissions at the point of end-use. Such upstream conversion of coal, however, is capital-intensive, incurs conversion losses, and requires grid distribution systems. Because of capital limitations, the direct use of coal will remain important in many countries for decades (Sun and Li, 1992). Transferring efficient residential and industrial coal appliances to developing countries is as important as transferring coal-cleaning equipment, power generation plants, and other central conversion plants and equipment (Pachauri, 1993; Topper, 1993; Graham-Bryce *et al.*, 1993; Ramakrishnan, 1993; Su and Gu, 1993).

19.2.2. Suppression of GHG Emissions and Fuel Switching

Suppression of CO_2 and methane (CH_4) emissions and switching to low-carbon fuels—for example, from coal to oil and gas, which is a shift to fuels with a lower carbon to hydrogen ratio—offer significant potential for reducing GHG emissions.

19.2.2.1. Suppression of Methane Emissions

Total CH_4 emissions are estimated at 560 ± 90 Mt/yr, of which 70% is from anthropogenic sources and 30% from natural sources (Lelieveld and Crutzen, 1993; IPCC, 1992). About 30% of the anthropogenic sources may be associated with the use of fossil fuels.

CH_4 emissions from coal mining and natural-gas venting, as well as leakage from pipeline and distribution systems, are significant. It has been estimated that the coal industry worldwide contributes 4–6% of global methane emissions (CIAB, 1992). Flaring and venting has been estimated to be about 5% of world natural-gas production (Barn and Edmonds, 1990; U.S. EPA, 1993a). Available technology can reduce emissions from coal mining by 30–90%, from venting and flaring by more than

50%, and from natural-gas distribution systems by up to 80% (U.S. EPA, 1993a). Options for limiting emissions from coal mining; natural-gas production, transmission, and distribution; and landfills (see Chapter 22) may be economically viable in many regions of the world, providing a range of benefits—including the use of CH_4 as an energy source (U.S. EPA, 1990a, 1990b, 1993a, 1993b; Blok and de Jager, 1993).

There are many options for suppressing emissions from the oil and natural gas industries, including capturing and using or recompressing residuals and purged gas, improving gas leakage-detection methods, applying pneumatic devices to control or eliminate venting, repairing or replacing pipelines, and using automatic shutoff valves (U.S. EPA, 1993a). Some of these measures are capital-intensive and could be difficult to carry out in some regions, due to specific geographical as well as economic conditions. Flaring is preferable to venting from a GHG point of view because a molecule of CH_4 leads to a much larger radiative forcing in the atmosphere than a molecule of CO_2.

CH_4 emissions from coal mining depend on several factors, but emissions from underground mines are one order of magnitude higher than from surface mines (Smith and Sloss, 1992). Only emissions from underground mines can be reduced *before* (pre-degasification), *during* (recovery of ventilation air), and *after* (gob-well recovery, from the highly fractured area of coal and rock that is created by caving in of the mine after mining has been completed) the mining of the coal (U.S. EPA, 1993a). Whereas premining and postmining degasification has been widely applied in many countries, it is not suitable for every coal deposit. The economic feasibility of CH_4 recovery from ventilation air has not yet been demonstrated, although technology is available. In optimal conditions, the combination of these three options—"integrated recovery"—can achieve an emissions reduction of up to 80–90% (Blok and de Jager, 1993; U.S. EPA, 1993a).

19.2.2.2. Flaring of Natural Gas and Alternatives to Flaring

An estimated average of 0.5% or more of natural-gas production is emitted into the atmosphere from upstream oil and gas operations (U.S. EPA, 1990b). In some areas, emissions are assumed to be as high as 15%, of which 6% is emitted from natural-gas use. Such high levels of emissions probably will decrease within 20 to 50 years (Picard *et al*, 1992). Also, many oil production facilities either produce very small amounts of gas in association with oil (after satisfying on-site fuel requirements) or are too far from gas-collecting systems for feasible conservation or reinjection of the gas. Therefore, gas usually is vented or flared if it is uncollected. Options for disposing of or utilizing waste gas at oil production facilities include small-scale on-site power generation, cogeneration, and transport fuel production. These options could reduce emissions by 50–99% (Picard and Sarkar, 1993). The largest reductions of gas venting and flaring from oil and associated gas facilities would result from making these activities economically attractive.

Natural gas is flared to prevent natural gas explosions in the air, to ensure continuous flow, and to keep production smooth in the downstream facilities. Options to reduce the volumes flared in continuous gas flows include using nitrogen as a purge gas and recovery of low-pressure gas. Gas flaring caused by faults in processing could be reduced by improving maintenance. Improving system reliability and storage capacity may reduce emissions of excess gas flared when demand is low. These options vary according to the location and characteristics of the oil industry.

19.2.2.3. Suppression of CO_2 from Natural Gas and Oil Wells

The CO_2 content in natural gas fields or oil wells varies, which significantly affects life-cycle CO_2 emissions. Depending on the ratio of CH_4 to other gases, the extraction and use of natural gas leads to CO_2 emissions of less than 14 kg C/GJ of natural gas (HHV) if the CO_2 content of the natural gas field is less than about 1%. Most fields exploited presently are in this range (Schroder and Schneich, 1986)—for example, the Groningen field in The Netherlands, which contains 0.89% CO_2 (Blok *et al.*, 1989). However, there are also natural gas fields with a much higher CO_2 content. For example, the Krahnberg field in Germany contains 53.4% CO_2 and the Catania field in Italy 48.8% CO_2. Although not yet developed due to high CO_2 content, the Natuna field in Indonesia contains more than 70% CO_2.

Exploitation of such fields requires removal of CO_2 to meet transport and sales specifications, typically less than 2–3%. Ordinarily the CO_2 is emitted to the atmosphere. In the case of the Sleipner Vest field (9.5% CO_2) in Norway, however, the CO_2 removed will be injected into an aquifer at 1,000 m below the main Sleipner platform. Approximately 1 Mt/yr CO_2 (~0.25 Mt/yr of carbon) will be removed from a 100-bar natural gas stream, which is costly but uses well-known technology. The decision to store the CO_2 was stimulated by the introduction of a carbon tax of about $180/t C in Norway (Kaarstad, 1992).

19.2.2.4. Fuel Switching

Switching from coal to oil or natural gas would reduce carbon emissions in proportion to the carbon intensity of the fuel. For example, switching from coal to natural gas would reduce emissions by 40% (see Box B-2 in Chapter B). In addition, the higher energy efficiency achievable with natural gas would reduce emissions further—for example, a shift from coal to natural gas in power generation by 20%.

19.2.3. Decarbonization of Fuels and Flue Gases, CO_2 Storage, and Sequestering

In the longer term, decarbonization would allow continued large-scale use of fossil fuels. Here, decarbonization implies utilization of the energy in carbon with greatly reduced CO_2 emissions. This can be done practically only in large-scale energy conversion facilities. It is logical, therefore, to begin decarbonization efforts in large fossil fuel-burning power stations, which at present account for a quarter of total CO_2 emissions from fossil fuels. Either CO_2 can be captured from flue gases or carbon-containing fuels can be converted to low-carbon, hydrogen-rich fuels before utilizing them (Pearce *et al.*, 1981; Blok *et al.*, 1991, 1992; U.S. DOE, 1993).

If deep CO_2 emission reductions are desired, it would be necessary to extend the effort beyond power generation. This is problematic, however, because most fuels used directly are consumed in small-scale conversion systems in which decarbonization is not practical. This problem might be solved by converting the fossil fuel to a low-carbon, hydrogen-rich fuel or to a carbon-free fuel (essentially hydrogen) and CO_2 in a centralized facility, followed by removal of the CO_2 and distribution of the low-carbon or carbon-free fuel to the consumer (Marchetti, 1989; Blok *et al.*, 1995; Williams, 1996).

In either case—flue gas decarbonization or fuel decarbonization—the captured CO_2 has to be utilized, stored, or isolated from the atmosphere in an environmentally acceptable manner.

19.2.3.1. Decarbonization of Flue Gases

The capture of CO_2 from the flue gases of fossil fuel-fired power plants and its subsequent use or disposal is being actively investigated in a number of countries (Blok *et al.*, 1992; Riemer, 1993; U.S. DOE, 1993; Herzog and Drake, 1993; Aresta *et al.*, 1993; Kondo *et al.*, 1995). Interest in the capture of CO_2 from power plant flue gases started before it was seen as a GHG mitigation option. The driving force was the desire for an inexpensive, readily available source of CO_2 to use in enhanced oil recovery (EOR). Three such plants were built in the United States to provide CO_2 for EOR using natural gas as a primary fuel. Another plant, still in operation, uses coal as a source of CO_2 for the production of soda ash. All of these plants have applied well-established technology to capture the CO_2 from the flue gases.

The use of these technologies incurs a cost and energy penalty. Starting with a conventional coal-fired power plant of 600 MW_e and a coal-to-busbar conversion efficiency of, for example, 41% (LHV), the efficiency might decrease to, for example, 30% if the CO_2 emission is reduced from 230 gC/kWh to about 30 gC/kWh in the modified plant. The costs of electricity production would then increase by about 80%, which is equivalent to $150/t C avoided. Starting with a natural gas-fired, combined-cycle plant of 600 MW_e and a conversion efficiency of 52% (LHV), the efficiency might decrease to 45% if the CO_2 emission is reduced from 110 gC/kWh to about 20 gC/kWh in the modified plant. In this case, the costs of electricity production would increase by about 50%, which is equivalent to $210/t C avoided. R&D efforts are focused on minimizing these penalties (Blok *et al.*, 1992; U.S. DOE,

1993; Herzog and Drake, 1993; Hendriks *et al.*, 1993; Kondo *et al.*, 1995). One option under investigation to reduce costs is the use of oxygen rather than air for combustion to obtain a flue gas that is essentially CO_2. For a coal-fired power station, the removal costs might then be less than \$80/t C avoided (Hendriks, 1994).

19.2.3.2. Decarbonization of Fuels

One frequently suggested scheme for decarbonization of fuels is the development of an IGCC power plant with CO_2 removal. In this scheme, the gasifier off-gas is converted with steam to CO_2 and hydrogen (via $H_2O + CO \longrightarrow CO_2 + H_2$) and then separated to make a fuel gas stream that is essentially hydrogen. Due to its high partial pressure, the CO_2 can be recovered by using a physical solvent for which regeneration requires only a release of pressure. After separation, the hydrogen-rich fuel is burned in a combined cycle to generate electricity. The CO_2 emission factor of the fuel would be smaller than 4 kgC/GJ, compared with 24 kgC/GJ for coal. Starting from an original IGCC plant with a coal-to-electricity efficiency of about 44% (LHV), this efficiency might decrease to about 37%, with the CO_2 emissions reduced from approximately 200 gC/kWh to less than 25 gC/kWh. Due to the recovery, the costs of electricity production might increase by 30–40%. The removal costs would then be less than \$80/t C avoided (Hendriks *et al*, 1993; Hendriks, 1994). These penalties might be reduced substantially if the gasification of coal and the recovery of CO_2 were integrated with the use of fuel cells to generate electricity. Such a configuration could result in a higher conversion efficiency (42–47%, LHV) (Jansen *et al.*, 1992).

The hydrogen-rich fuel also can be used for applications other than power generation, although doing so requires further purification of the fuel (Watson, 1983; Blok, 1991) and the build-up of a corresponding infrastructure (see Section 19.2.6).

Due to the increased costs of the hydrogen fuel compared to the original feedstock, some experts have concluded that decarbonization processes are inherently expensive. For the recovery of CO_2 by steam reforming of natural gas, they calculate costs ranging from \$210 to \$460/t C recovered (Kagoja *et al.*, 1993). It has been suggested that hydrogen has a greater value than the feedstock from which it is produced because it allows the use of more efficient conversion technologies. The costs of decarbonizing fuels therefore must be assessed at the systems level. For example, the production of hydrogen from natural gas or coal and its use in a fuel-cell vehicle typically would lead to lower primary energy consumption than if gasoline derived from crude oil were used in a comparable vehicle (see Section 19.2.6.4). At present, the least costly way to produce hydrogen often involves the use of natural gas as the feedstock; in the process, a stream of pure CO_2 is produced as a byproduct. If this CO_2 could be captured and stored in a nearby exhausted natural-gas field, the costs of avoiding the CO_2 emissions are estimated to be less than \$30/t C (Farla *et al.*, 1992). The net costs could be even less (and possibly close to zero) if possibilities for modest enhanced natural gas recovery as a result of reservoir repressurization by the CO_2 were exploited (Blok *et al.*, 1995).

Carbonaceous materials (fossil fuel, biomass, waste, etc.) also could be converted into chemically stable carbon and hydrogen or hydrogen-rich methanol (Steinberg, 1991). As a result, carbon could be stored instead of CO_2. Although theoretically possible, this approach is very difficult practically.

19.2.3.3. Storage of CO_2

The technology to capture CO_2 is available, but to have an impact on GHG emissions, credible and environmentally acceptable utilization, storage, and/or disposal options are required. Because of the small potential for utilization (Aresta *et al.*, 1993; Herzog and Drake, 1993), several possibilities for underground storage or ocean disposal of CO_2 are being investigated. An overview of storage options is presented in Table 19-3, together with an indication of their potential capacities based on low estimates in the literature. Enhanced oil recovery (EOR) using CO_2 as a miscible flooding agent has a high potential. The CO_2 is partly stored during the recovery of the oil. At present oil price levels, however, the application of CO_2 in EOR is not profitable unless there is access to CO_2 from a cheap source, such as a natural underground source. Examples can be found in the United States, where CO_2 from natural sources is transported hundreds of kilometers by pipeline for EOR use. For a typical case, total pipeline transportation cost of CO_2 is about \$8/t C for a 250-km, 750-mm pipeline for 5.5 Mt C of CO_2 per year (Skovholt, 1993). EOR using CO_2 from power plants might reduce the annual anthropogenic CO_2 emissions by about 1% (Taber, 1993).

Storage in exhausted oil and gas wells is a viable option. The capacity of natural-gas fields to sequester carbon at the original reservoir pressure is generally greater than the carbon content of the original natural gas. As a worldwide average, about twice as much carbon can be stored as CO_2 in depleted reservoirs as was in the original natural gas (Hendriks, 1994). The estimated storage capacity ranges from about 130 Gt C to 500 Gt C, based on different views of recoverable oil and gas. The cost of CO_2 storage in onshore natural-gas fields is estimated to be less than \$11/t C (Hendriks, 1994).

Table 19-3: *Low estimates of CO_2 storage potentials.*

Option	Potential Global CO_2 Storage Capacity (Gt C)
Enhanced Oil Recovery	>20
Exhausted Gas Wells	>90
Exhausted Oil Wells	>40
Saline Aquifers	>90
Ocean Disposal	>1200

Another option is storage in saline aquifers (i.e., permeable beds, mostly sandstone), which can be found at different depths all over the world. First estimates of their storage capacity range from about 90 to about 2,500 Gt C, due to different assumptions about the volume of aquifers, the percentage of the reservoir to be filled, the density of CO_2 under reservoir conditions, and the area suitable for CO_2 storage (Riemer, 1993; Hendriks *et al*., 1993). Depending on the availability of compressed CO_2—for example, from an IGCC plant with CO_2 removal—and other local circumstances, the costs of underground storage onshore might vary from about \$7 to \$30/t C, transportation costs excluded (Hendriks, 1994). CO_2 storage in aquifers has safety risks and environmental implications. Potential problems include CO_2 escape, dissolution of host rock, sterilization of mineral resources, and effects on groundwater (Riemer, 1993; Hendriks *et al*., 1993).

The deep ocean is the largest potential repository for CO_2. The oceans contain about 38,000 Gt C and will eventually absorb, after equilibration, perhaps 85% of the CO_2 that is released to the atmosphere from energy conversion processes (Houghton *et al*., 1990). CO_2 could be transferred directly to the oceans, ideally at a depth of perhaps 3,000 m—from where it would take at least several hundred years before it partly escaped to the atmosphere. Concern over potential environmental impacts, the practical limitations on pipeline depth, and the assurance of adequate retention time suggest that injection at 1,000 m at carefully selected sites could be a realistic option. Costs are probably marginally higher than for subterranean disposal (U.S. DOE, 1993), but—as with most options—the cost of transporting CO_2 to the disposal site often dominates.

Not much is known about the environmental effects of storing CO_2 in the oceans—for example, the impacts on marine life, either directly (as discussed here) or indirectly (via the atmosphere). Preliminary studies indicate that ecological perturbations would be confined to the release area, which would be a small percentage of the whole ocean volume (U.S. DOE, 1993). A maximum deviation of 0.2 pH units for coastal waters has been recommended (U.S. EPA, 1976). This would correspond to a buffer capacity of 1,200 Gt C (Spencer, 1993). These aspects need further research.

19.2.3.4. CO_2 Sequestering

Reforestation with the application of forest management techniques provides a method of offsetting CO_2 emissions (Maclaren *et al*., 1993; see also Chapter 24). Carbon is captured and stored during the growth time of a forest and would need to be stored for a long time thereafter. Costs are \$12–30/t C, assuming a land value of about \$800/ha in industrialized countries and about \$300/ha in developing countries (Huotari *et al*., 1993). Other studies indicate costs as low as \$3.5/t C (Face Foundation, 1995). At high levels of reforestation, costs can be expected to increase.

Offsetting carbon emissions from a 500 MW$_e$ coal-fired power station (emitting about 0.8 Mt C/yr) by growing a forest on unforested land would require an area of at least 1,700 km^2, on the basis of a productivity of 2–4 tons/ha/yr during 50 years and a storage of 100–200 tons of carbon per hectare in a mature forest.

Growing biomass for energy as a fossil fuel substitute is an alternative to growing biomass for sequestering carbon. The preferred strategy depends on various factors, including the current status of the land and the biomass yields that can be expected. For forests with large standing biomass, the most effective strategy is to protect the existing forest; for land with little standing biomass and low yields, the most effective strategy is to reforest the land for carbon storage. Where high yields can be expected and markets for the biomass are readily accessible, however, often the most effective strategy is to manage the forest as a harvestable energy crop for fossil fuel substitution (Hall *et al*., 1991; Marland and Marland, 1992).

19.2.4. Switching to Nuclear Energy[1]

In 1992, nuclear power generation totaled 2,030 TWh—about 17% of all electricity or more than 5% of commercial energy consumption worldwide (all statistical data on nuclear power quoted in this section are from IAEA, 1995a; OECD/NEA, 1993). The operational experience of electricity-generating nuclear power plants of all sizes exceeds 6,500 reactor-years. At the beginning of 1993, there were about 425 nuclear power reactors connected to electricity supply networks, with a total installed capacity of about 331 GW$_e$. More than 30 countries have nuclear power plants in operation or under construction.

If the entire upstream and downstream energy chains for electricity generation are included, nuclear power CO_2 equivalent emissions are 1/10 to 1/100 those of fossil fuel plants. The range depends on assumptions about the competing fossil fuel technology and on the uranium content of ores, the uranium enrichment technology, and the management of radioactive waste (The Netherlands Ministry of Economic Affairs, 1993; Uchiyama and Yamamoto, 1991). Nuclear plants producing electricity reduce CO_2 emissions from the energy sector by about 7% compared to the present world mix of fossil fuel-based power generation (Van de Vate, 1993).

For nuclear energy to play a major role in future GHG mitigation, a considerable expansion must take place. Historically, nuclear power expanded rapidly. Construction starts per year reached a peak in the late 1960s but declined by 90% during the last 6–7 years (see Figure 19-2). Grid connections peaked in the mid-1980s at more than 30 GW/yr and then decreased to a few GW/yr. For nuclear energy to assume an increased role in reducing GHG emissions, growth has to be resumed. It is therefore necessary to analyze the reasons behind the developments summarized in Figure 19-2 and to understand the issues that must be addressed for a revival of the nuclear option.

---

[1] A supporting document exists for this section (see IAEA/OECD, 1995).
Figure 19-2: Annual nuclear power plant construction starts and connections to the grid, 1955–1994 (IAEA, 1995b). Open bars indicate construction starts; filled bars indicate grid connections.

General acceptance: During the last decades, there has been a decrease in acceptance of nuclear power, especially of building new nuclear power plants. A review of opinion surveys concludes that public concerns about nuclear energy focus on the following issues: doubt about economic necessity, fear of large-scale catastrophes, storage of nuclear waste, and the misuse of fissile material (Renn, 1993; The Netherlands Ministry of Economic Affairs, 1993; Slovic, 1992). Nuclear power expansion has stopped in most countries, but plans for nuclear capacity expansion remain significant in a limited number of countries, such as China, France, Japan, and Korea.

Resource base: The availability of uranium and thorium is unlikely to place a major constraint on the future development of nuclear power (Pool, 1994). Reliance on uranium alone without fast-breeder development could introduce constraints in the longer term if demand for nuclear power were to increase substantially.

Present reactor technology: Several types of reactors have been commercially developed. About 80% of the nuclear units in operation and under construction are light-water reactors (LWR); about 5% are heavy-water reactors (HWR). Gas-cooled reactors (GCR) contribute about 9% of installed capacity, but none are under construction. Liquid metal-cooled reactors (LMR) were conceived and implemented at the start of nuclear power development to use uranium more efficiently, but their deployment has not gained momentum.

Costs: Investment costs for construction of nuclear units are a major component of the total cost of nuclear-generated electricity. They are sensitive to technical parameters; regulation aspects, such as licensing lead times; and, like other capital-intensive options, the interest rate. Nuclear fuel-cycle costs include mining, spent fuel management, and disposal of

low-, intermediate-, and high-level radioactive wastes (NEA, 1994). Although final repositories for high-level waste have not yet been implemented, the cost of disposal has been estimated to represent less than 20% of the undiscounted total nuclear fuel cycle cost (4.6% with 5% discount rate, 1% with 10% discount rate) (NEA, 1994). The operation and maintenance of nuclear power plants require industrial, organizational, and regulatory infrastructures, as well as highly qualified manpower—leading to generally higher operating and maintenance costs for nuclear than for fossil fuel-fired power plants.

Direct nuclear generating costs in a number of countries vary from 2.5¢ to 6¢ per kWh$_e$ (IAEA, 1993). The direct cost of electricity from new plants, including waste disposal and decommissioning, is 2.9–5.4¢/kWh$_e$ using a 5% discount rate and 4.0–7.7¢/kWh$_e$ using a 10% discount rate (IEA *et al.*, 1993). Direct costs for new reactors in the Netherlands are an estimated 5.3–6.0¢/kWh$_e$ for a 5% discount rate and 7.0–7.7¢/kWh$_e$ for a 10% discount rate (Beeldman *et al.*, 1993). Direct electricity production costs from a new nuclear power plant are estimated to be lower than or about as high as (IEA *et al.*, 1993) or higher than (Moore and Smith, 1990; Beeldman *et al.*, 1993) those estimated for a natural gas or coal-fired power plant. Uncertainties relating to governmental decisions on such matters as licensing and regulations may affect costs in some countries. Projected levelized costs of baseload electricity generation for plants connected to the grid by the turn of the century indicate that nuclear power will remain an option in several countries where nuclear power plants are in operation or under construction (IEA *et al.*, 1993).

Environmental impact: In routine operation, nuclear power plants and their associated fuel-cycle facilities release small quantities of radioactive materials to the environment. These

releases and direct exposure to radiation of workers and the public are monitored and controlled by national authorities, based upon the recommendations of the International Commission for Radiological Protection. The yearly collective dose to the world population from routine nuclear power electricity generation is less than an estimated 1% of the dose due to natural radiation sources (UNSCEAR, 1994).

The safety of nuclear facilities is assessed and regulated by independent authorities reporting to governments, taking into account international codes of practice (INSAG, 1988). The responsibilities and enforcement capabilities of these authorities vary. Before plants are licensed and throughout their operating lives, they are assessed by several techniques, including probabilistic safety assessment (INSAG, 1992). These methods are useful for identifying needs and opportunities for design improvements (U.S. NRC, 1991; INSAG, 1992). There are recognized limitations in applying this method to very-low-probability accident sequences (APS, 1975; Sørensen, 1979b). Safety is considered in design through the principle of defense-in-depth, employing successive barriers to accidental releases of radioactivity. For operational safety, a general appreciation of safety requirements through manpower training and fostering of a safety culture is central (INSAG, 1991). Deficiencies in these matters are believed to be at the root of the Chernobyl accident (INSAG, 1986). The reactor-core meltdown accident at Three Mile Island in the United States demonstrated the benefit of the defense-in-depth approach: Insignificant amounts of radioactivity were released from the plant.

Radioactive waste: All phases of the nuclear fuel cycle, other than the final disposal of spent fuel and high-level radioactive waste, are operating on an industrial scale.

High-level wastes, which contain more than 99% of the radioactivity from nuclear plants, represent after conditioning a few tens of $m^3/GW(e)$year. If spent fuel is reprocessed, the volume of waste would be one-tenth as large. These high-level wastes are now stored either near the reactors or at reprocessing plants. Geological repositories for high-level waste have been studied in salt and granite, for example (Carlson, 1988). Several countries are studying alternative final repositories of high-level waste, with a view toward implementation early in the next century.

Proliferation: The potential use of nuclear materials and technology for weapons has long been recognized. At the end of 1994, 178 states were parties to the 1970 Treaty on the Non-Proliferation of nuclear weapons (NPT). The treaty places conditions on the transfer of nuclear technology and materials to prevent the development of nuclear weapons. Verification is carried out by independent inspectors from the International Atomic Energy Agency (IAEA), which was established in 1957 (IAEA, 1993). An indication of the impact of the international safeguards regime is the limited number of nuclear weapon states existing at present as compared to fears expressed in the 1960s (Thorne, 1992). However, illicit trafficking of nuclear materials became a concern to governments in 1993–1994 (IAEA, 1994).

A 1-GW_e nuclear power plant of the current LWR generation produces about 200 kg of plutonium (Pu) per year; future breeder reactors will produce about 1,500 kg of plutonium per year. Concerns regarding the proliferation risk arise from the accessibility to plutonium because an explosive similar to the Nagasaki bomb could be produced with only about 10 kg of plutonium (Carson Mark, 1993), or with 4 kg of plutonium or less in advanced designs (U.S. DOE, 1994a). Plutonium may be mixed with uranium as a fuel for nuclear power plants and may also be used for nuclear explosives, although the use of power reactor-grade plutonium complicates bomb design. Countries that have produced plutonium-based nuclear explosives have produced weapons-grade plutonium in reactors designed for this purpose (National Academy of Science, 1994). However, the difference in proliferation risk posed by separated weapons-grade plutonium and separated reactor-grade plutonium is small in comparison to the difference between separated plutonium of any grade and unseparated material in spent fuel (National Academy of Sciences, 1994).

New technology: Evolutionary reactor designs are being used in reactors now under construction to provide increased safety, reduced radiation doses to operators, and improved economic performance through reduced construction lead times and reduced operation and maintenance costs (Juhn and Kupitz, 1994). Cost reductions can be obtained by streamlining the reactor's systems and reducing the amount of material and manufactured components required for construction. Reactors with such improved designs are under construction in Canada, France, and Japan.

Designs incorporating more innovative features are being developed in some countries, on the grounds that evolutionary improvements will not suffice to provide the safety that the public and the investors want. In particular, systems with inherently safe characteristics and more passive safety features are being developed to reduce the probabilistic risk of accidents, as well as on-site and off-site impacts in the event of a severe accident. In particular, the concept of Modular High-Temperature Gas-Cooled Reactors—in which graphite is used as the moderator and helium as the coolant—has attractive safety features. A 30-MW_{th} test reactor is under construction in Japan.

Advanced reactors also are being designed and developed to address the challenges of higher reliability and cost reductions while satisfying increasingly demanding safety and waste-management requirements (Kupitz, 1992; IAEA, 1995a). In a recent study for the Netherlands government, researchers have concluded that the majority of these concepts for new power plants are likely to meet current safety criteria (The Netherlands Ministry of Economic Affairs, 1993). The level of safety improvements, however, is unclear (Mårtensson, 1992).

Concerns about the future production of Pu in a world with a large nuclear capacity have stimulated proposals for criteria for diversion-resistant nuclear power (Williams and Feiveson, 1990). Preliminary proposals have been made for significant reductions in plutonium production through the use of fuels such

as denaturated thorium—for example, high-energy accelerator devices (Carminati *et al.*, 1993). Interest in LMRs has been revived in view of their potential use in the management and disposal of civil radioactive waste, as well as fissile materials arising from dismantling of nuclear weapons (National Academy of Science, 1994; Chang, 1993). The use of LMRs for transmutation of actinides contained in irradiated fuels from LWRs also has been investigated (NEA, 1995a). Other strategies are being investigated for reducing the period during which radioactive waste repositories need to be controlled. For example, partitioning actinides and transmuting them by neutrons or high-energy protons can substantially reduce the volume of long-lived isotopes (The Netherlands Ministry of Economic Affairs, 1993).

Other concepts are being developed with the objective of enhancing the use of nuclear power for nonelectrical applications. Some nuclear plants supply process and district heat. In the longer term, nuclear energy could be deployed for hydrogen production (Marchetti, 1989) (see Section 19.2.6.4). Market studies for small- and medium-size reactors (SMRs) have shown that nuclear power could in principle be more broadly deployed for district heating, heat supply to industrial complexes (IEA, 1993c), and production of potable water (IAEA, 1992a, 1992b).

In the longer term, it might also be possible to generate electricity from nuclear fusion instead of fission (IFRC, 1990). The primary fuels for fusion reactors—deuterium and lithium—are so abundant that fusion would be a practically inexhaustible source of energy. The conditions required for self-sustaining net power-producing fusion reactions on the Earth have not yet been attained, however. The development and implementation of fusion reactors requires demonstration of scientific, technological, and commercial feasibility. It is not expected that fusion plants could be available on a commercial scale before the second half of the next century (Colombo and Farinelli, 1992).

A major drive will be needed to achieve the early rehabilitation of nuclear energy if it is to contribute to fossil fuel use reductions in the next century. The continuing concern of many members of the general public and many policymakers with regards to safety and proliferation issues, however, may remain a severe constraint on nuclear power generation in many countries (WEC, 1993).

19.2.5. *Switching to Renewable Sources of Energy*

Renewable sources of energy, including biomass and hydropower, contributed about 20% of the world's primary energy consumption in 1990 (see Table B-2 in Chapter B).

The resource base for renewable energy technologies is very large in comparison to projected world energy needs (see Table B-4 in Chapter B). Impressive technical gains in renewable energy utilization have been made during the past decade (U.S. DOE, 1990; Johansson *et al.*, 1993b; Ahmed, 1994; Kassler, 1994; WEC, 1994).

Renewable sources of energy used sustainably have small emissions of GHGs. The establishment of an infrastructure for large-scale use of renewable sources of energy will generate indirect emissions of GHGs if this infrastructure is put in place using fossil fuels. On the other hand, renewable energy sources could be considered for this, thereby giving rise to very little of such indirect emissions. There are also some GHG emissions associated with the unsustainable use of biomass—for example, from reducing the amount of standing biomass and from decomposition of biomass associated with the establishment of some dams. By and large, the increased use of renewable sources of energy offers substantial reductions of GHG emissions compared to the use of fossil fuels.

19.2.5.1. *Hydropower*

Hydroelectricity, which depends ultimately on the natural evaporation of water by solar energy, is the only renewable resource used on a large scale for electricity. In 1990, 2,200 TWh were generated, accounting for 18% of the world's total electricity generation, with small or no emissions of GHG.

The energy potential of hydropower is determined by the annual volume of runoff water (47,000 km³) and by the height it falls before reaching the ocean. Estimates of the theoretical annual potential of world hydroelectricity range from 36,000 to 44,000 TWh, corresponding to 340 to 410 EJ_{th} with conventions from Table B-2 in Chapter B (Raabe, 1985; Boiteaux, 1989; Bloss *et al.*, 1980). This gross theoretical potential is much larger than the technically usable potential, which in turn is substantially larger than the economically exploitable potential. The technically usable potential is an estimated 14,000 TWh/yr (WEC, 1992). The economically exploitable potential—after social, environmental, geological, and other economic constraints are considered—is smaller. The world's long-term economic hydroelectric potential may be on the order of 6,000–9,000 TWh/yr (Moreira and Poole, 1993).

Hydroelectric plants vary in size and share of the world's hydropower potential. Small-scale hydropower, often defined as installations smaller than 10 MW, contributes about 4% of world hydroelectricity (WEC, 1992, 1994). Small plants have a large potential to contribute to socioeconomic development in rural areas. Their potential overall contribution to GHG emissions is limited, however.

Hydropower costs are most commonly measured in terms of the cost per kilowatt installed. With some exceptions, there is surprisingly little systematic data available on the cost of individual plants (Electrobras, 1987; Lazenby and Jones, 1987; Moore and Smith, 1990). Total investment costs for 70 developing countries for the 1990s (Moore and Smith, 1990) suggest that the cost of new hydroelectricity is 7.8¢/kWh.[2]

---

[2] This is the average value for hydropower plants under construction for this decade. The investment is from Moore and Smith (1990); electricity cost is obtained through average utilization factor (0.42), interest rate (10%), and operational cost (1 ¢/kWh).

An estimate of the value of hydropower must account for its capability to vary the power level over wide ranges, providing a means of handling variations in electricity demand and intermittent power generation from wind and solar sources (Kelly and Weinberg, 1993).

Hydropower is not free of GHG emissions. Bacterial decomposition of biomass in flooded reservoirs produces CH_4 and CO_2. The impact on global warming, in comparison to fossil fuel power generation, depends on the amount and timing of the gases formed. Dams that flood large areas with large quantities of biomass (including underground biomass) generate GHG emissions (Rudd *et al.*, 1993; Pinguelli Rosa and Schaeffer, 1994). The magnitude of this effect can be determined only on a case-by-case basis.

Most hydroplants require a reservoir, which can significantly affect people (through relocation), the terrestrial ecosystem, and the river itself. The social effects of relocation of people are not well known (Cernea, 1988). The area inundated by dams generally has higher agricultural value and a higher population density than the surrounding region as a whole.

The construction phase of a hydroelectric plant has social consequences and direct environmental impacts, such as water diversion, drilling, slope alteration, reservoir preparation, and the creation of an infrastructure for the large workforce (Moreira and Poole, 1993). The social consequences of a large workforce include migration, shanty towns with increased public-health problems, pockets of urban and rural poverty, destruction of the character of local communities, and intense deforestation (Moreira and Poole, 1990). On the positive side, the local transportation network and related industries often grow. The additional infrastructure stimulates regional economic development and has been widely viewed as a regional development tool (Moreira and Poole, 1993). Well-designed installations using modern technology that cascade the water through a number of smaller dams and power plants may reduce the environmental impact of the system (Henry, 1991).

Water quality is a major problem for hydroelectric planners. The inundation of land reduces the production potential for biomass for energy in addition to generating GHGs through biological decomposition (Garzon, 1984). Water management must allow for irrigation (Veltrop, 1991). Sedimentation is a problem in reservoirs and river deltas (Deudney, 1981).

Dams have a significant impact. Dam failure has caused significant losses of life and property (Smets, 1987; Laginha Serafim, 1984). Dams may prevent fish migration and stop water flow, which is a necessity for some fish (Petrere, 1990).

Disturbing aquatic ecosystems in tropical areas can induce indirect environmental effects; for example, increased pathogens and their intermediate hosts may lead to an increase in fatal human diseases such as malaria, schistosomiasis, filariasis, and yellow fever (Waddy, 1973).

The social and environmental constraints on hydropower development must be carefully evaluated in each situation. The evaluation should include the value of avoiding other forms of electricity generation that may bring unwanted social and environmental effects.

19.2.5.2. Biomass

Biomass energy is consumed at an annual rate of 47 EJ (WEC, 1994) to 55 EJ (Hall *et al.*, 1993), mainly for cooking and heating in developing countries. It is used for some small-scale industry, though there is some experience at larger scales.

There is no net atmospheric CO_2 build-up from using biomass grown sustainably because CO_2 released in combustion is compensated for by that withdrawn from the atmosphere during growth. Modern biomass energy also offers the potential for generating income in rural areas (Johansson *et al.*, 1993a). This income could allow developing-country farmers to modernize their farming techniques and reduce the need to expand output by bringing more marginal lands into production (Riedacker and Dessus, 1991). In industrialized countries, biomass production on excess agricultural lands could allow governments eventually to phase out agricultural subsidies (Williams, 1994a).

19.2.5.2.1. Biomass production

Potential biomass energy supplies include municipal solid waste (MSW), industrial and agricultural residues, existing forests, and energy plantations.

MSW: MSW is produced at per capita rates of 0.9–1.9 kg/day in industrialized countries. Energy contents range from 4–13 MJ/kg. Energy can be produced by incineration, biodigestion, or thermochemical gasification to produce electricity, process heat, or fluid fuels. An attraction is the low price to potential users, who may be paid to take the waste because of the high cost of disposal in landfills. If MSW is burned, attention must be given to controlling air pollutants, some of which are carcinogenic compounds (WEC, 1994). Air pollution may be virtually eliminated with some advanced energy-conversion technologies (Chen, 1995).

Industrial and agricultural residues: The energy content of organic waste byproducts of the food, fiber, and forest-product industries is more than one-third of total global commercial energy use (Hall *et al.*, 1993). Some residues should be left at the site, however, to ensure the sustainable production of the main product. If removed and converted to biogas, the nutrients recovered in the digester should be returned to the site. Some recoverable residues would be better used for other purposes, and it will not be practical or cost-effective to recover all residues. Recoverable crop, forest, and dung residues have been estimated to be about 10% of present global commercial energy use (Hall *et al.*, 1993).

Existing forests: The difference between annual increment and harvest for the world's forests has an energy content equal to one-third of world primary energy use (Hall *et al.*, 1993). Large increases in wood recovery for energy, however, would require more intensive forest management and raise concerns about potential loss of biodiversity and natural habitat. Thus, the contribution of existing forests to energy supplies depends on local conditions.

Plantation biomass: Dedicated plantations of woody or herbaceous (annual or perennial) crops offer a large potential for biomass energy. At present there are about 100 million hectares of industrial tree plantations worldwide, of which about 6 million hectares are fast-growing hardwoods, the trees most suitable for energy applications (Hall *et al.*, 1993).

Excess agricultural lands are good candidates for plantations in industrialized countries. The potential for using such lands for biomass energy in Europe has been estimated at 33 Mha by 2020 (Hall, 1994) and 40 Mha for the European Union in the long term (Wright, 1991). Also, it has been estimated that 50–100 Mha of agricultural lands in Europe might become available for other purposes (WRR, 1992). In the United States, idle cropland totaled 33 Mha in 1990 and is projected to grow to 52 Mha by 2030, despite an expected doubling of

exports of maize, wheat, and soybeans (SCS, 1989)—largely because of expected increased crop yields.

Concerns about future food supplies (Ehrlich *et al.*, 1993; Kendall and Pimentel, 1994; Brown, 1993) have led some to suggest that land will not be available for biomass production for energy in Africa and other developing regions (Alcamo *et al.*, 1994). The outlook for food production may not be so bleak, however, if agriculture can be modernized in the developing world. With a continuation of historical trends in grain yields, considerable unforested land would be available for biomass energy production in many developing regions despite increased food requirements for a growing population (Larson *et al.*, 1995). Such outcomes depend on the availability of income to modernize agriculture, as well as whether intensified agricultural production can be made environmentally acceptable (see Section 19.3.1.4 and Chapter 25).

Deforested and otherwise degraded lands might be targeted for energy plantations. For tropical regions, Grainger (1988, 1990) has estimated that there are nearly 2,100 Mha of degraded land, of which 30% is theoretically suitable for reforestation. The challenge of restoration is to find a sequence of plantings that can lower ground temperature and restore the organic and nutrient content as well as the moisture level of the soils to attain
Figure 19-3: Actual biomass yields from various activities.

high and sustainable crop yields (OTA, 1992). Intensive R&D is needed to identify the most promising sites and restoration strategies (Riedacker, 1993; Johansson *et al*., 1993a).

The objective is for plantations to achieve high sustainable yields at low costs with minimal environmental impact. The characteristics of an ideal energy crop have been described by Goudriaan *et al*. (1991). Biomass energy must be considered in integrated land-use planning (see Chapter 25), with attention given to the economic well-being of the local community and to environmental concerns such as chemical pollution of ground water, soil erosion, and loss of biodiversity and landscape diversity (Beyea *et al*., 1991; Shell/WWF, 1993; OTA, 1993; Gustafsson, 1994; NBR, 1994; WEC, 1994). Biomass used for energy via thermochemical processes offers much more flexibility than biomass used for food in the choice and mix of species and cultivation practices for addressing environmental concerns because the only biomass attribute of importance then is production cost (Williams, 1994a).

Little biomass has been grown on plantations for energy. Thus, estimates of prospective yields are based on experience with crops grown for food and fiber, limited commercial experience and considerable experimental work with candidate bioenergy crops, and expected improved yields from new technology. The highest biomass yields that have been achieved over large areas are for sugar cane (see Figure 19-3): The 1987 worldwide average, aboveground biomass yield was 36 dry tons per hectare per year (dt/ha/yr); the yield for Zambia (averaged over 10,000 ha) was 77 dt/ha/yr (Hall *et al*., 1993). At Aracruz in Brazil from 1986 to 1991, yields (stemwood diameter >7 cm) of eucalyptus grown for pulp averaged about 23 dt/ha/yr; the maximum stand yields achieved in the same period were 52 dt/ha/yr (see Figure 19-3). About 11,000 ha of willow plantations have been established for energy in southern Scandinavia. There the yield on the best 100 hectares has averaged 10–12 dt/ha/yr (Ledin *et al*., 1994) and is projected to be 14–17 dt/ha/yr in 20 years (Christofferson, 1995). In the United States, researchers project that by 2020 yields for hybrid poplar and switchgrass will average 15–20 dt/ha/yr in regions where conditions are favorable for such crops (Walsh and Graham, 1995).

Plantation biomass costs already are favorable in some developing countries. On the basis of commercial experience with eucalyptus in northeast Brazil, an estimated 13 EJ/yr of biomass could be produced on 50 Mha at an average cost for delivered wood chips of $1.7/GJ (Carpentieri *et al*., 1993). Costs are much higher in industrialized countries. A major U.S. Department of Energy/Department of Agriculture study estimates, however, that a strong and sustained R&D effort could lead by 2020 to 5 EJ/yr of plantation biomass in the United States at a delivered cost of $1.5/GJ or less (Graham *et al*., 1995). A related study carried out by the U.S. Environmental Protection Agency estimates that land-use competition could increase land rental rates. Thus, the biomass price in 2020 for 5 EJ/yr would be $1.8/GJ under essentially the same technical

assumptions about yields and costs (Turnure *et al*., 1995). For comparison, the U.S. Department of Energy projects that the average price of coal to U.S. utilities will be $1.3/GJ in 2010 (EIA, 1995) under projected demand conditions. Displacement of coal by biomass on a large scale would tend to drive future coal prices to levels that are lower than without this competition.

The energy output–input ratio for plantation biomass depends on crop species, yield, and production technology. Although this ratio can be low for high-quality food crops such as grain, it is generally high for energy crops with good economic prospects. Some estimates are 15:1 for willow (Johansson, 1993); 29:1 for trees grown in short-rotation coppices (Foster and Matthews, 1994); and, in the United States, 11:1 for switchgrass, 12:1 for sorghum, and 16:1 for hybrid poplar (Turhollow and Perlack, 1991).

19.2.5.2.2. Electric power generation

Electricity generation from biomass can take place at scales ranging from a few kilowatts for rural village or agricultural applications, to tens of megawatts for present industrial applications, to hundreds of megawatts for advanced industrial applications.

Producer gas engines: The electrical loads of many poor rural villages of the developing world are in the range of 10–200 kW$_e$. Producer gas-engine generator sets based on the use of biomass gasifiers coupled to small reciprocating engines are well-matched to these loads (Ravindranath, 1993; Ravindranath and Hall, 1995). These generators often use diesel fuel, but biomass-derived producer gas could replace 75–95% of this diesel fuel.

Modest resources have been committed to developing this technology, mostly since the early 1970s. Until recently, most biomass-producer gas-engine projects failed, largely because of excessive tar formation in the gasifier and maintenance problems posed by tars. These problems have been solved, however; successful field demonstrations have been carried out, and the technology is ready for large-scale commercial applications (Mukunda *et al*., 1993, 1994). For 100-kW$_e$ units operated on biomass costing $2/GJ, electricity can be produced for 10–15¢/kWh; for low-cost biomass (for example $0.85/GJ for a village plantation in south India), electricity can be produced for less than 10¢/kWh (Larson, 1993), making this technology an attractive option for applications remote from electric grids where biomass is available.

Conventional steam-turbine technology: In many countries, biomass residues are used to generate electricity or CHP with conventional steam turbine technologies. The United States has an installed biomass steam-electric generating capacity of more than 8,000 MW$_e$ (Turnbull, 1993a). Although they tend to be much smaller (typically

20 MW$_e$) than fossil fuel steam-electric plants, relatively capital-intensive, and energy inefficient (Turnbull, 1993b), commercial biomass steam-electric plants can provide cost-competitive power where biomass prices are low, especially in CHP applications.

Improving steam-turbine cycles: In the near term, steam-electric plant performance can be improved by cofiring large boilers with biomass. This can be achieved by converting existing grate-fired boilers to fluidized bed boilers at modest cost—$40–100/kW$_e$, including fuel handling (Saviharju, 1995). Biomass cofiring systems are used extensively in Nordic countries.

Because costly sulfur cleanup is not needed for biomass, optimizing steam-turbine cycle technology can lead to specific capital costs and efficiencies for 100 MW$_e$ plants that are comparable to those for 500 MW$_e$ coal plants requiring sulfur cleanup (RTI *et al*., 1993). Less capital-intensive, more energy-efficient technologies are needed to make the more abundant and costly biomass sources competitive.

Advanced power cycles involving gasification: Higher efficiency and lower unit capital costs can be realized with advanced conversion technologies. Biomass-integrated gasifier/gas turbine (BIG/GT) cycles are the focus of present development efforts (Williams and Larson, 1993).

Because biomass generally contains little sulfur, gases exiting the gasifier can be cleaned at higher temperatures than is feasible for coal (hot-gas sulfur-removal technology is not commercially proven). Thus, biomass is well-matched to air-blown gasifiers, which tend to be less costly than the oxygen-blown gasifiers used in commercial coal integrated gasifier/gas turbine systems at the scales of interest for biomass power systems. Efficiencies of 40–45% are expected to be achievable (Elliott and Booth, 1993; Consonni and Larson, 1994).

Various projects to demonstrate BIG/GT technology are underway. A 6-MW$_e$ pilot plant is being tested at Värnamo, Sweden. A 30-MW$_e$ commercial demonstration plant is being planned for the northeast of Brazil (with initial operation scheduled for 1997–1998), with support from the Global Environment Facility (Elliott and Booth, 1993). During 1993–1994, two Finnish gasification CHP power demonstration projects (larger than 50 MW$_e$) were announced, as were three relatively small-scale (7–12 MW$_e$) demonstration projects (a CHP plant for Denmark and two power-only plants for the UK and Italy) with support from the European Union. Other demonstration projects are being planned in Belgium, the Netherlands, and the United States.

BIG/GT power plants would have low sulfur dioxide (SO$_2$) particulate, and thermal NO$_x$ emissions, but NO$_x$ emissions could arise from fuel-bound nitrogen (N). NO$_x$ emissions could be kept low by growing biomass with low N content and/or selectively harvesting portions of the biomass having high C/N ratios. For example, trees could be harvested in winter, after

the leaves—in which the N is concentrated—have fallen (Ledin and Alriksson, 1992). Stack-gas emission controls might still be needed in areas where there are severe restrictions on NO$_x$. Gasifier and/or combustor modifications under development offer the promise of suppressing NO$_x$ formation (Leppalahti, 1993). Successful development would obviate the need for stack-gas controls.

The ability of biomass to compete with coal depends on relative fuel prices and relative performances and costs for conversion technologies. A U.S. Environmental Protection Agency assessment exploring prospective advances for both biomass and coal (Turnure *et al*., 1995) considers future biomass power plants with characteristics that range from a 0.5% lower heat rate and a unit capital cost that is approximately 2% less than for coal plants, to biomass plants characterized by an 8% higher heat rate and a unit capital cost that is 20% higher than for coal plants. Under the first set of conditions, differences in fuel cost alone would drive the economic comparison between biomass and coal; for the second, subsidies in excess of 1¢/kWh would be required to put biomass on a competitive footing with coal, even under relatively optimistic assumptions about biomass production costs.

Other studies suggest that if R&D goals are fully realized for biomass production (Graham *et al*., 1995) and for the commercialization of advanced BIG/GT technologies designed to exploit the intrinsic characteristics of biomass feedstocks (Williams, 1995a), biomass has good prospects for competing with coal by 2020 in many circumstances, even if the price of biomass is somewhat higher than the price of coal. In the long run, key distinguishing features of biomass and coal IG/GT technologies are likely to arise from the sulfur and moisture contents of the feedstocks.[3] A framework for a quantitative economic comparison highlighting these distinguishing features is offered by fixed-bed integrated gasifier/intercooled steam-injected gas

---

[3] Even though existing biomass steam-electric plants (fired with forest product and agricultural industry residues or MSW) are characterized by modest scales (25 MW$_e$ a typical plant size), scale is not likely to be a key distinguishing characteristic between biomass and coal plants when advanced BIG/GT technologies using plantation biomass become established in the market, because electric generation costs are not very sensitive to transport distances for the fuel (Faaij *et al*., 1995; van den Broek *et al*., 1995). Site-specific analyses of such applications of pressurized BIG/GT systems in the U.S. and Brazil—taking into account the areal distribution of biomass supplies and power plant scale economies—have shown that electricity costs are minimized for capacities in the range 230–320 MW$_e$ (Marrison and Larson, 1995a, 1995b). Moreover, if air-blown gasifiers with hot-gas sulfur cleanup are successfully developed (Corman, 1986), it will be possible to have low-cost coal IG/GT plants at scales much smaller than those optimal for current IG/GT technology based on oxygen-blown gasifiers, for which costs are very scale-sensitive. Even if oxygen-blown gasifiers remain the norm for coal, future coal IG/GT plants may be smaller than the optimal for current technology—because of ongoing progress in reducing costs for air separation generally and in particular for air separation at modest scales, as a result of advances relating to pressure swing adsorption and membrane gas separation systems (Simbeck, 1995).

turbine (IG/ISTIG) systems[4] at the same scale (~110 MW$_e$) for both coal and biomass (Williams and Larson, 1993). The coal variant of IG/ISTIG, which involves hot-gas sulfur cleanup, has been proposed as a low-cost option for coal (Corman, 1986). The biomass variant does not require sulfur cleanup but does require a biomass dryer. A promising dryer option involves drying biomass in pressurized superheated steam and using the water evaporated from biomass as steam in the BIG/ISTIG system via process integration. For IVOSDIG (involving steam drying of biomass coupled to a steam-injected gas turbine), the first generation of which is being developed in Finland, it has been shown that the plant efficiency (HHV basis) is nearly independent of the fuel moisture content (Hulkkonen *et al*., 1991). The capital cost penalty for such a steam dryer for BIG/ISTIG is estimated to be $100/kW, about 40% of the estimated incremental cost for hot gas sulfur cleanup for the coal IG/ISTIG. Largely because of the resulting net capital cost advantage to biomass, IG/ISTIG electricity from biomass costing $2/GJ could potentially compete with IG/ISTIG electricity from coal for coal prices in the range $1.4–1.7/GJ (depending on the market value of the sulfuric acid recovered as a byproduct) (Williams, 1995a).

Biomass-integrated gasifier/fuel cell (BIG/FC) systems involving molten carbonate or solid-oxide fuel cells prospectively would be even more energy-efficient than BIG/GT systems and would be especially well-suited for industrial cogeneration applications requiring high-temperature process heat. Although little attention has been given to such systems in development efforts, biomass would, in several respects, be a more attractive feedstock than coal for gasification-based fuel cell applications (Kartha *et al*., 1994). If successfully developed, BIG/FC systems could extend the range of economically attractive power generation options to smaller scales (~1 MW$_e$) than would be feasible with BIG/GT systems.

19.2.5.2.3. Biogas production

Simple anaerobic digesters are used in rural areas of some developing countries to produce biogas from manure and crop residues at scales ranging from household to village. They provide fuel for cooking and power (Rajabapaiah *et al*., 1993), byproducts in the form of fertilizer and feed for pigs and fish farms, and substantial environmental and human health benefits (DEPE, 1992). The future potential is large, particularly if organizational issues are satisfactorily resolved—for example, if local expertise is ensured in operation and maintenance and if users take responsibility for collecting biomass for the biogas plant (Rajabapaiah *et al*., 1993).

In industrialized countries, the focus is on industrial plants with capacities of several million cubic meters of biogas/yr, compared with 250–300 m^3/yr for household plants in China (Wang *et al*., 1992) and 10,000 m^3/yr for village-scale plants in India (Rajabapaiah *et al*., 1993).

In the most common application in industrialized countries, manure and other organic wastes are pretreated and passed through plants for pasteurization, digestion, separation, and gas purification to produce biogas, along with byproducts that include fertilizer and compost. The gas produced in large installations in Denmark is used in gas engines for CHP or in boilers for DH. Experiments with other uses are in progress, including compressed gas for vehicles (Stewart and McLeod, 1980; Danish Energy Agency, 1992).

Economics: Direct costs have declined with experience for Danish plants. Although the government has provided a 25–50% subsidy, the best plant, selling gas at $10 per GJ, would roughly break even in Denmark even if there had been no subsidy (Danish Energy Agency, 1992).

In India, after experiences well short of expectations (Comptroller and Auditor General of India, 1994), cattle-dung biogas plants have now been demonstrated at village scale to be economically viable for providing biogas-generated electricity (~5 kW$_e$) for lighting and pumping water. Plans are underway to replicate the technology in many villages (Reddy *et al*., 1994).

Energy balance: For the 10 large Danish biogas plants, the net external energy requirement—considering fuel for transporting manure to the plant and the fertilizer value of the returned residue—is just 0.7% of net production, corresponding to an energy payback of three days (Tafdrup, 1993).

GHG emissions: The average GHG emissions avoided by using the biogas produced by the 10 Danish plants instead of coal for CHP is 17 kgC/m^3 of biomass converted. Moreover, biogas production from manure reduces emissions from spreading manure directly on fields equivalent to about 15 kgC/m^3 of biomass converted, so that total GHG emissions are reduced by 32 kgC/m^3 of biomass converted (Tafdrup, 1993).

19.2.5.2.4. Biofuels for transport

Interest in alternative transport fuels has been driven largely by concerns about oil supply security and urban air quality. These concerns have led Brazil and the United States to adopt policies promoting alternative vehicles and fuels. In light of increasing air pollution in the world's megacities (UNEP/WHO, 1992), such policies are likely to become more widespread.

Traditional biofuels for transport: Efforts to produce biofuels for transport have focused on ethanol from maize, wheat, and sugar cane and on vegetable oils such as rapeseed oil. The most substantial commercial programs are in Brazil and the United States. In 1989, Brazil produced 12 billion liters of fuel ethanol from sugar cane, which was used to power 4.2 million

---

[4] While IG/ISTIG technology is not currently being developed, its successful development could lead to substantial electricity cost reductions relative to first generation IG/GT technologies for both coal and biomass. Comparing coal and biomass in the context of IG/ISTIG technology represents the competing feedstocks fairly and facilitates a comparison of their key distinguishing characteristics.

cars running on hydrated ethanol and 5 million cars on gaso-hol, a gasoline-ethanol blend (Goldemberg *et al.*, 1993). In 1993, the United States produced 4 billion liters of ethanol from maize for gasohol applications.

All traditional biomass-derived transport fuels are uneconomic at present. Substantial cost reductions are being made for sugar cane-derived ethanol, however (Goldemberg *et al.*, 1993). Moreover, there are good prospects for making cane-derived ethanol competitive at the present low world oil price if electricity is cogenerated from cane residues using BIG/GT technology along with ethanol from cane juice (Williams and Larson, 1993). In contrast, the prospects are poor for making ethanol economically from grain (Wyman *et al.*, 1993).

Most traditional biofuels are inefficient users of land, with low yields of transport services (vehicle km/ha/yr) compared with what is achievable with advanced technologies using woody bio-mass feedstocks (Table 19-4). Many also have marginal energy balances. Fossil energy inputs to produce ethanol from wheat, maize, or sugar beets are likely to be comparable to the energy content of the ethanol; for rape methyl ester derived from rape-seed, fossil energy inputs are likely to be about half the energy in the rape methyl ester (Lysen *et al.*, 1992; IEA, 1994b). Greenhouse performance also tends to be marginal. For maize, estimates of net fuel-cycle emissions of CO_2 have ranged from somewhat more (Ho, 1989) to somewhat less (Marland and Turhollow, 1990) than for gasoline. Total life-cycle GHG emissions may even be somewhat higher than for reformulated gasoline, which contains more oxygen to improve combusion and thereby reduce emissions (DeLuchi, 1991). For rape methyl ester, life-cycle CO_2 emissions are less than for fossil fuels (Lysen *et al.*, 1992). There also may be significant emissions of nitrous oxide (N_2O), a powerful GHG, as a result of the conversion of some nitrogen in fertilizer to N_2O. These emissions depend on the type of fertilizer and application (Lysen *et al.*, 1992; Muschalek and Sharmer, 1994), however, and there are large uncertainties (Gosse, 1994; Bernhardt, 1994).

It is now generally believed that alcohol fuels—especially when blended with gasoline and used in flexible-fuel internal-combustion engine vehicles (ICEVs)—offer little or no

Table 19-4: *Energy yield for alternative feedstock/conversion technologies.*

Option	Feedstock Yield (dry tons/ha/yr)	Transport Fuel Yield (GJ/ha/yr)	Transport Services Yield[8] (10³ v-km/ha/yr)
Rape Methyl Ester (Netherlands)[1]	3.7 of Rapeseed	47	21 (ICEV)
EthOH from Maize (USA)[2]	7.2 of Maize	76	27 (ICEV)
EthOH from Wheat (Netherlands)[3]	6.6 of Wheat	72	26 (ICEV)
EthOH from Sugar Beets (Netherlands)[4]	15.1 of Sugar Beets	132	48 (ICEV)
EthOH from Sugar Cane (Brazil)[5]	38.5 of Cane Stems	111	40 (ICEV)
EthOH, Enzymatic Hydrolysis of Wood (present technology)[6]	15 of Wood	122	44 (ICEV)
EthOH, Enzymatic Hydrolysis of Wood (improved technology)[6]	15 of Wood	179	64 (ICEV)
MeOH, Thermochemical Gasification of Wood[7]	15 of Wood	177	64/133 (ICEV/FCV)
H_2, Thermochemical Gasification of Wood[7]	15 of Wood	213	84/189 (ICEV/FCV)

[1]Per ton of seed: 370 liters of rape methyl ester plus (not listed) 1.4 tons of straw (Lysen *et al.*, 1992).

[2]For wet milling, assuming the U.S. average maize yield, 1989–1992; per ton of grain: 440 liters of ethanol plus (not listed) 0.35 tons of stover (out of 1 ton of total stover, assuming the rest must be left at the site for soil maintenance), 275 kg of corn gluten cattle feed, and 330 kg of CO_2 (Wyman *et al.*, 1993).

[3]Per ton of seed: 455 liters of ethanol plus (not listed) 0.6 tons of straw (Lysen *et al.*, 1992).

[4]Per ton of sugar beet: 364 liters of ethanol (Lysen *et al.*, 1992).

[5]For the average sugar cane yield in Brazil in 1987 (63.3 tons of harvested cane stems, wet weight); per ton of wet cane stems: 73 liters of ethanol (Goldemberg *et al.*, 1993). In addition, (not listed) the dry weight of the attached tops and leaves amounts to 0.092 tons and that for the detached leaves amounts to 0.188 tons per ton of wet stems—altogether some 18 dry tons/ha/yr (Alexander, 1985).

[6]Per ton of feedstock: 338 liters of ethanol plus (not listed) 183 kWh (0.658 GJ) of electricity, present technology; 497 liters of ethanol plus (not listed) 101 kWh (0.365 GJ) of electricity, improved technology (Wyman *et al.*, 1993).

[7]For the indirectly heated Battelle Columbus Laboratory biomass gasifier; per ton of feedstock: 11.8 GJ of methanol or 14.2 GJ of hydrogen; per ton of feedstock, external electricity requirements are 107 kWh (0.38 GJ) for methanol or 309 kWh (1.11 GJ) for hydrogen (Williams *et al.*, 1995a, 1995b).

[8]Fuel consumption rate of the vehicles (in liters of gasoline-equivalent per 100 km) assumed to be 6.30 for rapeseed oil (assumed to be the same as for diesel), 7.97 for ethanol, 7.90 for methanol, and 7.31 for hydrogen used in internal combustion engine vehicles (ICEVs), and 3.81 for methanol and 3.24 for hydrogen used in fuel-cell vehicles (FCVs) (DeLuchi, 1991). Note that 1 liter of gasoline equivalent = 0.0348 GJ, HHV.

air-quality advantages, other than reduction in carbon monoxide (CO) emissions (Calvert *et al.*, 1993). Moreover, reformulated gasolines can meet or surpass the air-pollution reductions of alcohol-gasoline blends (BEST, 1991). With methanol, CO emissions would be reduced, and emissions of volatile organic compounds would be less problematic than for gasoline, but NO_x emissions would probably not be reduced. Ethanol offers lesser air-quality benefits than methanol and may produce more ozone per carbon atom (Calvert *et al.*, 1993). Because of such problems with traditional biofuels, advanced technologies are receiving increased attention.

Advanced biofuels: Advanced biofuels derived from low-cost woody biomass could offer higher energy yields at lower cost and with lower environmental impacts than most traditional biofuels (IEA, 1994b). The advanced biofuel that has received the most attention is ethanol derived from wood via enzymatic hydrolysis (Wyman *et al.*, 1993). For a woody feedstock yield of 15 dry t/ha/yr—which is generally believed to be achievable in large-scale production—the ethanol yield could be more than twice that from grain (Table 19-4). If the U.S. Department of Energy's year-2000 goals for performance and cost are met, energy balances would be favorable; life-cycle emissions of CO_2 for ethanol production and use in ICEVs (in gC/km) would be only about 2% of those from such vehicles operated on reformulated gasoline (Wyman *et al.*, 1993). Furthermore, ethanol will be competitive with gasoline if oil prices are greater than about $25/bbl (Wyman *et al.*, 1993). For comparison, French studies indicate that ethanol from grain will not be competitive until oil prices reach $40–45/bbl (Torck *et al.*, 1988). The major shortcoming of the technology is that it may not lead to air-quality improvements beyond what can be achieved with reformulated gasoline. However, low emissions, along with a two to three-fold gain in fuel economy, might be practically achievable using either fuel with a so-called hybrid car that has an electric drive train, an electric generator driven by a small internal-combustion engine that would provide baseload power, and a small battery or other device for providing peak power (Ross, 1994; Colombo and Farinelli, 1994).

Other advanced fuels include methanol and hydrogen derived from biomass via processes that begin with thermochemical gasification. Used in fuel-cell vehicles (FCVs), they offer good prospects for dealing with the multiple challenges of transportation. Recent advances suggest that the proton-exchange-membrane (PEM) fuel cell is an attractive alternative to the internal combustion engine for cars (AGTD, 1994; Williams, 1993, 1994b), buses, trucks, and trains (see Section 19.2.6.4).

If FCVs were introduced, hydrogen or methanol fuel would be produced initially by steam-reforming natural gas. This is the least-costly route, for which the required technology is commercially available. On the basis of projected prices for natural gas, coal, and biomass, production costs would be comparable for these three feedstocks before 2025 (Williams, 1996).

The prospect that biomass could compete with coal in the longer term reflects the more favorable characteristics of biomass as a feedstock for gasification (Williams *et al.*, 1995a, 1995b). Low sulfur content gives biomass a processing cost advantage compared with coal. In addition, if the biomass gasifier is designed to exploit the much higher reactivity of biomass compared to coal, unit capital costs can be reduced. For both coal and biomass, the initial step involves gasification to produce a synthesis gas (mainly CO and H_2). Coal is gasified in oxygen to produce the desired synthesis gas. The high gasification temperatures needed are achieved by direct heating—that is, by burning some of the coal in place. To take advantage of economies of scale for the oxygen plant, the coal conversion facilities would be large. Because of its much higher reactivity, biomass can be gasified at much lower temperatures—a property that makes it possible to avoid the use of costly oxygen-blown gasifiers and instead to gasify the biomass in steam using indirectly heated gasifiers in smaller facilities.

The yield for methanol or hydrogen produced from woody biomass would be comparable to that for ethanol derived via enzymatic hydrolysis (see Table 19-4). The potential for displacing gasoline used in ICEVs with biomass-derived methanol or hydrogen used in FCVs, however, would be more than twice that for ethanol used in ICEV applications because FCVs would be more than twice as energy-efficient as ICEVs. The FCV thus offers the potential for substantially increasing the role of biomass in transportation, supporting up to seven times as many vehicle-km of transport services per hectare as ethanol derived from grain used in ICEVs (see Table 19-4).

19.2.5.3. Wind Energy

19.2.5.3.1. Stage of development

The technology related to grid-connected wind turbines has become commercially available and mature. The most successful commercial wind turbines have installed capacities of up to 600 kW. A new generation of machines in the 1 MW size range and above is now being investigated. At the end of 1993, the global installed capacity of high-efficiency wind turbines was 3,100 MW, of which approximately 1,700 MW is in the Americas and 1,200 MW in Europe. While many different designs are in use, the "stock average" technology consists of three-bladed, horizontal-axis machines operating at near-fixed rotation speed. In 1993, the global new installation of wind energy was on the order of 550 MW; the annual manufacturing capacity was over 1,000 MW. This capacity could increase rapidly due to the decentralized structure of production in the wind power industry. Technical availability (the capability to operate when the wind is higher than the starting wind speed of the machine) is now typically 95–99%. Small-scale applications of wind energy such as water pumping, battery charging, and stand-alone electricity supply systems also are being developed (Cavallo *et al.*, 1993; WEC, 1994; Sørensen, 1988).

Methods for evaluating wind resources have improved (Troen and Petersen, 1989). In several regions, reviews of resources

have been carried out, and siting methods are now being employed regularly to identify the most valuable wind turbine sites (Turkenburg, 1992).

19.2.5.3.2. Technology development

To decrease the cost of electricity, new generations of wind turbines are bigger than current turbines. The reduction of the blade number to two and the introduction of cost-effective power electronic systems to allow for variable-speed operation may further reduce costs.

Intermittent wind power on a large grid can contribute an estimated 15–20% of annual electricity production without special arrangements (see also Section 19.2.6.1). In large utility systems with a small fraction of wind power, savings in fuels and emissions are approximately proportional to the average wind energy input. Employing the so-called loss-of-load-expectation method, the capacity value is typically found to be close to that of a conventional thermal plant with the same energy output at low levels of wind power penetration (supply fraction) and to decline with increasing penetration (van Wijk, 1990; Tande and Hansen, 1991; Grubb and Meyer, 1993). Energy storage facilities probably will be integrated into the utility system, which would allow efficient utilization of wind energy at high penetrations. The wind energy and the storage facility together may supply "firm" power actually substituting for baseload power (Cavallo, 1995; Cavallo and Keck, 1995).

19.2.5.3.3. Economy

The present stock average cost of energy from wind power is approximately 10¢/kWh, although the range is wide. By 2005 to 2010, wind power may be widely competitive with fossil and nuclear power (IAEA, 1991).

A study by Godtfredsen (1993) on new, commercially available wind-power technology gives the distribution of investment cost and the cost of energy. For average new technology, this study shows investment costs of $1,200/kW and electricity production costs of 6¢/kWh. For the best new technology, the figures are $900/kW and 5.5¢/kWh, respectively. The figures are based on an average windspeed of 10 m/s at 10 m above ground level, using single machines or small groups of machines, and do not include long-range transmission costs. Costs could be significantly lower for large wind farms.

The average annual windspeed on the site strongly affects the cost of energy. As a rule of thumb, the wind turbines' production increases with the windspeed to the third power, and the cost of energy decreases accordingly. Wind turbines at very windy sites (for example, coastal regions in northwest Europe) produce electricity at a total cost of 4.0–4.5¢/kWh. Some Danish utility-owned turbines produce electricity at 4.5¢/kWh (Elsamprojekt, 1994).

One set of projections of future costs is presented in Table 19-5. For comparison, Cavallo *et al*. (1993) project a cost of 3.2¢/kWh for 2020, assuming a wind turbine hub height of 50 m, an average wind speed of 5.8 m/s at 10 m, a 6% discount rate, and a useful equipment life of 25 years.

The payback time of the energy invested (energy balance) in the production of the wind turbine is less than one year for average new technology (see Table 19-5).

19.2.5.3.4. Markets

Formulated political goals for the next 20–30 years add up to 150 TWh$_e$ global annual generation. The potential is considerably higher and could be further exploited (see Table B-4 in Chapter B). For example, the World Energy Council presents a "Current

Table 19-5: *Development of wind energy technology: technology level and characteristics, energy payback time for wind turbine, cost of electricity, and barriers to widespread dissemination. Assumptions include discount rates of 6 and 10%, average windspeed at 10 m altitude of 5.5 m/s (roughness class 1), and useful lifetime of 20 years. All costs are in 1990 US$. External costs and CO_2 emissions are not included.*

Technology Level	Technology Characteristics	Energy Balance (months)	Direct Cost (¢/kWh) 6%	10%	Institutional Barriers
Stock Average, 1975–90	Three-bladed, induction generator	12	10		kWh-cost
Average New Technology, 1993	Three-bladed, induction generator	9	6	7.4	Cost, public acceptance
Best New Technology, 1993	Three-bladed, induction generator	9	5	6.3	Public acceptance
Near-Term Technology, 2003	Three-bladed, variable speed	6	4.2	5.4	Public acceptance, load management
Long-Term Technology, 2020	Two-bladed, variable speed, flexible structure	6	3.4	4.3	Load management, transmission

Policy Scenario" and an "Ecologically Driven Scenario"—the latter showing an annual production of electricity from wind turbines of close to 1,000 TWh$_e$ in the year 2020 (Van Wijk *et al.*, 1993; WEC, 1994), which is close to 8% of the global annual electricity consumption in 1990.

19.2.5.3.5. *Public acceptance*

Countries with large numbers of operating wind turbines sometimes experience strong public resistance before installation. Local values, circumstances, and decisionmaking procedures influence the degree of resistance to the noise of turbines, the visual impact on the landscape, the disturbance of wildlife (birds), and the disturbance of telecommunications (Arkesteijn and Havinga, 1992). In areas of Britain and Denmark with wind turbines installed, 70–85% of the citizens are supportive or not concerned (Carver and Page, 1994; DTI, 1993). The little evidence of the impact of turbines on wildlife (Grubb and Meyer, 1993) suggests that it is generally low and species-dependent (Still *et al.*, 1994). Case stories of birds killed by wind turbines have initiated new research that should illuminate the matter. At a 269-unit wind farm near Tarifa, Spain—on the main western bird-migration route between Africa and Europe—dozens of dead birds have been found (*Windpower Monthly*, February 1994). Closure and covering of a nearby waste pit is expected and intended to reduce bird mortality. New blades and gearboxes may generate less noise. Colors, tower type and shape, and number of blades are being studied to improve the appearance of turbines. Still, there are likely to be some sites of exceptional landscape or historic value where wind power plants cannot be accepted.

Experience also indicates how public acceptance can be secured. The most important means are information about wind energy's environmental benefits, a proactive style of communication, and considerate conduct by developers and authorities when wind-farm sites are identified and claimed for wind energy use (Turkenburg, 1992). In Denmark and the Netherlands, private/cooperative ownership of wind turbines also has helped in achieving public acceptance.

19.2.5.4. *Solar Electric Technologies*

Direct conversion of sunlight to electricity can be achieved by photovoltaic and solar thermal electric technologies.

19.2.5.4.1 *Photovoltaic technologies*

Photovoltaic (PV) devices made of layers of semiconductor materials convert sunlight directly into electricity. Since they are modular, create no pollution in operation, can be operated unattended, and require little maintenance, PV systems often will be deployed at small scales and close to users. PV technologies can be deployed virtually anywhere—even in areas with frequent cloudiness.

Centralized and distributed grid-connected power generation is most important for GHG emissions reductions. Small-scale applications for rural electrification for lighting, water pumping, refrigeration, and educational purposes are important for development but are less significant for GHG emissions reductions.

For several years, PV has been competitive in stand-alone power sources remote from electric utility grids. It has not been competitive, however, in bulk electric grid-connected applications. System capital costs are $7,000–10,000/kW; the corresponding electricity cost is 23–33¢/kWh, even in areas of high insolation (2,400 kWh/m²/yr). New fossil fuel power plants cost less than 5¢/kWh. PV costs are declining, however. PV module prices in 1992 were one-tenth those in 1976 as cumulative production increased 1,000-fold. There are good prospects for continuing cost reduction, as indicated in Table 19-6 (Kelly, 1993; Ahmed, 1994; INEL *et al.*, 1990; WEC, 1994).

Two basic types of PV devices are flat-plate systems that convert both direct and diffuse radiation; and concentrators that must have direct radiation to work effectively and use mirrors or lenses to concentrate the incident light onto a small area equipped with solar cells. The prospects for major cost reductions are especially good for thin-film PV modules that would be used in flat-plate devices (Carlson and Wagner, 1993; Zweibel and Barnett, 1993) and for sun-tracking, concentrating systems (Boes and Luque, 1993).

Thin-film devices: The active PV materials for thin-film devices are layers 1- to 2-μm thick deposited on appropriate substrate materials (e.g., glass plates) for modules with areas of about 0.5 m² or more. Although they are less efficient than the more conventional, thick crystalline silicon devices, the small quantities of active materials required imply a potential for achieving very low costs at acceptable efficiencies (Carlson and Wagner, 1993; Zweibel and Barnett, 1993).

Amorphous silicon (a-Si) is the only thin-film technology established commercially, accounting for 27% of world PV sales of about 63 MW in 1993. The 5% efficiencies of commercial modules are far from the long-term goal of 15% for flat-plate devices (Kelly, 1993). Stabilized efficiencies of 10% have been realized for submodules (Zweibel, 1995). The relative ease of manufacturing a-Si modules (Carlson and Wagner, 1993) may make it possible to design cost-effective a-Si systems that are integrated into building rooftops, windows, and walls. PV electricity generation could become an integral part of the living environment (Hill *et al.*, 1994; Humm and Toggweiler, 1993; Strong and Wills, 1993).

How much it will be feasible to increase a-Si module efficiencies is uncertain. With the current glow-discharge deposition technique, a-Si films must be made ultrathin to compensate for the initial degradation of efficiency following exposure to light. This Staebler-Wronski effect (Carlson and Wagner, 1993) makes efficiencies greater than about 10% difficult. Light-induced efficiency degradation may not be a problem for an alternative hot-wire deposition technique (Vanecek *et*

Table 19-6: *Alternative projections of installed photovoltaic system costs (1990 US$).*

| Parameter | U.S. DOE Interlaboratory White Paper[1] | | Williams and Terzian[2] | | Zweibel and Luft[3] |
	Business As Usual	Intensification of RD&D	Business As Usual	Accelerated Development	Thin-Film Systems
Installed Capital Cost ($/kW)					
2000	3820	2540	4470	3610	3500
2005	–	–	3500	2170	2000
2010	2290	1770	2770	1520	1000
2020	1530	1250	1850	1060	800
2030	1280	1010	–	–	640

[4]Calculated assuming 6% discount rate.

al., 1992; Haage *et al.*, 1994), but it remains to be demonstrated whether high efficiencies can be achieved with this technique (Zweibel, 1995). There are good prospects of achieving the 15% goal with at least one thin-film technology. Besides a-Si, two polycrystalline technologies show great promise: $CuInSe_2$ and CdTe (Zweibel and Barnett, 1993). Although there has not been as much development effort focused on these as for a-Si, progress has been rapid. Between 1977 and 1994, efficiencies of laboratory cells have increased from 6% to about 17% for $CuInSe_2$ and from 8% to about 16% for CdTe (Zweibel, 1995), without serious stability problems. Stable efficiencies for submodules about 0.1 m² in size already are comparable to or greater than what has been realized with a-Si.

Because of its modularity, PV technology is a good candidate for cost-cutting through "learning-by-doing" as well as technological innovation (Cody and Tiedje, 1992; Tsuchiya, 1989). A design exercise exploring what can be achieved by mass-producing near-term $CuInSe_2$ technology (Bradaric *et al.*, 1992) generated estimates that a 50-MW power plant based on 1995 $CuInSe_2$ technology would have an installed cost of $2300/kW, corresponding to a generation cost of about 8¢/kWh in areas with good insolation, and the value of the electricity to the utility would be comparable if the plant were sited where the output is well-correlated with peak electrical demand.

In the transition period to large-scale PV development, the value of PV in grid-connected applications often can be enhanced by locating the PV system close to users—at utility substations and on commercial and residential rooftops—instead of in central stations. For such distributed applications in areas where there is a good correlation between PV output and utility subsystem peak demand, the electricity is worth substantially more to the utility than in central-station configurations (Shugar, 1990; Kelly and Weinberg, 1993; Wenger and Hoff, 1995; Hoff *et al.*, 1995). Moreover, net system costs could be reduced in configurations where PV modules serve dual purposes (for example, being roof tiles as well as providing power). Markets for high-value, grid-connected, distributed PV are likely to be large in both the United States and in many developing countries (Williams and Terzian, 1993).

Although the long-term prospects for thin films are much harder to predict than the prospects for cost-cutting through learning-by-doing, thin-film researchers tend to be optimistic. Thin-film program management at the National Renewable Energy Laboratory in the United States projects that installed system costs will fall to about $1,000/kW by 2010 and ultimately to $600–700/kW (Table 19-6; Zweibel and Luft, 1993).

Concentrating, tracking PV technology: Much higher efficiencies can be achieved with crystalline PV technologies than is

possible at present with thin films. Already, efficiencies of 28% for crystalline silicon and 34% for mechanically stacked gallium arsenide/gallium antimony multijunction cells have been achieved, and higher efficiencies are expected. Although such cells are much more costly to make than thin films, the higher costs can be offset by using devices that concentrate the sun's rays by a factor of anywhere from 2 to 1,000. The contribution of the cell cost to the module cost is reduced by this concentrating factor, and the concentrating device is expected to be much less costly per unit area than the cell.

Bradaric *et al*. (1992) have designed a 50-MW$_e$ power plant based on the use of expected 1995-vintage concentrating technology (27.4%-efficient cells used in a two-axis tracking concentrator) brought to technological maturity. Their estimated installed cost is about $3,200/kW for mass-produced modules; the corresponding cost of electricity in a sunny area would be about 9¢/kWh. Whereas high-concentration ratio devices would be most suitably deployed in central-station configurations, low-concentration ratio devices—for example, flat-plate, thin-film devices—would be suitable for many distributed applications, both grid-isolated and grid-connected.

Life-cycle analysis: Life-cycle issues of concern for PV systems are energy payback time, toxic emissions, and the use of scarce materials.

The energy payback time is the ratio of the primary energy required to manufacture 1 m^2 of module plus balance-of-system (support structure, wiring, installation) for the power plant to the rate of primary fossil energy avoided by the electricity production with 1 m^2 of module. Most studies have focused on energy inputs for modules and have found that the energy payback time is strongly correlated with the amount of active PV material used. For silicon devices, the payback time is an estimated 5–10 years for monocrystalline, 3–5 years for polycrystalline, and 0.5–2 years for a-Si modules (von Meier, 1994). For monocrystalline and polycrystalline power plants, the payback is dominated by the energy required to make cells.

For thin-film devices, the difference between current and future technology is expected to be large. The payback for a-Si modules is estimated (for global average insolation of 1,700 kWh/m^2/yr) to be 2.5 years for 6%-efficient modules and generally pessimistic conditions versus 0.5 years for 10%-efficient modules and "base case" conditions (van Engelenburg and Alsema, 1994). Assuming future 15%-efficient modules, paybacks are expected to be even lower for polycrystalline modules: 1.6 months for CdTe and 4 months for CuInSe$_2$ (Alsema and van Engelenburg, 1992). For grid-connected systems, the balance-of-system is estimated to contribute an additional 1.8 years with today's technology but only 0.6 years with future systems using 10%-efficient modules (Hagedorn, 1989).

Emissions: Although PV devices emit no pollution in normal operation, some systems involve the use of toxic materials, which can pose risks in manufacture, use, and disposal. Life-cycle risks posed by silicon PV systems are small (Sørensen

and Watt, 1993), but the potential hazards posed by the cadmium in CdTe and the selenium in CuInSe$_2$ devices warrant scrutiny—especially air emissions resulting from fires involving rooftop systems and incineration of unrecycled module waste. Such life-cycle emissions per kWh generated would be comparable to those from modern coal-fired power plants (Alsema and van Engelenburg, 1992).

Resources: There are no resource constraints for silicon PV systems. Although thin-film polycrystalline devices use only tiny amounts of active material, some materials are scarce. Of particular concern are the tellurium used in CdTe and especially the indium used in CuInSe$_2$ systems. Recycling might be required in order for these technologies to play major roles in the global energy economy (Alsema and van Engelenburg, 1992).

The societal cost of research, development, and commercialization: PV is the furthest of the renewable energy technologies from being commercially attractive in large-scale applications. How fast costs come down in the future depends on the level of the societal commitment to develop the technology. Williams and Terzian (1993) conclude that it would be worthwhile to accelerate rapidly the pace of development via intensification of the R&D effort and market incentives because the public-sector costs involved are expected to be small compared with the direct societal benefits, measured as the present value of reduced future consumer expenditures on electricity. Williams and Terzian (1993) estimate the public-sector subsidy to develop 400 GW$_e$ of installed PV capacity worldwide by 2020 to be $1 billion/yr for more R&D in the early years, plus a present value of $3.3 billion for future market incentives. These estimates are similar to those made by the World Energy Council in estimating what would be required to commercialize PV technologies: a market stimulation incentive of $2.5–4.0 billion, plus another $5 billion for R&D (WEC, 1994). These costs are very small compared with the costs of commercializing fossil and nuclear technologies, largely because of the small scale of the technology.

19.2.5.4.2. Solar thermal-electric technologies

Solar thermal-electric technologies use mirrors or lenses to concentrate the sun's rays onto a heat exchanger, where a heat-transfer fluid is heated and used to drive a conventional power-conversion system. Applications for solar thermal-electric systems range from central-station power plants to modular, remote power systems. Such systems can be hybridized to run on both solar energy and fossil fuel; some systems contain integral thermal energy storage, allowing dispatchable, solar-only operation. These systems use only direct rays from the sun and are best located in regions of high sunlight intensity. Solar thermal-electric systems have the long-term potential to provide a significant fraction of the world's electricity and energy needs (WEC, 1994; Brower, 1993).

Between 1984 and 1990, nine utility-scale solar thermal power plants—cumulatively over 350 MW$_e$—were constructed in southern California using solar parabolic-trough technology

driving a steam turbine in a hybrid configuration co-fired with natural gas. Developers of this technology in Europe and the United States are pursuing new power plant projects in several developing countries that could result in several hundred megawatts of new installations before the year 2000. In Australia, a tilted, polar-tracking-oriented, parabolic-trough system, with selective surfaces improving absorption and reducing losses and low concentration for higher diffuse radiation acceptance, is being developed that incorporates a storage system to allow high solar capacity factors (Mills and Keepin, 1993).

A solar central receiver—also called a "power tower"—uses a field of sun-tracking mirror assemblies to concentrate sunlight onto a tower-mounted receiver, where a circulating fluid is heated and used to produce power. Power towers typically contain cost-effective thermal energy storage and are intended as central-station power plants for peaking and intermediate load applications in 100–200 MW_e plant sizes (Hillesland and De Laquil, 1988; Hillesland, 1988). The technology is in the demonstration phase and could enter the utility-generation marketplace in the second half of the 1990s. In the United States, the 10-MW_e Solar Two Project, which will demonstrate nitrate salt receiver and storage technology, is scheduled to be operating by 1995 (Von Kleinsmid and De Laquil, 1993). A European industry consortium is planning to develop a 30-MW_e demonstration plant in Jordan using a volumetric air receiver and ceramic storage (De Laquil *et al.*, 1990; Phoebus, 1990; Haeger *et al.*, 1994); this plant could be operational by 1997. In Israel, the Weizmann Institute is developing a pressurized volumetric air receiver that could be used to drive a gas turbine or combined-cycle power plant. Initial receiver testing was encouraging, and scale-up and system integration are now being addressed (Karni, 1994).

Parabolic dishes supplying the external heat for a Stirling heat engine have achieved a maximum net solar-to-electric conversion efficiency of 29.4% and an average daily net efficiency of 22.7% (Washom, 1984). Dish-engine system modules range from 2 to 25 kW, and several companies in the United States and in Europe are developing systems for remote applications as well as grid-connected, distributed-power application (Kubo and Diver, 1993). In the United States, design validation systems are currently undergoing field tests; early commercial systems are expected to be available in 1996. The Australian National University has developed a 50-kW dish concentrator system driving a small, ground-mounted steam power plant (Kaneff, 1994; Stein, 1994).

Table 19-7 lists projections for cost and performance of each solar thermal-electric technology (De Laquil *et al.*, 1993). Parabolic-trough technology has achieved significant cost reductions and current plants have energy costs of 9–13¢/kWh in the hybrid mode. Power towers have significantly lower projected energy costs, 4–6¢/kWh, which can be achieved at production rates of 200 MW/yr without technological breakthroughs. These costs must be proven at commercial scale, however. The thermal-storage feature of the nitrate salt power-tower technology allows electricity to be generated when it is

most valuable and, in principle, allows annual solar-only capacity factors of 100%. With high-volume manufacturing, dish-engine systems have a cost potential as low as 5.5¢/kWh in a solar-only mode. They also can be hybridized using most gaseous or liquid fuels to provide continuous operation. In general, all solar thermal-electric technologies require the installation of a few hundred MW_e of systems before they reach their expected cost targets.

Integrated solar, combined-cycle plant configurations, which are being developed for both parabolic-trough and power-tower technology, promise to lower costs significantly for early commercial plants. Capital costs are in the range of $1,000–1,500 per kW, and electricity costs have been calculated to be within 0.5¢/kWh of conventional, natural gas-fired, combined-cycle power plants; the annual solar fraction (the share of demand covered by solar) for these integrated, combined-cycle configurations typically is 20% or lower. Because they reduce both the market entry cost and risk hurdles, such hybrids may lead to earlier introduction of commercial plants. Higher-solar fraction plants can be built as the cost of solar-based electricity approaches the cost of natural gas-based electricity.

Land use, water consumption, compatibility with desert species, and aesthetics are the principal environmental considerations. Because large plants will be best located in desert regions, water consumption is likely to be the most serious environmental issue.

In addition to electricity production, solar thermal systems can provide high-temperature process heat, and central receivers can be used to process advanced fuels and chemicals—for example, hydrogen—which may enhance their long-term potential.

19.2.5.5. Solar Thermal Heating

Solar thermal systems provide heating and hot water for domestic, commercial, or industrial uses (Duffie and Beckman, 1991). Solar cooking and solar cooling cycles are described in Sørensen (1979a). Simple solar thermal systems comprise:

- *Passive solar thermal systems*: Controlled solar collection through building design and the use of proper materials and practices, including smart windows, solar walls, and evaporative cooling (see Chapter 22).
- *Active solar thermal collectors*: Available designs range from unglazed, uninsulated plastic collectors for temperatures just above the ambient temperature to evacuated concentrating collectors for temperatures above 200°C. Flat-plate collectors based on a thermosyphon principle or with forced circulation for 60–80°C dominate at present.
- *Systems for use with solar thermal technologies*: Energy storage in building materials, water (including aquifers), rocks, and soil for individual houses and community systems (Dahlenbäck, 1993), and consideration of fuel backup and proper system management.

Table 19-7: *Levelized energy cost projections.[1]*

	Parabolic Trough			Central Receiver				Dish-Stirling		
	80 MW$_e$	80 MW$_e$	200 MW$_e$	100 MW$_e$	200 MW$_e$	200 MW$_e$	200 MW$_e$	3 MW$_e$ per year *early remote market*	30 MW$_e$ per year *early utility market*	300 MW$_e$ per year *utility market*

Hybrid LEC Range (¢/kWh)	13.0–9.3	13.5–7.9	9.3–6.5	–	–	–	–	–	–	–

[1] From De Laquil *et al*. (1993), which compiled these data from several sources. The levelized energy cost (LEC) calculations are based on a 6% real discount rate; the fixed charge rate for capital is 7.8%.

[2] Typical southwest U.S. site.

Domestic hot water currently is the most important application. For one household, the typical collector area is 3–6 m², with a 300-liter water-storage tank. Because the available roof space generally is not a limiting factor, system efficiency is the result of a cost/benefit optimization for the entire system. A typical annual average value is 30–40%. The solar fraction is limited by the seasonal variation in irradiation levels. In equatorial areas it can be 100%, whereas it does not exceed 50% in high-latitude areas without significant storage.

Investment costs for an installed domestic solar hot-water system for one household range from $600 for a 2-m² thermosyphon system in the Middle East to $6,000 for a 4-m² pumped system in northwest Europe. Annual system output varies from 300 to 600 kWh$_{th}$/m². At a real rate of return of 6% (10%), heat costs range from $8 ($14) to $80 ($140) per GJ$_{th}$. The production and use of domestic solar hot-water systems does not have significant environmental effects. The energy payback time is about one year.

Large numbers of solar thermal collectors are installed, notably in Europe, Asia, and North America. An estimated 20–30 million m² deliver 40–60 PJ/yr (Nitsch, 1992). The technical potential is much larger. The installed capacity varies greatly, even between countries with similar climate and geography. Thus, attention to implementation issues may help—for example, the adjustment of building codes to accept solar collectors. Several countries offer subsidies in view of the environmental advantages of solar thermal systems (Gregory *et al*., 1993). Demonstration systems for space heating with up to 7,500 m² of collectors have been realized together with seasonal heat storage (Dalenbäck, 1993).

Future prospects include an expected lowering of cost. The main stock of collectors have absorbers of steel with selective coating, glass cover, and aluminum frame and backplate, plus insulating material such as mineral wool. Cheaper constructions use plastic absorbers (polypropylene ribbons), polycarbonate covers, and fiber backplates. Another development is high-efficiency evacuated tubes providing two to three times

higher annual collection per unit area. Costs are expected to decline due to higher volume, more efficient manufacturing processes, and reduced installation costs. An important topic for further R&D is the optimization of heat distribution systems with contributions from different heat sources (cogeneration, heat pumps, solar energy, and storage).

19.2.5.6. Geothermal and Ocean Energy

The two remaining renewable sources of energy are geothermal energy and ocean energy.

19.2.5.6.1. Geothermal energy

Geothermal energy resources are made up of both nonrenewable and renewable parts: The nonrenewable is stored from the time of the Earth's formation, and the renewable is due to the isotopic decay of radioactive elements in the Earth's interior.

Electricity is generated from geothermal energy in 21 countries. Commercial production on the scale of hundreds of MW has been undertaken for more than three decades, both for electricity generation and direct heat utilization. The installed capacity is nearly 6,300 MW_e. Four developing countries produce more than 10% of their total electricity from geothermal (El Salvador, 18%; Kenya, 11%; Nicaragua, 28%; the Philippines, 21%). The cost of electric generation is estimated to be around 4¢/kWh_e. Direct use of geothermal water (space heating, horticulture, fish farming, industry, and/or bathing) occurs in about 40 countries; 14 countries have an installed capacity of more than 100 MW_{th}. The overall installed capacity for direct use is about 11,400 MW_{th}, and the annual energy production is about 36 TWh_{th} (Fridleifsson and Frecston, 1994). The production cost for direct use is highly variable but commonly under 2¢/kWh_{th}. In addition, low-temperature heat stored in soil, water, and air can be upgraded by heat pumps and used for space heating and hot water.

Various emissions are associated with geothermal energy, including CO_2, hydrogen sulfide, and mercury. Advanced technologies are almost closed-loop and have very low emissions (WEC, 1994).

In recent decades, installed geothermal energy capacity has grown 10% a year for direct uses and from 8–17% for power generation. The growth is expected to continue but at slightly lower rates (Fridleifsson and Frecston, 1994).

Geothermal energy reserves that might be exploited in the next 2 decades are estimated to be 500 EJ, mostly relatively low-grade heat. Most geothermal systems are hydrothermal, but geopressured, magma, and hot dry rock systems are in the demonstration stage (Palmerini, 1993). Although it can make substantial local contributions in some areas, geothermal energy is unlikely to contribute more than 2% of total global energy requirements, even if hot dry rock geothermal technology is developed at an accelerated rate (Palmerini, 1993).

19.2.5.6.2. Ocean energy

Energy is stored in the tides, waves, and thermal and salinity gradients of the world's oceans. Although the total energy flux of each of these renewable resources is large, only a small fraction of their potential is likely to be exploited in the next 100 years. Ocean energy is spread over a wide area and would require large and expensive plants for collection, and much of the energy is available only in areas far from centers of consumption.

Tidal energy, which uses barrages at sites having a high tidal range, has considerable technical potential (Cavanagh *et al.*, 1993). Many sites with the most potential, however, also have been considered to be of great environmental significance—for example, some are bird habitats (Rodier, 1992; WEC, 1994).

The technology to use wave energy is in its infancy. Near-shore devices are likely to be developed first, but their applicability and potential are limited. Most wave energy is offshore. Because of technological problems and high costs, more powerful large-wave offshore energy plants are unlikely to be deployed for a few decades. Ocean thermal energy conversion (OTEC), which is currently in the prototype stage, is very costly and largely restricted to tropical locations (Cavanagh *et al.*, 1993).

19.2.6. Energy Systems Issues

System design and management issues are important for many new energy technologies that can significantly reduce GHG emissions. The most important are the management of intermittent power generation; the choice of a mix of renewable, fossil, and nuclear electric-generating technologies; the use of electricity transmission technologies; and the use of hydrogen or hydrogen-rich energy carriers.

19.2.6.1. Managing Intermittent Power Generation

Intermittent power-generating supplies can be managed by new load-management techniques; an appropriate mix of dispatchable generating capacity for backing up intermittent sources; interconnecting grid systems; and mechanical, electrochemical, thermal, or other forms of storage (Sørensen, 1984).

If energy users knew the current and expected availability of intermittent energy sources and associated energy prices, they might change their patterns of energy demand. Price signals and related information could be transmitted to users through power lines or other information channels so they could plan their use of electricity accordingly. This kind of demand management can be automated by using intelligent appliances and equipment responding to signals received through the grid according to selections programmed by users.

Energy suppliers might apply transmission planning, including the transfer of electricity over large distances to cope with some of the daily variations of wind and solar energy. The

management of interconnected grids could be optimized to allow maximum inputs from variable power sources, as is currently done to make the best use of baseload power plants.

Hydropower plants allow prompt regulation and can back up intermittent energy generators, as can some types of thermal power plants. The ideal thermal complements to intermittent renewable energy plants on grid systems are plants characterized by low unit capital cost (so they can be operated cost-effectively at low capacity factor) and fast response times (so they can adjust to rapid changes in intermittent supply output). Gas turbines and combined cycles satisfy these criteria, but supercritical fossil and nuclear steam-electric plants do not. Thus, nuclear and intermittent renewable power sources are competitive rather than complementary strategies at high grid-penetration levels.

The levels of electricity generation from intermittent sources (for example, from wind turbines or photovoltaic arrays) that can be accepted in a supply system depend strongly on the nature of the system and the measures that manage time variations in load. Typical percentages of wind or solar shares in systems without storage are about 20% for grid systems and up to 50% for large systems with reservoir-based hydro or time-zone variations of loads (Sørensen, 1981, 1987; Grubb and Meyer, 1993; Kelly and Weinberg, 1993).

Short-term storage will ease regulation and possibly improve power quality, but only intermediate and long-term storage will allow large systems to have shares of variable renewable-energy sources that significantly exceed 50% (Jensen and Sørensen, 1984). One important use of storage is to convert a remotely located intermittent electric supply into baseload power to obtain a high level of utilization of electric transmission capacity and thereby reduce the specific cost of long-distance transmission to electric demand centers. The use of compressed-air energy storage (Cavallo, 1995) and even seasonal compressed-air energy storage (Cavallo and Keck, 1995) in conjunction with large wind energy farms has been shown to be an economically promising way to exploit remotely located wind resources.

Round-trip efficiencies for storage range from 65–70% for lead-acid batteries, pumped hydro, and compressed air to 95% for superconducting storage (Jensen and Sørensen, 1984). Some storage technologies pose environmental problems that need to be addressed—including metal contamination from batteries and riverbed erosion problems with water surges from hydropower.

19.2.6.2. Electric Power System Characteristics and Costs

In the decades immediately ahead, many renewable electric systems will be introduced in stand-alone configurations remote from electric utility grids and used in connection with small-scale electrical storage and fossil energy backup systems. In the longer term, however, most renewable electric systems will be connected to electric utility grids. Managing grid-connected renewable electric technologies poses new challenges for utilities. Unlike the thermal power plants that utilities

are accustomed to managing, intermittent renewable power plants are not dispatchable. Moreover, many of these technologies produce electricity in plants that are much smaller than those used in today's power systems. Scales range from 1 kW_e for some photovoltaic and fuel-cell systems to 25–300 MW_e for biomass systems because the costs per unit of capacity for such technologies will be relatively insensitive to scale. For these systems, the economies of mass-produced standardized units are more important than the economies achievable with large unit sizes. Many of the smaller-scale technologies will be sited not in central-station plants but at or near customers' premises. Some photovoltaic and fuel-cell systems can be operated unattended and installed even at individual houses. Electricity produced from such "distributed power systems" is worth more to the utility than central-station power whenever the electrical output is highly correlated with the utility peak demand, largely because such siting makes it possible to defer transmission/distribution investments (Shugar, 1990; Hoff *et al*., 1995).

New analytical tools are being developed to integrate such technologies into electric utility grids and to value and manage power systems that involve combinations of intermittent and dispatchable power sources. One such tool, the SUTIL simulation model (Kelly and Weinberg, 1993), calculates the average cost of electric generation as the result of an hour-by-hour simulation that takes into account demand, the variable output of intermittent renewable equipment, the load-leveling capabilities of hydroelectric facilities, and the dispatching characteristics of alternative thermal-electric plants. Results of a SUTIL simulation of 10 alternative portfolios for a hypothetical utility—based on assumed values of the demand load profile, insolation, fuel costs, and capital costs—are shown in Figure 19-4.[5] Note that the assumed costs for conventional fuels and technologies, particularly for natural gas and for

---

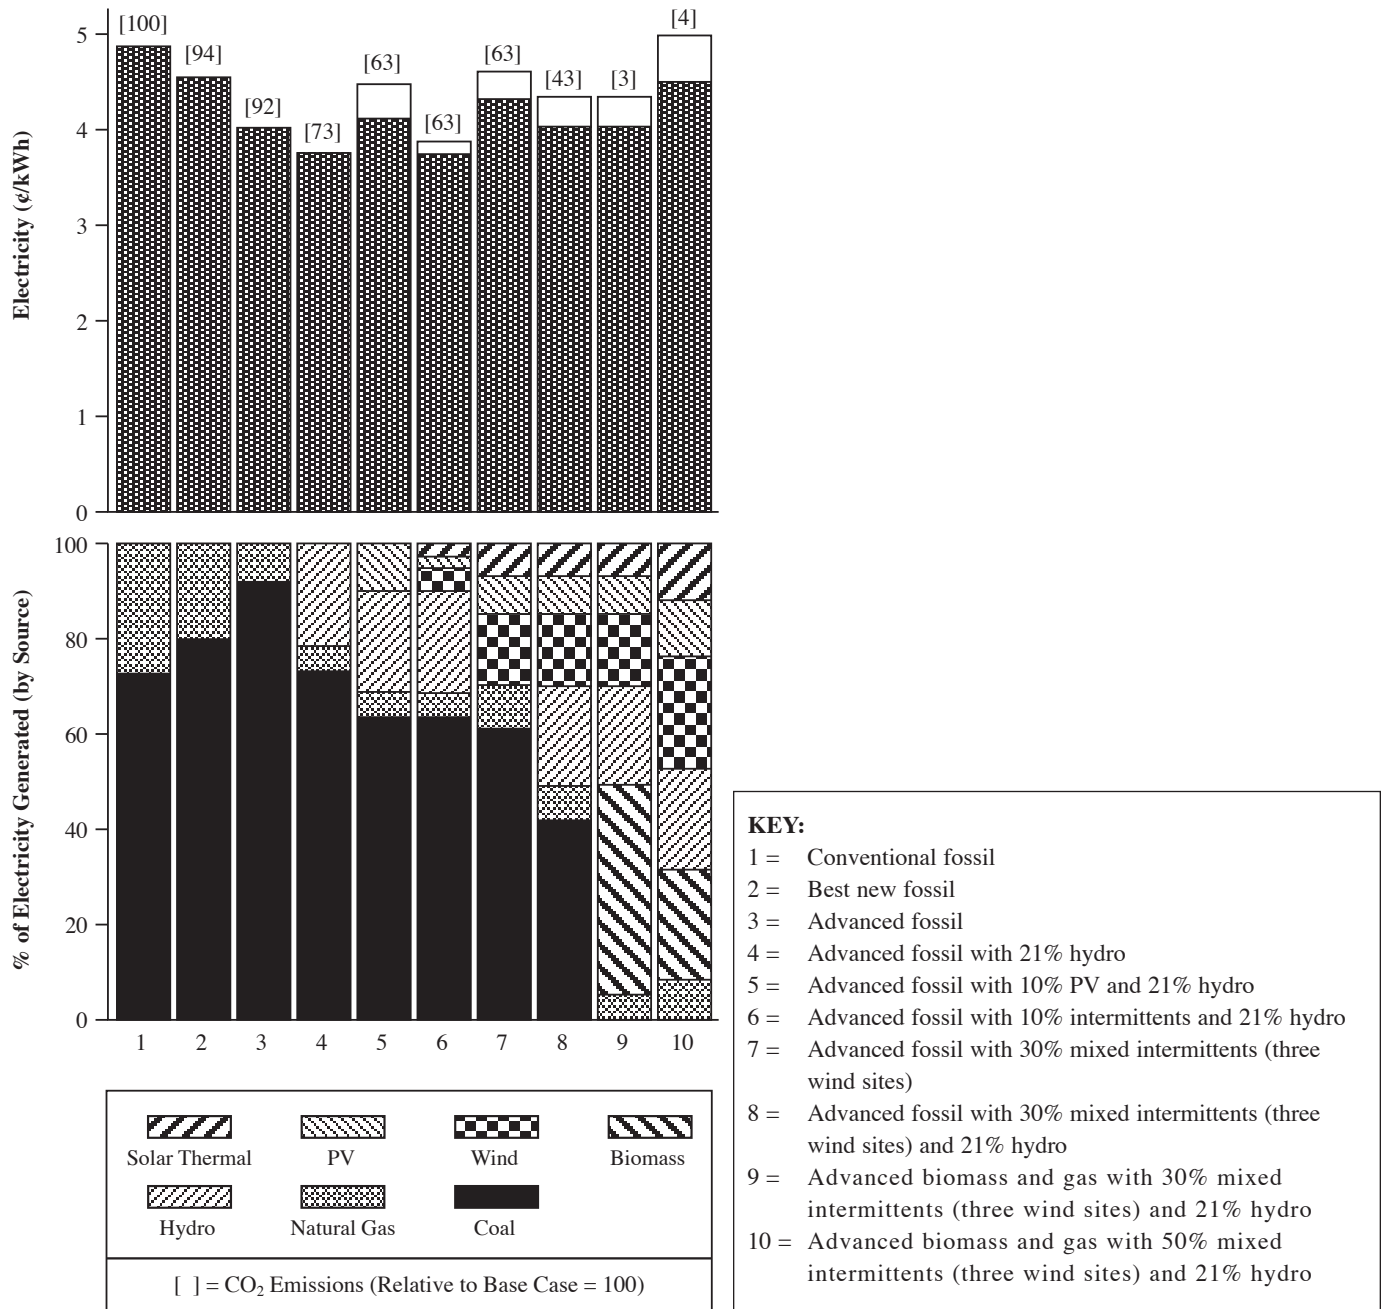
[5] Since this SUTIL modeling exercise was carried out, present and projected fuel prices and technology costs have changed significantly. For example, compared to the assumed overnight construction costs of $525/kW and $625/kW for conventional and advanced natural gas combined cycle plants, respectively, combined cycle plants are being installed at present in the U.S. at costs as low as $400/kW. As a sensitivity analysis, the SUTIL model was run again with assumed coal and natural gas prices of $1.3/GJ and $3.2/GJ, respectively [equal to national average prices projected for electric utilities in the U.S. in the year 2010 by the U.S. Department of Energy (EIA, 1995)], with an assumed biomass price of $1.5/GJ [an estimated long-run marginal cost for producing 5 EJ/yr of plantation biomass in the U.S. using biomass production technology projected for the year 2020 (Graham *et al*., 1995)], together with the original SUTIL technology cost assumptions. Although overall generation cost levels are lower with these new fuel price assumptions, the relative costs of alternative investment portfolios differ only modestly from those shown in Figure 19-4. For example, the average generation cost for the updated version of case 9 is 8% higher than for case 4 (3.37¢/kWh vs. 3.12¢/kWh) (Williams, 1995a). Note that differences in marginal costs associated with the introduction of intermittent renewables are significantly greater than is indicated by these average portfolio cost differences.


Figure 19-4: *Comparing Investment Portfolios for a Hypothetical Electric Utility*—The average life-cycle cost and relative CO_2 emissions for meeting the annual electricity needs (top) and the fraction of electricity generated by each energy source (bottom) are displayed for alternative configurations of a hypothetical utility. The life-cycle costs were calculated for a 6% discount rate using the SUTIL model (Kelly and Weinberg, 1993). The calculations involved a simulation of the utility that considered the variability of electricity demand and the output of intermittent renewable equipment, the load-leveling capabilities of hydroelectric facilities, and the dispatching of natural gas, coal, and biomass thermal electric plants. The electricity demand profile (that for an actual large utility in northern California) was specified on an hour-by-hour basis throughout the year. The assumed insolation values are for northern California. For the given demand profile, alternative electricity supply portfolios having the same degree of system reliability were constructed. Each portfolio involves specified levels of penetration by intermittent renewable electric and hydroelectric sources, and the model determines the least costly mix of thermal-electric equipment and fuels that would meet the remaining load, assuming alternative levels of technology for the thermal generating equipment and specified 30-year levelized life-cycle fuel prices. For all advanced fossil and renewable energy technologies highlighted in these constructions, it was assumed that R&D is successful in meeting performance and cost goals for the period near 2010. Thirty-year levelized coal, natural gas, and biomass prices were assumed to be $2.0/GJ, $4.4/GJ, and $2.4/GJ, respectively. Assumptions about capital and operations and maintenance costs, and about performance characteristics of alternative technologies, are presented elsewhere (Johansson *et al.*, 1993a). For the six cases displayed on the right, the photovoltaic (pv) systems are sited in distributed configurations; the clear segments at the tops of the bars represent the value of distributed pv power to the utility; the net cost is given by the level at the tops of the shaded bars—the gross cost less the distributed pv benefit.

natural gas-fired combined cycles, are significantly higher than currently prevailing values and projections to 2010 for the U.S. For this set of alternative utility investment portfolios:

- All configurations involving advanced technology (cases 3–10) are less costly than the base case (case 1), which involves conventional fossil fuel technologies.
- There is little variation in cost among the advanced technology options, although there are no less costly options than the advanced fossil fuel options (cases 3 and 4).
- The fraction of electrical energy provided by intermittents can rise up to about 30%, without the use of new electrical storage technology, before costs start rising significantly.
- At high levels of penetration of intermittent renewables, baseload thermal power becomes less important and load-following and peaking power become more important.
- The advanced fossil fuel options offer relatively modest reductions in CO_2 emissions.
- The option offering the greatest reduction in CO_2 emissions [case 9, involving biomass for baseload power and a 30% contribution from intermittent renewables and for which emissions are only 4% of those for the least costly case (case 4)] has an average generation cost that is only 7% higher than for the least costly case.

Although costs for technologies that are not yet commercially available cannot be known precisely, it is plausible—on the basis of what is presently known about the prospective costs of advanced renewable and fossil fuel electric-generating technologies—that in the early decades of the next century, utility planners will be able to assemble alternative electric power systems (involving substantial contributions from renewable energy sources) that generate very low CO_2 emissions. These judgments are based on the assumption that various promising renewable-energy technologies will be targeted for R&D and commercialization programs. At the same time, of course, advances will continue to be made in fossil fuel technologies. In many cases, it will be difficult to provide electricity at lower direct cost than with fossil fuels (for example, because both coal and biomass will be able to exploit the same basic advances in gas turbine and fuel-cell conversion technologies).

19.2.6.3. Electricity Transmission Technology

For transporting electric power over more than about 700 km, DC transmission at high voltage (500 to 1,000 kV) via either overhead lines or underwater cables is less costly than AC transmission. Ohmic losses amount to about 4% of the energy transmitted per 1,000 km, while losses associated with DC/AC conversion amount to about 0.6–0.8% per station. Typically, DC transmission increases the cost of electricity about 7% for a 1,000-km line. The low losses and relatively low costs of long-distance DC transmission make it feasible to transport solar power across multiple time zones and to exploit good

hydropower (Moreira and Poole, 1993), wind (Cavallo, 1995), and solar power resources that are remote from demand centers. High transmission capacity utilization can be realized with intermittent renewable resources when used in conjunction with compressed air or other energy-storage schemes (Cavallo, 1995).

19.2.6.4. A Long-Term Electricity/Hydrogen Energy System

Since it was first introduced, electricity has accounted for a growing share of the energy carriers used in the energy economy—a trend that is expected to continue. For the longer term, hydrogen is another high-quality energy carrier that society might adopt for large-scale applications. Both electricity and hydrogen offer good prospects for simultaneously dealing with the challenges facing the energy system in the 21st century—local, regional, and global environmental challenges, as well as security of energy supply (Marchetti, 1989; Rogner and Britton, 1991; Leydon and Glocker, 1992). Both are clean, versatile, and easy to use and can be derived from a wide range of primary energy sources. Because of their very different characteristics, hydrogen and electricity would have complementary roles in the energy economy. Hydrogen can be stored in any quantity, but electricity cannot (though this could change if high-temperature superconductivity could be successfully developed). Electricity can transmit energy without moving material; hydrogen cannot. Hydrogen can be a chemical or material feedstock; electricity cannot. Electricity can process, transmit, and store information; hydrogen cannot.

Hydrogen can be produced from any fossil fuel or from biomass via thermochemical conversion and from any electricity source via electrolysis. Conversion to hydrogen and sequestration of separated CO_2 makes it possible to use fossil fuels with modest life-cycle CO_2 emissions (see Sections 19.2.3.2 and 19.2.3.3). Emissions from the production of hydrogen from biomass grown on a sustainable basis would be especially low and negative if the separated CO_2 were sequestered. For the foreseeable future, thermochemically derived hydrogen will be much less costly than electrolytic hydrogen, even taking into account the costs of sequestering the separated CO_2 (see Figure 19-5).

As is the case for any synthetic fuel, hydrogen generally will cost more to produce than conventional hydrocarbon fuels. Natural gas-derived hydrogen (the least-costly option for at least the next couple of decades) delivered to consumers is likely to be much more costly than gasoline, on a dollar per GJ basis—50% higher for energy prices expected for the United States in 2010 (see Figure 19-5). However, this cost penalty does not imply that hydrogen would not be competitive. The choice of energy carrier, its price, and its source are of little concern to the consumer. The consumer cares about the quality and cost of the energy services provided (Scott, 1993). Just as electricity is competitive as an energy carrier—even though it is much more expensive than coal, oil, or natural gas—high-cost hydrogen could be competitive if the market were to place a high value on hydrogen. It would be difficult for hydrogen to
Figure 19-5: *Estimated Life-Cycle Costs to Consumers and CO$_2$ Emissions per GJ of Hydrogen (H$_2$) from Alternative Sources for Transport Applications, with a Comparison to Gasoline Derived from Crude Oil*—This figure and Figures 19-6 and 19-7 present alternative measures of cost and life-cycle CO$_2$ emissions characteristics for systems that provide H$_2$ derived from natural gas (via steam reforming), coal and biomass (via thermochemical gasification), and electrolytic sources, with comparisons to gasoline (Williams, 1996). Costs were calculated assuming a 10% discount rate, and fuel taxes were excluded. The assumed crude oil, natural gas, and coal prices are, respectively, the world oil price, the U.S. average wellhead price, and the average U.S. electric utility price projected for 2010 by U.S. DOE (EIA, 1995). The consumer gasoline price is for reformulated gasoline, which is estimated to be 16% higher than the price of ordinary gasoline derived from crude at the assumed price of $22/barrel. Plantation biomass prices that are comparable to or lower than the assumed price could be realized in large-scale applications in Brazil today and in the U.S. by 2020 if yield and cost goals for 2020 are realized as a result of successful R&D (see Section 19.2.5.2.1). The assumed electricity costs are for a 600 MW advanced passively safe nuclear plant having an installed cost of $1680/kW (EPRI, 1993); for post-2000 wind technology with an installed cost of $780/kW (Ogden and Nitsch, 1993); and for photovoltaic (pv) systems in areas with high insolation and installed costs of $550–1125 per kW—targets that plausibly could be met using advanced thin-film pv technologies in the long term (Ogden and Nitsch, 1993). Thermochemical production of H$_2$ generates a byproduct stream of pure CO$_2$, which can either be released to the atmosphere or compressed and piped to a site where it might be sequestered. The first bar for natural gas, coal, and biomass is the cost when this CO$_2$ is vented; the second and third bars are for when the separated CO$_2$ is sequestered, assuming low and high estimates of the sequestering cost (Hendriks, 1994). In the natural gas cases, it is assumed that the H$_2$ plant is located near a natural gas field and that the separated CO$_2$ is sequestered in depleted gas wells. For the coal and biomass cases, it is assumed that the separated CO$_2$ is sequestered in saline aquifers located 250 km from the plant. The numbers at the tops of the bars are the life-cycle CO$_2$ emissions in kg C per GJ of delivered fuel, relative to life-cycle emissions for gasoline.

compete in markets where energy-conversion equipment designed for hydrocarbon fuels is used. The situation would change markedly if conversion equipment designed to exploit the unique characteristics of hydrogen were used instead.

A class of technologies that could make a hydrogen economy feasible is represented by the fuel cell, which converts fuel directly into electricity without first burning it. The hydrogen fuel cell offers the potential for major contributions in transportation (Williams, 1993; Mark *et al*., 1994) and in distributed combined heat and power applications (A.D. Little, 1995; Dunnison and Wilson, 1994). The hydrogen fuel cell offers high thermodynamic performance, zero local air-pollution emissions, low maintenance requirements, and quiet operation. In mass production, automobiles powered by the proton exchange membrane (PEM) fuel cell would have much lower costs and much longer ranges between refuelings than battery-powered electric cars (Kircher *et al*., 1994; Ogden *et al*., 1994). Powered by either compressed hydrogen or methanol (a hydrogen carrier that would be "reformed" onboard the vehicle into a suitable hydrogen-rich gaseous fuel), PEM fuel-cell cars would require much less fuel and emit much less local pollution than hybrid internal-combustion engine/battery-powered cars, while offering comparable or greater range and comparable or lower life-cycle costs (Kircher *et al*., 1994; Biedermann *et al*., 1994).

Because of the much higher fuel economy, the cost of fuel per km of driving a fuel-cell car powered by thermochemically derived hydrogen is likely to be less than 65% of the cost for a gasoline-fired internal combustion engine car of comparable performance (see Figure 19-6)[6], and the total life-cycle cost of owning and operating a fuel-cell car is likely to be slightly less (see Figure 19-7), even though the cost of this hydrogen to the consumer, measured in $/GJ, would be up to about 75% more than for gasoline (see Figure 19-5).[7]

19.3. Low CO$_2$-Emitting Energy Supply Systems for the World

Each of the options discussed in Section 19.2 has the potential to reduce GHG emissions. To understand better their combined potential contributions to future energy supplies and emissions reductions, assessments are needed at the level of the global energy system. Such assessments should consider internal functional aspects of the energy system (such as the intermittency of solar and wind energy resources) and the linkages between the energy system and other areas for societal concern (such as land-use competition and security issues).

In order to start an assessment at the energy systems level, alternative versions of a Low-Emissions Supply System (LESS) were constructed. These LESS constructions illustrate the potential for reducing emissions by using energy more efficiently and by using various combinations of low CO$_2$-emitting energy supply technologies—including shifts to low-carbon fossil fuels, shifts to renewable or nuclear energy sources, and

decarbonization of fuels, in alternative combinations. Energy supply systems were constructed for this exercise both from "the bottom up" (Section 19.3.1) and "the top down" (Section 19.3.2).

Emphasis in the LESS constructions is on the long term (2025–2100), the prospects for achieving deep reductions in CO$_2$ emissions from the energy sector with alternative supply mixes, and prospective costs. The need for a long-term focus is stressed in the Working Group I evaluations. Accordingly, emphasis was given to new or improved energy supply technologies that offer the potential for achieving deep reductions in emissions. By the year 2100, the global commercial energy system will have been replaced two to three times—providing many opportunities to change system performance through the use of various new technologies at the time of investment, both for capacity expansion and for replacement.

It is not realistic to probe the deep future taking into account only commercial technologies. The prospective performance and relative cost characteristics for the technologies selected for emphasis in the LESS constructions can be described with a reasonable degree of confidence with present knowledge; all are commercially available, commercially ready, or have good prospects for becoming commercial products within the next 1 or 2 decades, if adequate incentives are provided for the needed R&D and for launching the new industries involved.

To help clarify the options, alternative versions of the LESS were constructed with features that make each option markedly different from the others, and some important features distinguishing the alternatives are highlighted. In the bottom-up constructions, focused attention is given to five LESS variants. Four variants involve a high degree of emphasis on the efficient use of energy. Two of these—which were analyzed in the greatest detail, thus taken to be the reference cases—are a biomass-intensive (BI) variant and a nuclear-intensive (NI) variant. Also, a natural gas-intensive (NGI) variant and a coal-intensive (CI) variant were constructed to explore the extent to which deep reductions in emissions could be achieved using more fossil fuels. A fifth high-demand (HD) variant explores the implication of much greater energy demand growth.

A central finding of the LESS construction exercise is that deep reductions of CO$_2$ emissions from the energy sector are technically possible within 50 to 100 years, using alternative strategies. Many combinations of the options identified in this assessment could reduce global CO$_2$ emissions from fossil

---

[6] As shown in Figure 19-6, the fuel cost per km of thermochemical H$_2$ would increase only modestly, if the CO$_2$ separated at the H$_2$ production plant were isolated from the atmosphere and the extra cost of sequestering this CO$_2$ were charged to the consumer.

[7] Moreover, because the cost of fuel represents such a small fraction of the total cost of owning and operating a fuel-cell car, the total life-cycle cost for a fuel-cell car operated on electrolytic hydrogen would be less than 7% more than for a gasoline internal combustion engine car, even though the cost of electrolytic hydrogen per km for a PEM fuel-cell car would be up to 50% more costly (see Figure 19-7).

fuels from about 6 Gt C in 1990 to about 4 Gt C per year by 2050, and to about 2 Gt C per year by 2100. Because of the large number of combinations of options, there is flexibility as to how the energy supply system could evolve, and paths to

energy system development could be influenced by considerations other than climate change, including political, environmental, and socioeconomic circumstances. However, higher energy demand levels reduce the flexibility for constructing

Legend: Extra Cost for CO₂ Sequestration | Cost without CO₂ Sequestration | [ ] = Life-Cycle CO₂ Emissions per km of Travel (Gasoline ICEV = 100)

Figure 19-6: *Estimated Life-Cycle Fuel Costs to Consumers and CO₂ Emissions, per km of Driving Fuel Cell Vehicles (FCVs), for H₂ from Alternative Sources for Transport Applications, with a Comparison to Gasoline Derived from Crude Oil and Used in Internal Combustion Engine Vehicles (ICEVs) and FCVs*—The consumer prices and life-cycle CO₂ emissions for H₂ shown in Figure 19-5 are converted here to fuel costs and life-cycle CO₂ emissions per km of driving an FCV, along with a comparison of gasoline costs and lifecycle CO₂ emissions per km of driving, for both ICEV and FCV applications (Williams, 1996). Fuel taxes are not included. The reference gasoline ICEV is a year-2000 version of the Ford Taurus automobile with a fuel economy of 11.0 km/l. The H₂ FCV has performance characteristics that are comparable to those for this ICEV and a gasoline-equivalent fuel economy of 30.4 km/l. Fuel costs are also shown for an FCV operating on gasoline. In this case, the gasoline is converted via partial oxidation onboard the vehicle to a gaseous mixture of H₂ and CO₂, which is a suitable fuel gas for operating the fuel cell; the estimated fuel economy for the gasoline FCV is 18.0 km/l.

| | Gasoline | H$_2$ Produced via Thermochemical Processing of Fuels | | | Electrolytic H$_2$ | | |
Figure 19-7: *Estimated Life-Cycle Costs to Consumers for Owning and Operating FCVs and CO$_2$ Emissions, per km of Driving an FCV, for H$_2$ from Alternative Sources for Transport Applications, with a Comparison to Gasoline Derived from Crude Oil and Used in ICEVs and FCVs*—Vehicle performance and cost characteristics are based on Ogden *et al*. (1994). The estimated fuel-economy characteristics of these vehicles are indicated in Figure 19-6. An operating lifetime of 11 years is assumed for both ICEVs and FCVs; however, FCVs are assumed to be driven 23,000 km per year, compared to 17,800 km per year for ICEVs; this reflects the lower operating costs expected for FCVs operated on thermochemically derived fuels. It is assumed that H$_2$ is stored onboard vehicles in carbon-fiber-wrapped aluminum tanks at high pressure (550 bar). Because of the bulkiness of gaseous H$_2$ storage, the H$_2$ FCV is designed for a range between refuelings of 400 km, compared to 640 km for a gasoline ICEV. The weight of the H$_2$ FCV is estimated to be 1.3 tons, compared to 1.4 tons for the ICEV. Initial costs are estimated to be $17,800 for an ICEV and $25,100 for an H$_2$ FCV (in mass production). The initial cost for a gasoline FCV is assumed to be $21,700—the same as the estimated cost for a methanol FCV (Ogden *et al*., 1994). Retail fuel taxes are included under "other non-fuel operating costs" at the average U.S. rate for gasoline used in ICEVs; to ensure that road tax revenues are the same for all options, it is assumed that retail taxes are 0.75¢ per km for all options (equivalent to 8.2¢ per liter or 31¢ per gallon for gasoline used in ICEVs).

supply-side combinations for deep reductions in emissions and increase overall energy system costs—underscoring the importance of higher energy efficiency.

Costs for energy services in each LESS variant relative to costs for conventional energy depend on relative future energy prices, which are uncertain within a wide range, and on the performance and cost characteristics assumed for alternative technologies. However, within the wide range of future energy prices, one or more of the variants would plausibily be capable of providing the demanded energy services at estimated costs that are approximately the same as estimated future costs for current conventional energy (see, for example, Figures 19-4, 19-6, and 19-7). It is not possible to identify a least-cost future energy system for the longer term, as the relative costs of options depend on resource constraints and technological

opportunities that are imperfectly known, and on future actions to be taken by governments and the private sector.

The literature provides strong support for the feasibility of achieving the performance and cost characteristics assumed for energy technologies in the LESS constructions within the next 1 or 2 decades, though it is impossible to be certain until the research and development is complete and the technologies have been tested in the market. Moreover, these performance and cost characteristics cannot be achieved without a strong and sustained investment in R&D. Many of the technologies being developed would need initial support to enter the market, and to reach sufficient volume to lower costs to become competitive.

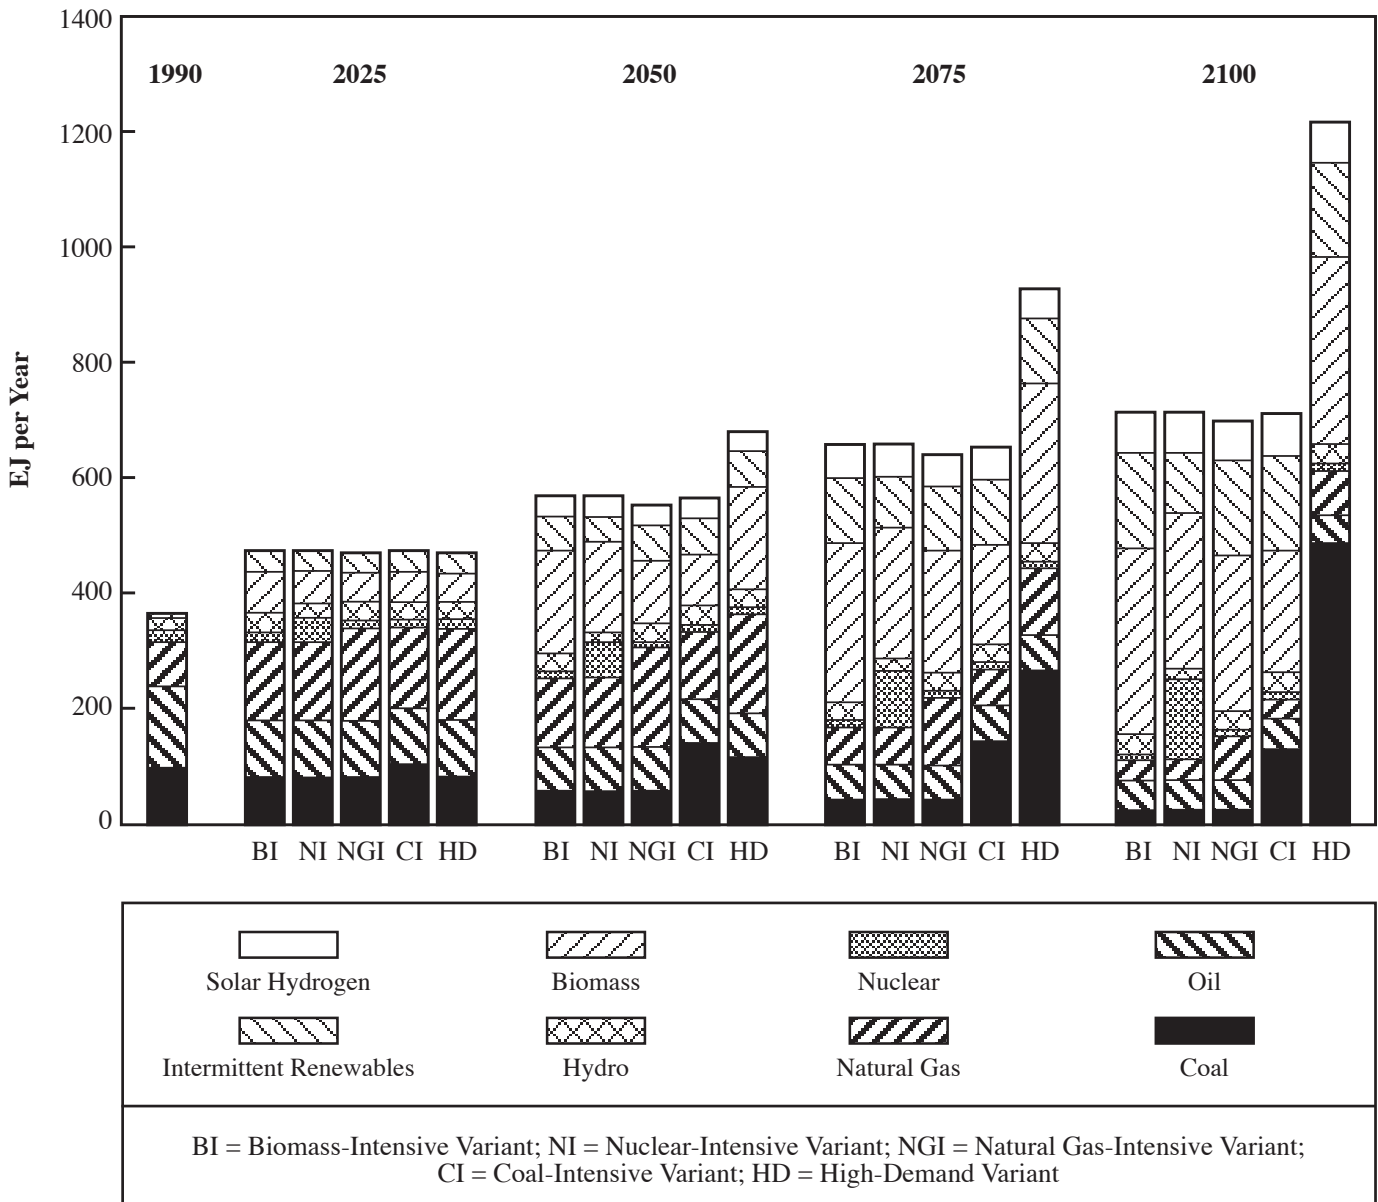
Market penetration and continued acceptability of different technologies ultimately depends on their relative cost,


Figure 19-8: Global primary energy use for alternative LESS constructions.

performance (including environmental performance), institutional arrangements, and regulations and policies. Because costs vary by location and application, the wide variety of circumstances creates initial opportunities for new technologies to enter the market. Deeper understanding of the opportunities for emissions reductions would require more detailed analysis of options, taking into account local conditions.

The LESS alternatives are not forecasts; rather, they are self-consistent constructions indicative of what might be accomplished by pursuing particular technological strategies. These alternative paths to the energy future should be regarded as "thought experiments" exploring the possibilities of achieving deep reductions in emissions. Actual strategies for achieving deep reductions might combine elements from alternative LESS constructions. Moreover, there may well be other plausible technological paths that could lead to comparable reductions in emissions. More work is required to provide a comprehensive understanding of the prospects for and implications

of alternative global energy supply systems that would lead to deep reductions in CO_2 emissions.

19.3.1. A Bottom-Up Construction for the LESS Reference Cases

The bottom-up LESS reference analysis involved constructing alternative sets of energy supplies for each of 11 regions of the world matched to energy demand levels adopted from a previous IPCC study. The study used a set of demand projections for electricity and for solid, liquid, and gaseous fuels used directly, by world region, for the years 2025, 2050, 2075, and 2100. These projections were developed by the Response Strategies Working Group (RSWG) of IPCC for its 1990 Assessment Report (RSWG, 1990). The RSWG prepared high and low economic growth variants of alternative energy scenarios, including Accelerated Policies (AP) scenarios characterized on the demand side by high rates of improvement in energy efficiency. The energy demand projections for the high
Figure 19-9: Annual CO_2 emissions from fossil fuels for alternative LESS constructions, with comparison to the IPCC IS92a-f scenarios.

economic growth variant of the AP scenarios were adopted for the reference cases of the LESS constructions. These projections are consistent with analysis in the energy demand sections of this report (Chapters 20–22). The demand profiles of the AP scenario were assumed as exogenous inputs to the supply analysis and were not critically reviewed here.

An AP scenario was chosen as the point of departure for the LESS constructions because typically there are large opportunities to reduce CO_2 emissions more cost-effectively via investments in more energy-efficient equipment than via investments in energy supply. The high economic growth variant was chosen to

make clear that the potential for emissions reduction illustrated by the LESS constructions is the result of technological choice rather than reduced economic output. The LESS reference constructions are extensions and variants of a methodology developed in a previous study exploring the long-term prospects for renewable energy in the context of the same set of energy demand projections (Johansson *et al*., 1993a).

Given the AP energy demands for each region, energy supplies were constructed for the LESS variants that are consistent with each region's endowments of conventional and renewable energy sources and general expectations of relative prices.

BI = Biomass-Intensive Variant; NI = Nuclear-Intensive Variant; NGI = Natural Gas-Intensive Variant; CI = Coal-Intensive Variant; HD = High-Demand Variant
Figure 19-10: Cumulative CO_2 emissions from fossil fuel burning and CO_2 sequestration requirements, 1990–2100, for alternative LESS constructions, with a comparison to the IPCC IS92a scenario (IPCC, 1992).

Highlights of the LESS reference cases are presented in Box 19-2; salient global characteristics of these and other LESS variants are presented in Figures 19-8 to 19-12. Primary energy requirements for one of the reference cases, disaggregated into industrialized and developing regions, are presented in Figure 19-13. Details of the assumed demand projections and supply constructions are in Williams (1995a).

19.3.1.1. *Fossil Fuels in the LESS Reference Cases*

The roles for fossil fuels in the LESS constructions are estimated on the basis of private costs, without consideration of carbon taxes. Particular attention is given to resource constraints on oil and natural gas and local environmental restrictions on the use of coal.

For oil and natural gas, the key assumption is that they will be developed consistent with widely accepted estimates of

ultimately recoverable quantities of conventional oil and gas. For undiscovered resources, the mean estimates of the U.S. Geological Survey (Masters *et al.*, 1994) are assumed for regions outside the United States, and U.S. Department of Energy estimates (Energy Information Administration, 1990) are assumed for the United States. Unconventional oil and gas resources are not taken into account. It is assumed that all reserves and estimated recoverable, undiscovered conventional oil and gas resources (some 11,300 EJ of oil and 12,500 EJ of natural gas as of 1993—equivalent to 80 and 160 years of supply at 1990 production rates) will eventually be used for energy.

From a GHG perspective, it matters little how oil and gas consumption evolves over time within this general framework. From an energy policy perspective, it makes sense to shift the mix more to gas in light of comparable amounts of estimated ultimately recoverable conventional resources and a present oil consumption rate that is nearly twice that for gas. To increase the transparency of the analysis, two simplifying assumptions
Figure 19-11: Land areas of biomass energy plantations by region for alternative LESS constructions.

were made: For each region, oil production declines at a constant exponential rate such that 80% of the estimated remaining ultimately recoverable resources is used up by 2100; and 80% of the ultimately recoverable natural gas resources also is used up for each region by 2100, but natural gas use first increases to the year 2025 (at the same rates as in the IPCC IS92a scenario) and thereafter declines at a constant exponential rate.

The LESS constructions assume that hydrogen becomes an important energy carrier (for example, for use in fuel-cell vehicles). Hydrogen derived from natural gas often will be one of the least-costly supplies of hydrogen (see Figure 19-5), and sequestration in depleted natural gas fields of CO_2 recovered at hydrogen production plants (containing two-thirds of the carbon in the original natural gas) is used as a decarbonizing strategy (see Figure 19-5). Thus, it is assumed that some natural gas (0% by 2025, 25% by 2050, 50% by 2075, and 75% by 2100)

is reformed near the wellhead to hydrogen and that the stream of pure CO_2 generated in conversion is sequestered in depleted natural gas fields, increasing the cost of hydrogen to consumers by 1–3% (see Figure 19-5).

Under these conditions, cumulative CO_2 emissions from 1990 to 2100 from the use of oil and natural gas would be 275 Gt C. If there were no other fossil fuels, it might be feasible to stabilize the atmospheric concentration of CO_2 at or near the present level. IPCC Working Group I has estimated that cumulative CO_2 emissions of 300–430 Gt C in the 21st century would be consistent with stabilization of the atmospheric CO_2 level at a concentration of 350 ppm (IPCC, 1994).

Remaining coal resources are huge, however. Without decarbonization, burning all of the estimated ultimately recoverable coal resources (see Table B-3 in Chapter B) would lead to the
Figure 19-12: Methanol and hydrogen production from alternative sources for alternative LESS constructions.

cumulative release of 3,100 Gt C. Moreover, even if the rate of coal use remained constant at the 1990 level, the burning of coal without decarbonization would add about 270 Gt C to the atmosphere between 1990 and 2100.

The LESS constructions present alternative strategies for reducing emissions from burning coal. In the reference cases, a strategy for reducing coal use is articulated. In the coal-intensive (CI) and high-demand (HD) variants presented later, emissions are reduced instead by pursuing coal decarbonization strategies.

Although coal is abundant and cheap, it is also a dirtier, more difficult-to-use fuel than oil or natural gas. Where there are strict rules to ensure that coal is used in clean ways, coal will face stiff economic competition from many alternative energy sources, both for power generation (see Section 19.3.1.2) and for the production of synthetic fuels that are used directly (see Section 19.3.1.3). Key assumptions underlying the LESS reference cases are that by the time frame of interest (2025–2100), all regions of the world will have adopted environmental standards for using coal equivalent to the most stringent standards now in place in the industrialized world; and, if a nonfossil fuel alternative to coal is available at approximately the same cost for the final product (electricity or synthetic fuel) with these environmental standards under the assumptions about future technology, the alternative is selected. Under these conditions, coal can be plausibly greatly reduced in the LESS reference cases, although in developing countries coal use increases
Figure 19-13: Primary commercial energy use by source for the biomass-intensive variant of the LESS constructions, for the world and for industrialized and developing countries.

Box 19-2. Highlights of the LESS Reference Cases (BI and NI Variants)

World population grows from 5.3 billion in 1990 to 9.5 billion by 2050 and 10.5 billion by 2100. Gross domestic product (GDP) grows 6.9-fold by 2050 (5.3-fold and 13.6-fold in industrialized and developing countries, respectively) and 24.6-fold by 2100 (12.8-fold and 68.3-fold in industrialized and developing countries, respectively), relative to 1990. Because of emphasis on energy efficiency, primary energy consumption rises much more slowly than GDP. Global primary commercial energy use roughly doubles, with no net change for industrialized countries but a 4.4-fold increase for developing countries, 1990–2100 (Figure 19-13).

Oil production declines in all regions, at a global average rate of 1.0% per year until 2100, when oil production is produced at 35% of the 1990 rate. Global natural gas production rises 84% by 2025, before beginning a decline at an average rate of 1.8% per year, 2025–2100; by 2100, natural gas is produced at 48% of the 1990 rate. Global coal production declines continually, but in developing countries it first rises 70% by 2025 before beginning to decline (see Figure 19-13). Whereas the decline in oil and gas production is determined by resource constraints, declining coal production is due to competition from nonfossil energy.

Total fossil fuel use stays roughly constant, 1990–2025, but its share in global energy declines from 86% to 67% in this period and to 15% by 2100, as a result of a shift to renewables in the BI variant and to nuclear plus renewables in the NI variant (see Figure 19-8). The NI variant involves increasing nuclear capacity worldwide 10-fold by 2100, so that nuclear accounts for 46% of total electricity in 2100, while hydro, biomass, and intermittent renewables (wind, photovoltaic, and solar thermal-electric power) account for 6%, 10%, and 34%, respectively. In the BI variant, nuclear provides 3% of electricity in 2100; hydro, biomass, and intermittent renewables contribute 10%, 29% and 54%, respectively.

Biomass plays a major role (especially as a feedstock for MeOH and H_2 production and power generation), accounting for 72 EJ or 15% of primary energy in 2025 (47% of biomass is for power generation) and rising to 325 EJ or 46% of primary energy by 2100 (29% for power generation) in the BI variant. In the NI variant, the contribution from biomass is 12% in 2025 (of which 35% is for power generation) and 38% in 2100 (of which 14% is for power generation).

MeOH and H_2 play growing roles as energy carriers in both the BI and NI variants (see Figure 19-12). Their production accounts for 10% of primary energy in 2025, rising to 40% by 2100 (about the same as for electric power generation by then). Natural gas provides nearly 60% of the energy from these energy carriers in 2025, but its share declines to 14% by 2100, while the biomass share increases from about 40% in 2025 to 67% by 2100. Electrolytic H_2 makes no contribution in 2025 but provides 12.5% of the energy from these energy carriers in 2050 and 20% in 2100.

Oil exports from the Middle East decline absolutely but grow as a percentage of global oil consumption—from about 20% in 1990 to more than 25% in 2025 and 33% in 2100. Total energy exports from the Middle East double, 1990–2050, before declining back to the 1990 level by the year 2100 (see Figure 19-14) as a result of growth in exports of natural gas and H_2 derived from both natural gas and solar electricity via electrolysis, which offset the decline in oil exports. Since H_2 is far more valuable than natural gas and oil, the monetary value of Middle East exports increases continually throughout the next century.
Figure 19-14: Net exports of fuels from the Middle East in the biomass-, nuclear-, and coal-intensive variants of the LESS constructions.

through 2025 before declining (see Figure 19-13 and Box 19-2). If nations elect not to control SO_x or other local pollutant emissions to these levels, prices for coal-derived energy would be lower, and alternatives to coal less attractive in economic terms.

Under these conditions, global CO_2 emissions decline from 6.2 Gt C in 1990 to 5.9 Gt C in 2025 and to 1.8 Gt C in 2100 for both of the LESS reference cases. Cumulative emissions from 1990 to 2100 amount to 448 Gt C, of which 182 Gt C comes from oil, 93 Gt C is from natural gas, and 172 Gt C is from coal.

19.3.1.2. The Electricity Sector in the LESS Reference Cases

Under the demand assumptions of the AP scenario, there is a continuing shift to electricity in the LESS reference cases, with total generation increasing 2.9- and 4.2-fold by 2050 and 2100, respectively. Total primary energy use increases only 1.6- and 1.9-fold, respectively. In the reference cases, the possibilities for achieving deep reductions in emissions both without (BI variant) and with (NI variant) a major expansion of nuclear power are explored.

19.3.1.2.1. The biomass-intensive variant for the electric sector

The BI variant explores the potential for using renewable electric sources in power generation by combining the results of modeling exercises, such as those described in Section 19.2.6.2 using the SUTIL model with considerations of regionally varying resource endowments and constraints. Under these conditions, estimates were made of potential contributions to electric grids from renewables—both intermittent renewables (wind, photovoltaic, and solar thermal-electric technologies) and advanced biomass electric-generating technologies (biomass-integrated gasifier/gas turbine technologies through 2025 and biomass-integrated gasifier/fuel-cell technologies for 2050 and beyond). Advanced gas turbine and fuel-cell technologies fueled with natural gas-derived hydrogen also are stressed. The level of nuclear generation remains constant from 1990 to 2100.

At the global level, 30% of electricity is supplied by intermittent renewables by 2050 in the BI variant, with substantial regional variations (for example, 10% in Africa; 18% in OECD Europe). This appears to be achievable without the use of new storage technologies if these systems are backed up by thermal power systems having characteristics similar to those of natural gas-fired combined cycles and peaking turbines (see, for example, Figure 19-4). Storage technologies make it possible to increase the global average contribution to more than 50% by 2100.

Natural gas is emphasized in the BI variant because of its favorable economics and relatively low CO_2 emissions in combined-cycle and fuel-cell configurations. Also, because natural gas-fired gas turbines and combined cycles have low unit capital costs and can change output levels quickly, they are good complements to intermittent renewable technologies. The share of natural gas in electricity generation increases from 16% in 1990 to 25% by 2050 but falls thereafter to 5% by 2100.

Biomass can provide baseload renewable electricity without ancillary storage. Its contribution to global electricity supply in the BI variant averages one-sixth of the total from 2025 to 2050, increasing to one-quarter from 2075 to 2100. Initial biomass applications involve mainly biomass residues in industrial cogeneration applications, but over time plantation biomass plays an increasing role.

At the global level, coal-based power generation declines nearly 50% by 2050 and 100% by 2100, but it increases 2.7-fold in centrally planned Asia plus South and East Asia from 1990 to 2050 before declining. It is assumed that the rapidly expanding market for coal power there provides a favorable environment for innovation—so energy-efficient, coal-integrated gasifier/gas turbine power cycles become the norm by 2025, and coal-integrated gasifier/fuel-cell technologies become the norm by 2050.

For the power sector as a whole, emissions decline from 1.7 Gt C/yr in 1990 to 1.0 Gt C/yr by 2050 and to 0.06 Gt C/yr by 2100.

The central result of this analysis—that deep reductions in emissions from the power sector are achievable with the BI variant—would not be qualitatively changed by making a significant change in an individual component of the power supply. Consider, for example, the hydropower contribution. By 2050, hydropower generation increases 2.2-fold relative to 1990 and then remains constant. Although this is only 50–80% of the estimated economically exploitable potential (Moreira and Poole, 1993), large hydropower projects are increasingly being challenged on social and environmental grounds. Cutting the hydro increment by half between 1990 and 2050 might be compensated by a 14% increase in the contribution from intermittent renewables by 2050 without fundamentally changing the basic structure of the BI variant and with no increase in global emissions. If the cut in the increment were compensated instead by natural gas power generation, global gas supply requirements in 2050 would go up only 7%, and global emissions would increase only 0.12 Gt C/yr (if the gas were not decarbonized) or 0.03 Gt C/yr (if it were).

Key to the economics of the BI variant are assumptions about relative fuel prices. The results of the SUTIL modeling exercise shown in Figure 19-4 are for electric utility fossil fuel prices projected by the U.S. Department of Energy (U.S. DOE) for the United States in the period near 2010 (Kelly and Weinberg, 1993). Since that modeling exercise was carried out, the coal price projected by U.S. DOE for U.S. electric utilities in 2010 has fallen from \$2.0/GJ to \$1.3/GJ. This reduction in coal price implies a 15% reduction in the busbar cost for the advanced coal power-generation technology to which the advanced biomass power-generation technology was compared in Figure 19-4. Such a sharp drop in coal prices makes it much more difficult for biomass to compete. However, more detailed estimates of future plantation biomass costs have been made since the modeling exercise illustrated in Figure 19-4 was carried out (Graham *et al.*, 1995; Turnure *et al.*, 1995), indicating that biomass prices of \$1.5–1.8/GJ could be expected in the U.S. for plantation production levels

up to 5 EJ/yr by 2020 (see Section 19.2.5.2.1). This implies that the electric generation cost reduction for biomass would be about the same as for coal, relative to what was modeled in Figure 19-4 (see footnote 5). But if coal prices turn out to be lower still, as projected in some private forecasts (DRI/McGraw-Hill, 1995), and if biomass conversion technologies turn out to be less efficient and more capital-intensive than coal conversion technologies [e.g., if the more pessimistic assumptions of Turnure *et al*. (1995) relating to biomass turn out to be true], then biomass would require a significant subsidy to compete (see Section 19.2.5.2.2).

The fossil fuel prices for electric utility users assumed in Figure 19-4 are consistent with long-term prices generated independently by the "top-down" global model described in Section 19.3.2. However, other "top-down" models produce different results. In a recent modeling exercise carried out by the Energy Modeling Forum (Gaskins and Weyant, forthcoming), five different models estimated five different average electric-utility coal prices for 2020; these estimates ranged from $1.1 to $2.3/GJ and averaged $1.6/GJ.

The largest uncertainty regarding the prospects for an economically competitive, renewables-intensive electric future probably is the trend in relative fuel prices. However, the BI variant could plausibly provide demanded energy services at costs that are approximately the same as estimated future costs for current conventional technology, unless the lowest estimates for fossil fuels are realized and the costs projected for renewables turn out to be much too low.

19.3.1.2.2. *The nuclear-intensive variant for the electric sector*

The nuclear-intensive (NI) variant of the reference case involves a revitalization of the nuclear option and extensive deployment of nuclear electric power technology worldwide.

Because the power sector is largely decarbonized in the next century under the BI variant (with CO_2 emissions amounting to only 0.06 Gt C/yr in 2100), it is assumed that the energy contributions from fossil fuels are identical for the NI and BI variants. Thus, the NI variant represents an alternative way to achieve the LESS reference case level of CO_2 emissions reduction from the power sector. It involves a major expansion of nuclear power along with a lesser (but still substantial) contribution from renewable electric sources than with the BI variant. The projections for nuclear electric capacity and generation worldwide in the long term would be technically feasible but would require the removal of policy barriers such as moratoria on construction, political decisions to abandon nuclear power, and the absence of support from development banks for nuclear power projects.

The main technical constraints on the growth of nuclear capacity are construction lead times and industrial capabilities for building power plants and fuel-cycle facilities. The availability of sites for nuclear installations—including radioactive waste repositories—was checked by region, taking into account the risk of earthquakes, the need for cooling, and population density.

The nuclear electricity generation projections were derived from penetration curves in each region, based upon the present status and trends of national nuclear programs. The asymptotic share of nuclear power in electricity generation was estimated by region, taking into account the availability of alternative energy sources and the size of the grid-connected electricity network (Semenov *et al*., 1995).

Under this set of assumptions and constraints, the installed nuclear capacity would grow from the present 330 GW_e to about 3,300 GW_e in 2100 (see Table 19-8). Nuclear power

Table 19-8: *Nuclear power in the nuclear-intensive (NI) variant of the LESS base case.*

Region	2025 Nuclear Elect. Gen. (TWh/yr)	2025 Nuclear Share of Total Elect. (%)	2025 Nuclear Capacity (GWe)	2050 Nuclear Elect. Gen. (TWh/yr)	2050 Nuclear Share of Total Elect. Middle East	89	10	15	212	12	32	342	15	52	471	17	71
North America	1053	30	159	1525	39	231	2008	48	304	2566	57	389
Western Europe	634	30	96	1090	45	165	1598	60	242	2159	75	327
Total	**4764**	**23**	**721**	**9352**	**30**	**1447**	**15524**	**38**	**2352**	**21948**	**46**	**3327**

would be a major contributor to electricity generation in North and Latin America, Asia, and Europe, with a share ranging from 40–75% by 2100; in Africa, Australia, New Zealand, and the Middle East, the share is less than 20%. Worldwide, nuclear power would provide 46% of electricity by 2100, compared with 17% at present; nuclear's share of electricity would be half as large as that for renewables by 2025, rising to a comparable share by 2100.

With breeder reactors, the availability of natural resources would not place any major constraint on the development of nuclear electricity generation (see Section 19.2.4). It is assumed for the NI variant that the first breeder reactors are commercially deployed in 2025. This would make it possible to support projected nuclear electricity generation over the next century with currently known uranium resources.

At the back end of the fuel cycle, the management of spent fuel would require interim storage capacities and the implementation of final disposal repositories for radioactive waste. Nuclear power plants currently generate about 5 tons of spent fuel per TWh of electricity. With the development of advanced reactors, this quantity will decrease. The NI variant would lead to some 6.3 million tons of accumulated spent fuel by 2100 with current technologies. Efficiency improvements in nuclear fuel utilization—for example, higher burn-up—and deployment of advanced fission reactors are likely to reduce the amount of spent fuel. Because the deployment of breeder reactors is assumed for the NI variant, most spent fuel would be reprocessed, and the volume of high-level waste created would be on the order of 1 m^3/GW_e/yr. The accumulated volumes to be disposed of would be some 200,000 m^3 by 2100.

Because the deployment of breeder reactors is assumed for the NI variant, a significant amount of spent fuel would be reprocessed and the fissile materials recycled in reactors. In the long term, the deployment of breeders would reduce plutonium inventories to materials contained in fuel-cycle facilities—that is, reprocessing and mixed-oxide (MOX) fuel fabrication plants or in reactors. The plutonium generation rate in 2100 would be in the range of 0.1–3 million kg/yr, depending on the mix of nuclear technologies. The plutonium inventory would be on the order of 50–100 million kg and would require technical and institutional safeguards to prevent diversions to nuclear weapons purposes (see Section 19.2.4).

The challenges of managing material usable for weapons would be considerably less daunting if the deployment of plutonium breeder reactors could be avoided. This might be possible if uranium could one day be economically recoverable from seawater, if denatured thorium-based fuel cycles could be successfully developed, or if much of the nuclear expansion after 2050 were based on fusion instead of fission. Fusion plants would be less likely to contribute to the acquisition of nuclear-weapons capabilities by subnational groups and would be easier to safeguard against clandestine use for fissile material production by governments (Holdren, 1991).

Nuclear power could be expanded more than is projected for the NI variant if potential nonelectric markets also were taken into account—notably if nuclear energy were used for industrial process heat, for DH, for potable water production, and for electrolytic hydrogen production (see, for example, Figure 19-4).

19.3.1.3. Fuels Used Directly in the LESS Reference Cases

Activities that involve the direct use of fuels account for nearly three-quarters of CO_2 emissions at present. Although the direct use of fuels is projected to grow much more slowly than electricity use, the present high level of emissions and expected rapid growth in transport make the realization of deep reductions in this area a daunting challenge.

The challenge of reducing emissions for fuels used directly is met in the LESS reference cases by shifting to natural gas (with some decarbonization—see Section 19.3.1.1) and biomass and to synthetic fuels derived from them. The options stressed include solid biomass fuel for industry, biogas from dung, and especially methanol and hydrogen derived from natural gas and biomass that would be used mainly in fuel cells.

It is assumed for all the LESS constructions that low-temperature fuel cells come into wide use for transportation and other applications before the end of the first quarter of the next century. Although hydrogen is the preferred fuel for fuel-cell vehicles, it is assumed for the LESS constructions that in the early decades of the next century, the dominant fuel would be methanol (see Figure 19-12), an easy-to-use liquid fuel that poses fewer challenges to the infrastructure than hydrogen. For applications to fuel-cell vehicles, the costs per kilometer of driving to the consumer for methanol derived from natural gas and biomass would be comparable to the costs for hydrogen derived from these fuels (Williams *et al.*, 1995a, 1995b)—and thus to the cost of gasoline derived from crude oil in this period (see, for example, Figure 19-6).

In the first two decades of the next century, natural gas prices are likely to be relatively low. Thus, it is assumed that about 60% of the methanol is derived from natural gas in 2025 (see Figure 19-12). After 2025, it is expected that natural gas prices would rise and natural gas supplies would decline in the BI variant. Thus, there would be a shift in the mix of primary feedstocks from natural gas to biomass and at the same time a shift in the methanol/hydrogen mix toward greater use of hydrogen. The share of hydrogen would grow from 0% in 2025 to more than 50% in 2100 (see Figure 19-12).

Because of the assumption that biomass could be widely competitive in applications where biofuels are used directly, the demand for biomass energy is high in the BI variant. Because nuclear power provides only electric power in the NI variant, the contributions from biomass (see Figure 19-8) and from biomass plantations (see Figure 19-11) are almost as large for this variant as for the BI variant.

Until 2025, most biomass supplies would be residues of the forest-product and agricultural industries and urban refuse. Later, however, the dominant source would be biomass energy farms or plantations. The land area committed to plantations in the BI variant is 83 Mha in 2025 and increases to 572 Mha by 2100. The corresponding land areas for the NI variant are 55 and 433 Mha, respectively. The distribution of land use in plantations by region is indicated in Figure 19-11.

In the LESS reference cases, methanol would become a major commodity traded in international energy markets. Thus, by the middle of the next century, regions such as Latin America and sub-Saharan Africa—where there are large areas potentially available for growing biomass—would become major exporters of biomass-derived methanol.

There are no contributions from electrolytic hydrogen in the LESS reference cases in 2025. Costs for hydrogen derived electrolytically from photovoltaic, wind, or nuclear sources are likely to be much higher than for hydrogen or methanol derived from natural gas or biomass (see Figure 19-5). It is assumed, however, that by 2050 land-use constraints begin to limit the expansion of production of biomass-derived methanol and hydrogen in some areas, so that some electrolytic hydrogen enters the mix (see Figure 19-12 and Box 19-2).

19.3.1.4. Challenges Posed by Biomass Energy in the LESS Reference Cases

Several studies carried out in recent years suggest that "modernized biomass" could play a major role in the world's energy economy in the 21st century (see Box 19-3). Other long-term energy studies have ignored biomass; some that have not expect that biomass energy will evolve more slowly even if biomass energy is encouraged by public policies [for example, WEC's Ecologically Driven Scenario (WEC, 1993, 1994)].

The envisaged development of biomass energy is possible in principle. The assumed average biomass plantation yields—11 dry tons/hectare/year (dt/ha/y) in 2025, rising to 15 dt/ha/y in 2050 and 20 dt/ha/y, 2075-2100—though much higher than the yields for natural forests, are not unreasonable in light of experience with various cultivated crops (see Figure 19-3). Many studies indicate that these yields can be realized at the high net energy output/input ratios assumed for the LESS reference cases (see Section 19.2.5.2). Likewise, although the projected plantation areas are large (see Figure 19-11), even the 572 Mha targeted for the year 2100 in the BI variant is only 12% of the total amount of land in cropland plus permanent pasture (Hall *et al.*, 1993). Yet concerns have been raised about the potential

---

Box 19-3. The Role of Biomass Energy in Some Recent Global Energy Studies

Five recent studies exploring alternative energy futures provide alternative views of the prospects for biomass energy:

- The World Energy Council projects (WEC, 1994) in its Current Policies Scenario for global energy that traditional (noncommercial) biomass energy use increases from 42 EJ in 1990 to 59 EJ in 2020 and that modern (commercial) biomass energy increases from 5 to 11 EJ. For the WEC Ecologically Driven Scenario (EDS), however, these totals for 2020 are 47 EJ and 25 EJ, respectively [compared to a total biomass energy use rate (all commercial) of 74 EJ/yr in 2025 for the BI variant of the LESS]; the projected 5.5%/yr growth rate for modern biomass energy use, 1990–2020, is regarded as a plausible but ambitious growth schedule, considering all of the new technologies involved and the institutional hurdles that must be overcome.
- Dessus *et al.* (1992) project total world biomass use as 135 EJ in 2020, of which 51% and 17%, respectively, are accounted for by commercial and noncommercial wood recovered from forests, 20% by biomass waste resources, and 12% by biomass crops grown on plantations. Dessus *et al.* (1992) apparently focus their expansion on biomass from forests because this large potential resource might be the most easily exploited potential biomass supply.
- The U.S. Environmental Protection Agency advances a scenario for a greenhouse-constrained world (Rapidly Changing World with Stabilizing Policies) in which the role of commercial biomass energy increases to 136 EJ by 2025 and to 215 EJ by 2050 (Lashof and Tirpak, 1990).
- In their Renewables-Intensive Global Energy Scenario (RIGES), Johansson *et al.* (1993a) project the biomass contribution (all commercial) to be 145 EJ by 2025 and 206 EJ by 2050; plantations account for 55–62% of the total, while forests account for only 5–7%. In the RIGES, the use of modernized biomass was projected to grow rapidly (10%/yr, 1990–2025) because of the multiple benefits it offers.
- In its 1994 long-term global energy scenario exercise, the Shell International Petroleum Company developed a "Sustained Growth" scenario in which it projects that by 2050—as in the BI variant of the LESS—more than half of total world primary energy comes from renewable energy sources. (The projected overall level of renewable energy development is twice the level in the BI variant of the LESS, however, because the overall projected level of energy demand is about twice as high at that time.) In this scenario, the overall contribution from biomass in 2050 is about 15% higher than in the BI variant of the LESS, although about 30% of total biomass in the Shell scenario is for noncommercial uses (Kassler, 1994).

conflict with food production, especially in developing regions (see Section 19.2.5.2 and Chapter 25).

If agricultural production can be modernized and intensified in environmentally acceptable ways, however, large increases in cropland probably will not be needed for food production (e.g., Waggoner, 1994; Smil, 1994). Indeed, low-cost bioenergy could attract industry to rural areas to provide the income growth needed to modernize agriculture (see Section 19.2.5.2). Preliminary analyses indicate good prospects in Brazil for large-scale development of bioenergy plantations without serious competition from food production (Carpentieri *et al*., 1993). Even in densely populated India, it has been suggested that some 60–70 million hectares of degraded lands might be good for energy plantations. In India, the potential conflict with food production is not expected to be great. Between 1970 and 1990, food production per capita increased while the total land area under cultivation stayed about the same, despite a 60% growth in population. Also, there are good prospects for substantial further gains in food crop yields (Ravindranath and Hall, 1994). Moreover, a preliminary country-by-country analysis exploring the potential for biomass energy production in the context of future food requirements in the developing world projects that there could reasonably be considerable amounts of land committed to biomass energy production in Africa, Asia, and Latin America without posing major conflicts with food production in the period to the year 2025 (Larson *et al*., 1995). Further investigations of these issues are needed, however.

19.3.1.5. Natural Gas-Intensive Variant of a LESS

The natural gas-intensive (NGI) variant of the LESS constructions (see Figure 19-8) is based on the following assumptions:

- Remaining recoverable natural gas resources are substantially higher than in the reference cases.
- All of the natural gas in excess of that for the references cases is used to make methanol and hydrogen. These displace methanol and hydrogen that would otherwise be produced from plantation biomass in the BI variant to the extent that this is feasible at the higher production levels of natural gas.
- Hydrogen production for this extra natural gas is carried out near depleted natural gas fields, so the stream of CO_2 recovered at the hydrogen production facility can be sequestered there (see Figure 19-5).
- The energy demand levels and structures are the same as for the BI variant.
- Except for the shift from biomass to natural gas for the production of methanol and hydrogen, the energy supply mix is the same as for the BI variant.

In this variant, remaining, ultimately recoverable natural gas resources for the United States are assumed to be the same as in the reference cases. For other regions, the high natural gas resource estimates of Masters *et al*. (1994) are assumed. Thus, total remaining, ultimately recoverable natural gas resources as

of 1993 are 17,400 EJ—nearly 40% higher than in the reference cases. As in the reference cases, it is assumed that 80% of these resources are used up by the year 2100. In this case, global natural gas production increases to a level 2.3 times the 1990 level by the year 2050 before global production declines at a constant exponential rate.

In this variant, natural gas would be less costly than in the reference cases, which would make it harder for fuels derived from plantation biomass to compete. In the NGI variant, there would be no plantations in 2025; plantation requirements would be only about 40% of those in the BI variant in 2050 and 75% of those in 2100 (see Figure 19-11).

Annual CO_2 emissions would fall to 2 Gt C/yr by the year 2100 (see Figure 19-9), and cumulative emissions between 1990 and 2100 would be 476 Gt C (see Figure 19-10)—only slightly more than in the reference cases. Cumulative requirements from 1990 to 2100 for sequestering the CO_2 recovered in hydrogen production would be nearly three times as large as in the reference cases (44 Gt C vs. 17 Gt C), but this is small compared with the sequestering capacity of natural gas fields that would be theoretically available by 2100 via natural gas extraction (see Section 19.2.3).

19.3.1.6. Coal-Intensive Variant

Another strategy for achieving deep reductions involves using coal and biomass for methanol and hydrogen production, along with sequestration of the CO_2 separated out at the synthetic fuel production facilities. This strategy is pursued in a way that emphasizes the use of coal relative to biomass, subject to the constraint that the overall level of annual CO_2 emissions is the same as for the NGI variant. It is assumed that for this coal-intensive (CI) variant, all characteristics of the variant other than for methanol and hydrogen production are identical to those for the BI variant (for example, reference-case assumptions about remaining natural gas resources).

The separated CO_2 might be sequestered in saline aquifers or in depleted oil and gas fields (Williams, 1996). Because the cost of the coal or biomass contributes such a small amount to the overall cost of making hydrogen (see Figure 19-5) or methanol (Williams *et al*., 1995a, 1995b), it would not change the overall economics very much to ship the coal or biomass to a depleted natural gas field site for processing.

This variant offers considerably greater potential for reducing dependence on biomass than is feasible for the NGI variant (see Figure 19-11) because of the specification that CO_2 recovered at hydrogen and methanol conversion facilities be sequestered for biomass as well as coal feedstocks. Costs would be slightly higher because of the added complications of sequestering CO_2 recovered at coal and biomass fuel-processing facilities, but costs for demanded energy services could plausibly still qualify as being approximately the same as estimated future costs for current conventional energy (see Figure 19-6).

Cumulative sequestering requirements for this variant from 1990 to 2100 would be 145 Gt C (see Figure 19-10).

In this variant, global coal use would increase 47% by 2075, followed by a slow decline. Coal use in 2100 would be 31% higher than in 1990.

Two important lessons are highlighted by this variant. First, the production of hydrogen-rich fuels for fuel-cell applications allows coal to have a significant role as an energy source in a GHG-constrained world. Second, in this strategy, coal and biomass play complementary roles. Having some biomass in the energy system allows greater use of coal because for biomass grown on a sustainable basis with sequestration of the CO_2 separated at the conversion facilities, net life-cycle CO_2 emissions are negative (see Figure 19-5).

It is noteworthy that ongoing efforts to commercialize oxygen-blown coal gasifiers for integrated coal gasification/combined cycle power generation help to realize this strategy because the same kind of gasifier is needed for the production of methanol and hydrogen from coal.

19.3.1.7. High-Demand Variant

The LESS reference cases involve a high degree of decoupling of energy demand from economic growth for the entire period to the end of the next century. By 2100, primary energy demand doubles, compared to a quadrupling of energy demand in IPCC's IS92a scenario. The high-demand (HD) variant explores the potential for achieving deep reductions in emissions if energy demand and economic growth follow historical trends in the period beyond 2025. Overall demand for fuels used directly and for electricity are equal to those for the reference cases through the year 2025 but rise thereafter at constant exponential rates to the demand levels for the IS92a scenario by the year 2100. The energy supply base, to which are added the supplies for additional electricity and fuels used directly, is that for the NGI variant.

The major challenge of the HD variant is providing the extra fuels used directly with low emissions. The extra electricity might be provided entirely by some mix of intermittent renewable and nuclear electric sources, so that incremental power generation would pose no CO_2 management problems. To illustrate the possibilities, the HD variant is constructed with all of the incremental electricity provided by intermittent renewables. In principle, all of the incremental power could be provided from these sources. All incremental power requirements would come after the year 2050, by which time storage technology would plausibly be widely available to shape the output of intermittent resources to meet most electrical demand profiles. Also, there do not appear to be physical limits on intermittent resources at these generation levels, although power plant siting constraints in this time frame might limit additional capacity mainly to distributed photovoltaic systems and remotely

sited, central-station, renewable electric power plants (Williams, 1995a).

All incremental requirements for fuel used directly are provided by hydrogen derived by thermochemical means from natural gas, biomass, and coal (see Figure 19-12), with sequestering of the CO_2 recovered at the fuel-conversion plants. By 2050 and beyond, the HD variant uses as much primary biomass energy as in the BI variant and as much natural gas as in the NGI variant. The extent of sequestration is dictated by a requirement that annual CO_2 emissions not exceed those for the NGI variant (see Figure 19-9).

Coal use increases 5-fold between 1990 and 2100 (see Figure 19-8); annual sequestration requirements increase from 0 in 2025 to 2.0 Gt C/yr in 2050 and 11.6 Gt C/yr in 2100. Cumulative sequestration requirements from 1990 to 2100 amount to 321 Gt C. In principle, sequestering might be accomplished entirely in natural gas fields until the year 2100 (Williams, 1995a). However, additional secure storage capacity would be needed to continue sequestering CO_2 at high rates and to maintain low emissions levels with continued intensive use of coal well beyond the year 2100.

The achievement of low emissions in this variant appears to be feasible. There would be much less flexibility, however, to choose among alternative options for achieving deep reductions at the high energy-demand levels of the HD variant than under reference-case energy-demand conditions. This exercise underscores the importance of energy efficiency in achieving deep reductions in GHG emissions.

19.3.2. A Top-Down Construction of a LESS

To test the robustness of the bottom-up energy supply analysis indicating that deep reductions in CO_2 emissions could be realized by 2100, a top-down global energy modeling analysis also was carried out for the Working Group (Edmonds *et al.*, 1994), incorporating performance and cost parameters for some of the key energy technologies used in the construction of the BI variant of the reference cases. Six technology cases were modeled using this top-down approach. The trajectories of global energy and the corresponding CO_2 emissions are shown in Figure 19-15.

The Edmonds-Reilly-Barns (ERB) model used here comprises four modules: demand, supply, energy balance, and GHG emissions. The first two modules determine the supply and demand for each of six major primary energy categories in each of nine global regions. The energy balance module ensures model equilibrium in each global fuel market, based on assumptions regarding resources and fuel technologies. The final module calculates energy-related emissions of CO_2. Demand for each fuel is determined by population; labor productivity; energy end-use intensity; energy prices; and energy taxes, subsidies, and tariffs. Energy end-use intensity is a time-dependent index of energy productivity. Demand for energy services in each
Figure 19-15: Global annual CO_2 emissions from fossil fuel burning (top) and global annual primary energy production and use (bottom) for six alternative cases constructed by Edmonds *et al.* (1994) in a "top-down" modeling exercise aimed at constructing a LESS. Case 1 is the reference scenario, with features very similar to the IPCC IS92a scenario; the exogenous end-use energy intensity improvement rate is 0.5%/yr by 2005, rising to 1%/yr by 2035, and reaching 1.5%/yr by 2065. Case 2 emphasizes energy-efficient power generation from fossil fuels (with efficiencies reaching 66% by 2095), but is otherwise like Case 1. In Case 3, liquefied hydrogen from natural gas, biomass, and electrolytic sources is used in fuel cells for transportation, and solar and wind power become highly competitive. Case 4 is like Case 3 except that compressed hydrogen is used instead of liquefied hydrogen. Case 5 is like Case 4, except that biomass prices are more competitive. Case 6 is like Case 5, except that the exogenous energy end-use intensity improvement rate reaches 2%/yr by 2050.

region's end-use sectors is determined by the cost of providing these services, and by income and population. For OECD regions, energy demand is disaggregated into residential/commercial, industrial, and transportation sectors. Energy supply is disaggregated into renewable and nonrenewable sources. Fossil fuel energy supplies are related to the resource base by grade of the resource, cost of production, and historic production capacity. The rate of technological change on the supply side varies by fuel. The energy balance module chooses energy prices that bring demand and supply into balance, given technological assumptions.

The point of departure for the top-down analysis is a scenario (case 1) that is very similar to IPCC's 1992 IS92a scenario (the same overall levels of population growth, GDP growth, primary energy use, CO_2 emissions, etc.). Five alternative technology cases were then modeled, each incorporating successively more of the characteristics of the technologies assumed for the construction of the BI variant of the reference case.

Two of the options (cases 5 and 6) are characterized by about the same level of CO_2 emissions as the LESS reference case in 2100 [compare Figure 19-15 (top) with Figure 19-9], even though their primary energy-use levels at that time are very different: For case 5 it is 40% higher than for the LESS reference case, and for case 6 it is 20% lower. These energy balances are arrived at with natural gas prices increasing to $8–10/GJ, oil prices increasing to $10–15/GJ, and coal prices increasing to $2–3/GJ by 2100.

All six cases have about the same level of exogenously defined global GDP in 2100 (although global GDP is slightly higher for cases 5 and 6 than for case 1). This shows that if the assumed technological characteristics are realized, deep reductions could be achieved without economic penalty. What is needed is a technology policy that facilitates the development and commercialization of GHG-friendly technologies that offer the potential at maturity of being competitive under market conditions with fossil fuel technologies.

This important result shows that the large differences in outcomes often observed between top-down and bottom-up modeling exercises are not due to irreconcilable differences between these very different approaches, as some have suggested, but rather to differences in assumptions.

19.3.3. Concluding Remarks

Costs for energy services in each LESS variant relative to costs for conventional energy depend on relative future energy prices, which are uncertain within a wide range, and on the performance and cost characteristics assumed for alternative technologies. However, within the wide range of future energy prices, one or more of the variants would plausibly be capable of providing the demanded energy services at estimated costs that are approximately the same as estimated future costs for current conventional energy. In a LESS scenario, substantial

reductions in CO_2 emissions would result from the deployment of advanced energy supply technologies, along with more efficient energy-using equipment. Such outcomes appear to be possible given adequate time (several decades) and an economic climate and public- and private-sector policies conducive to the needed innovations. Strong and sustained investments would be needed for research and development, demonstration, and diffusion of energy technologies characterized by low or zero CO_2 emissions; at present, the levels of investment in such activities are low and declining (see Section 19.4).

The LESS constructions show that with modest rather than steep energy demand growth, deep reductions in emissions could plausibly be achieved with a variety of mixes of low-carbon fossil fuels, decarbonized fuels, renewable energy sources, and nuclear energy. Thus, society would not have to pursue all options but would have the flexibility to choose mixes of GHG-friendly technologies based largely on their effects on the local and regional environment, energy security, developmental benefits, and cost. Moreover, society could shift course to a different path if, for unforeseen reasons, an initial choice proved to be problematic or if more attractive options emerged as a result of unexpected technological innovations. Less flexibility would be possible at high levels of energy demand.

Finally, it is hoped that these LESS constructions will encourage others to explore in more detail the advantages and drawbacks of the options described here and to identify and articulate other paths to an energy future characterized by low emissions of CO_2.

19.4. Implementation Issues

The preceding section identified technology options that together could make significant reductions in long-term GHG emissions with projected costs to society of energy services that are approximately the same as estimated future costs for current conventional energy. The ability of any of these technologies to realize its potential depends on the rate and extent of its adoption under widely differing institutional, economic, and natural-resource constraints in various countries and regions. This section briefly addresses some of the associated implementation issues.

A transition to renewable and other low-CO_2-emitting energy technologies is not likely to occur at the pace envisioned under business-as-usual conditions. A variety of problems inhibit their development and deployment. For example, private companies are unlikely to make the investments necessary to develop renewable technologies at a rapid rate because the benefits are distant and not easily captured by individual firms; they also will not invest in large volumes of commercially available technologies to the extent justified by the external benefits (for example, reduced emissions). Also, conventional energy technologies benefit from direct subsidies of more than $300 billion per year worldwide (Koplow, 1993; OECD, 1992; IEA, 1993b; Larsen and Shah, 1994).

Actions conducive to a transition to an energy system based on low CO_2-emitting energy technologies should include policy changes that address seven key areas: energy system planning; financing; technology research and development; technology transfer, adaptation, and deployment; local environmental impacts; capacity building; and institutional arrangements (UNSEGED, 1992; WEC, 1994; Johansson *et al.*, 1993a; UNCNRSEED, 1994, 1995).

Economic instruments such as tradable emissions permits and emissions fees (taxes) could be designed to partly incorporate the true social and environmental cost of existing technologies in the price of the energy that they produce (IEA, 1993b). Others, such as temporary subsidies, could help accelerate the development and implementation of new technologies.

Regulations—defined as legislation or government or private-sector rules (supported by sanctions)—can be designed to influence public and private decisionmakers in their transactions. Regulations might focus on technology performance, influence the use of technology (for example, use of electricity-dispatch rules to prioritize low-emitting technologies), or promote the training of operating personnel through licensing arrangements. Particularly important in the power sector are rules that determine if and under what terms small, independent producers of renewable electricity (including intermittent generation) may gain access to the utility grid. For biomass energy, agricultural, forestry, and land-use policies are important.

For example, in the United States, an effective regulatory instrument—the Public Utilities Regulatory Policy Act (PURPA) in 1978—led to the creation of a competitive, decentralized market. PURPA required electric utilities to buy power from independent producers at the long-term avoided cost. This law is largely responsible for the introduction of 8,000

MW_e from biomass, 1,500 MW_e from wind, 730 MW_e from small-scale hydropower, and 350 MW_e from solar thermal-electric technology (WEC, 1994).

There is a worldwide trend toward increasing competition in the power sector. This will generally be helpful to small, high-efficiency, and more economical cogeneration systems, while discouraging large, less-efficient, and less-economical stand-alone steam turbine-based power plants. On the other hand, this trend will reduce interest in the long term and the measures that need to be taken to bring new technologies to the market.

Research and Development (R&D): High rates of innovation in the energy sector would be needed to realize any of the LESS constructions. The trend in recent years, however, has been declining investment in energy R&D on the part of both the private sector (Williams, 1995b) and the public sector (see Table 19-9). Over the last decade, public-sector support for energy R&D has declined absolutely by one-third and by half as a percentage of GDP. Moreover, government-supported R&D has generally focused on nonrenewable energy technologies. Less than 10% of IEA member governments' support is for renewable energy technologies.

It is important to have a government energy R&D strategy that does not attempt to pick winners. Fortunately, many of the promising technologies for reducing emissions, such as fuel cells and most renewable energy technologies, require relatively modest investments in R&D. This is a reflection largely of the small scale and modularity of these technologies and the fact that they are generally clean and safe (Williams, 1995b). As a result, it should be feasible, even with limited resources for R&D, to support a diversified portfolio of options. It has been estimated that research and development of a range of renewable energy technologies would require on the order of $10 billion (WEC, 1994).

Table 19-9: *Total reported IEA government R&D budgets (columns 1–7; US$ billion at 1994 prices and exchange rates) and GDP (column 8; US$ trillion at 1993 prices).*

Year	(1) Fossil Energy	(2) Nuclear Fission	(3) Nuclear Fusion	(4) Energy Conservation	(5) Renewable Energy	(6) Other	(7) Total	(8) GDP	(9) % of GDP
1983	1.70	6.38	1.43	0.79	1.05	1.08	12.40	10.68	0.12
1984	1.60	6.12	1.44	0.70	1.02	0.99	11.88	11.20	0.11
1985	1.51	6.26	1.42	0.70	0.85	1.04	11.77	11.58	0.10
1986	1.51	5.72	1.31	0.59	0.66	0.94	10.74	11.90	0.09
1987	1.37	4.36	1.23	0.65	0.62	1.04	9.27	12.29	0.08
1988	1.46	3.64	1.13	0.53	0.62	1.19	8.58	12.82	0.07
1989	1.30	4.42	1.07	0.45	0.57	1.33	9.13	13.23	0.07
1990	1.75	4.48	1.09	0.55	0.61	1.15	9.62	13.52	0.07
1991	1.52	4.45	0.99	0.59	0.64	1.39	9.57	13.58	0.07
1992	1.07	3.90	0.96	0.56	0.70	1.28	8.48	13.82	0.06
1993	1.07	3.81	1.05	0.65	0.71	1.38	8.66		
1994	0.98	3.74	1.05	0.94	0.70	1.30	8.72		

Sources: Government energy R&D expenditure data are from IEA (1995); GDP data are from OECD (1994).

Demonstration and Commercialization: R&D programs are necessary but not sufficient to establish new technologies in the marketplace. Commercial demonstration projects and programs to stimulate markets for new technologies also are needed. For a wide range of small-scale, modular technologies—including most renewable energy technologies and fuel cells—energy production costs can be expected to decline with the cumulative volume of production, as a result of "learning by doing" (Williams and Terzian, 1993; WEC, 1994).

The World Energy Council estimates that subsidies on the order of $7–12 billion are needed to support initial deployment of various renewable energy technologies until manufacturing economies of scale are achieved, to compete with conventional options (WEC, 1994). Thus, the World Energy Council estimates that the total investment needed for R&D on and support of initial deployment of renewables to be $15–20 billion. This is 0.1% of the annual global gross national product at the turn of the century and would, of course, be distributed over a couple of decades (WEC, 1994).

Information is a commodity that is especially subject to problems of market failure. One important area for government action is resource evaluation. Unfortunately, sufficiently detailed resource evaluations to facilitate investments are unlikely to be carried out by the private sector. Investigations of a wide range of potentially recoverable renewable resources, especially wind resources and land for energy plantations, would help reduce investment risks considerably (Johansson *et al.*, 1993a; UNCNRSEED, 1994).

In several countries, government encouragement of development and commercialization has been successful in introducing new energy supply technologies in national or regional markets—for example, wind energy in Denmark (Sørensen *et al.*, 1994); grid-connected cogeneration and renewable electric systems in the United States and home-scale photovoltaic systems in Indonesia (WEC, 1994); a sugar cane-based ethanol industry in Brazil (Goldemberg *et al.*, 1993); and a nuclear energy industry in France (Souviron, 1994).

CONTENTS

EXECUTIVE SUMMARY

This chapter provides a summary of options for reducing greenhouse gas emissions from industry, based on a survey of relevant literature. The main purposes are to outline the major sources and trends of emissions from industrial activity and to indicate possible abatement strategies from technological and institutional viewpoints. Emissions from power-generating utilities are not covered; the reader is referred to Chapter 19 for a discussion of this subject. Cogeneration emissions are included in this chapter only to the extent that they take place within an industry. The main findings and conclusions of the chapter follow:

- Industrial sources contribute to greenhouse gas (GHG) emissions in two major ways—fossil fuel combustion for energy and process-related emissions.
- The industrial sector is responsible for more than one-third of global carbon dioxide (CO_2) emissions through energy use. Based on current energy-use patterns, global energy use is expected to rise 75% by the year 2025, with an increasing portion of growth expected to occur in developing countries.
- Several technologies, processes, and new product design concepts exist that could substantially reduce GHG emissions:
  - For industrialized countries, reducing the material content of products, improving energy efficiency, and using fuels with a lower carbon content are essential to lower CO_2 emissions from the industrial sector.
  - For the reindustrializing, transitional countries of eastern and central Europe, as well as the world's developing countries, seizing the opportunity to shift to more advanced technologies will place these countries on a much lower GHG development trajectory.
- Technology transfer from industrial to industrializing countries and the establishment of innovative capacity building in developing countries are expected to generate lower GHG emissions.

Industry Emissions of Greenhouse Gases

Industrial sources of greenhouse gases are related to industrial energy use and to specific industrial production processes. The major industrial trends influencing the growth of future industry-related CO_2 emissions are the aggregate growth rate of industrial output; the structure of industrial growth (in particular the relative share of the energy-intensive, materials-producing subsector); the average energy intensity of specific products; and the fuel mix used in industry. The major challenge for future reductions in the period 1990–2020 is in the area of CO_2 from fossil fuels.

Examples of the historic correlation between growth in per capita gross domestic product (GDP) and fossil fuel CO_2 are examined for several industrialized and developing countries. The industrial-sector contribution of CO_2 varies greatly among countries. The consequences of different technological choices and strategies to date demonstrate that different industrial development paths—with substantially lower greenhouse gas emissions—are possible.

Regarding specific industry emissions, energy-intensive industries such as chemicals, cement, and steel have shown substantial improvements in energy efficiency during the past 20 years, albeit unevenly in different countries. The switch to less carbon-intensive fuels also has continued, so that CO_2 decreases have occurred in some industries during this period. The wood and paper industries in industrialized countries have reduced fossil fuel carbon emissions dramatically by using waste biomass in efficient cogeneration systems. In newly industrializing economies, efficiency gains have been slower because of a lack of economic resources and access to newer technologies. Some industrial processes are beginning to approach thermodynamic energy-efficiency limits; future gains will have to come from materials substitution, process changes, energy supply shifts, and alternative resource and industrial strategies.

Traditional emissions accounting has included all CO_2 emissions from fossil fuels as though they were part of the energy sector. In steel, aluminium, hydrogen, and ammonia production, much of the carbon release actually is process related and could be eliminated by changing production processes. Controlling process-related greenhouse gases, such as halocarbons and hydrohalocarbons, also is important, given their large greenhouse warming potential and long atmospheric lifetimes. Finally, altering chemical manufacturing processes can reduce nitrous oxide (N_2O).

Technical Abatement Options

Different strategies for reducing greenhouse gas emissions deserve attention, particularly fuel substitution—with increased use of lower-carbon fuels, biomass, and renewable energies in industrial processing—and efficiency improvement of energy supply (e.g., cogeneration) and energy use in industrial

processes, including less materials-intensive production methods and renewable feedstocks and raw materials. Implementation would be most cost-effective during normal capital stock turnover.

Industries often have high energy-consumption levels, with large amounts of waste heat being released to bodies of water or the atmosphere. Heat cascading can be incorporated into a new or existing factory if careful attention is paid to the temperatures of its various industrial processes. Waste-heat recovery, which usually is aimed at rationalizing specific industrial processes, can be more effective at the level of coordinated manufacturing and energy industrial complexes. Further improvements could involve integrating energy-use issues into urban infrastructure from the initial stages of city planning with the development of support systems such as thermal-management technologies, regulations, and social mechanisms.

The manufacturing sector uses materials and chemicals to generate production and consumption goods, which ultimately are discarded or recycled. Recycling can involve restoring the material to its original use or "cascading" the material by successively downgrading its use into applications requiring lower quality. Materials cascading is well-established in the paper industry, for example, and is effective when recycling products back into the same ones is too energy-intensive or difficult. Generating materials from scrap tends to produce fewer GHGs and is less expensive than the use of primary raw materials, but there may not always be markets for downgraded materials. Emphasis also is needed on technological innovation to upgrade the quality of recycled products.

Analysis of opportunities and priorities entails preventive environmental management based on environmental, material, energy, health, and safety audits. Life-cycle analyses of energy and material flows and costs from an industrial ecosystem perspective also are essential to implement adequate solutions. Industrial systems that efficiently use waste materials and energy could produce major reductions in GHGs. Structural economic changes also are needed, as is a greater emphasis on

choosing inherently lower-emitting technologies, designing products for greater reuse and recycling potential, and the replacement of nonrenewable resources with a biologically renewable resource base.

Implementation Aspects

Implementation problems to improve energy and material efficiency in industry may involve information and training aspects, financial and economic conditions, or legal and institutional issues. In the case of industrialized countries, efficiency improvements become more difficult when world energy prices are low. Imposition of ecotaxes to stimulate efficiency in industry is a complex issue because taxes that are not levied on a global scale may provoke industry relocation, which may in turn have adverse effects on emissions efficiency. Systems of internationally traded emission permits and opportunities for joint implementation are other alternatives that require careful consideration, given their economic and political implications.

In developing countries, raising efficiency levels involves complex factors such as the higher capital and foreign-exchange requirements usually associated with more-efficient processes. Moreover, the scale of operations, the scarcity of management resources, and the age composition of equipment creates additional difficulties that are not easily overcome from a purely energy-oriented point of view. Although technology transfer programs could potentially assist in the early adoption of efficient equipment, there is no reason to be more optimistic about their success in the case of energy technology than in the case of other technologies. In all countries, the tendency to look exclusively at short-term financial and economic factors to determine efficiency improvement potential overlooks institutional and organizational issues that are equally important in realizing those potentials. This is particularly true of improvements in materials efficiency, where institutional arrangements for collecting and recycling materials are crucial for a proper functioning of markets.

20.1. Introduction

A range of industrial activities and the use of manufactured products contribute significantly to the buildup of greenhouse gases (GHGs) in the atmosphere. Therefore, any attempt to slow the release of greenhouse gases will require a major restructuring of existing development patterns. The challenge is to determine if existing and future needs (and wants) for goods and services can be met without adversely altering the composition of the atmosphere and the planet's climate system.

The major contribution of greenhouse gases by the industrial sector is from carbon dioxide (CO_2) released by the burning of fossil fuels for energy. In addition, the industrial sector is responsible for significant releases of process-related greenhouse gases, including CO_2, methane (CH_4), nitrous oxide (N_2O), and other industrial gases, of which the most prominent are halocarbons and hydro-halocarbons. Sulfur oxide emissions associated with energy use and from the smelting of sulfide ores appear to be responsible for some cooling as well as for regional environmental damage.

Technological mitigation options for greenhouse gases are increasingly being sought so that societies can continue meeting human needs without jeopardizing the global climate system. This effort must be part of a comprehensive reexamination of industrial activity to address a full range of environmental and economic issues in the context of industrial ecology (i.e., meeting development goals within local and global sustainability capacities). Industrial ecology approaches attempt to emulate natural systems by utilizing waste from one industrial process as feedstock for another; efficiently utilizing "waste heat"; designing industrial processes to minimize energy and materials use; and replacing hazardous substances with more environmentally benign substitutes. Several recent works describe the industrial ecology approach and cite examples of recent attempts to implement it (Socolow *et al*., 1994; Ayres and Simonis, 1994; Allenby and Richards, 1994).

This chapter attempts to identify existing and possible future technologies and industrial processes that can be adopted by industrial societies—which now produce the majority of greenhouse gases—by transitional economies, and by developing countries where emissions are increasing as efforts are made to improve the standard of living and material well-being of citizens. Technology transfer from industrial countries to industrializing nations and the establishment of innovative capacity-building in developing countries in accordance with the principles of Agenda 21 (UN Conference on Environment and Development, Rio de Janeiro, Brazil, 1992) are essential if the unwanted global consequences of increased atmospheric concentrations of greenhouse gases, sulfate aerosols, and climate change are to be avoided.

20.2. Industrial-Sector Emissions of Greenhouse Gases

20.2.1. Industrial Energy from Fossil Fuels

In 1990, the world industrial sector consumed an estimated 98 EJ of end-use energy (including biomass) and 19 EJ of feedstocks to produce \$6.7 x 10^{12} of value added. This consumption resulted in the direct release of an estimated 1,200 Mt C. Electricity and cogenerated process heat added an additional 883 Mt C, for a total industrial-sector contribution of 2,083 Mt C—more than one-third of the total (Grubler and Messner, 1993).

Because countries differ significantly in their methods for recording and maintaining energy and economic data, precise comparisons are not always possible. The industrial use of energy for manufacturing, mining, construction, and feedstocks in Organisation for Economic Cooperation and Development (OECD) countries has fluctuated around 40 EJ since 1970 and typically is only 25–30% of total energy use. Developing countries are estimated to have raised their industrial energy use to 30 EJ by 1988 (35–45% of total energy); the transitional Eastern and Central European economies peaked at around 28 EJ of industrial energy in 1988, but experienced estimated declines of as much as 12% in the next 3 years. The industrial fraction of energy use by the Soviet Union was approximately 40% and that of China 60% in 1988 (Schipper and Meyers, 1992). In part, this variation reflects not only differences in energy intensity but also the more-rapid growth of the industrial sectors of developing countries, the restructuring of OECD economies from manufacturing to service, improved energy efficiency in manufacturing, and the transfer of some energy-intensive industries to developing countries. Within this context, attention should be paid to the potential danger of transferring greenhouse gas-intensive, ecologically damaging processes and production of chlorofluorocarbons (CFCs) to transitional and developing countries.

Worldwide future trends of industrial energy have been projected by inputting data from the Energy Modeling Forum report (EMF, 1994) into the Asian Pacific Integrated Model (AIM) (Morita *et al.,* 1994; Matsuoka *et al.,* 1994). These projections indicate that worldwide industrial energy use could rise from about 107 EJ/yr in 1990 to 140 and 190 EJ/yr in 2025 and 2100, respectively, if emissions are stabilized. These figures would increase to yearly consumption of 242 EJ in 2025 and 500 EJ in 2100 if based on an accelerated-technology scenario (EMF, 1994), where it is assumed that 400 EJ/yr of low-cost biomass becomes available in 2020; 20% of this resource is available at \$1.40/EJ and the remaining 80% at \$2.40/EJ.

The energy sector as a whole is thought to contribute about 57% of global warming (IPCC, 1990). Energy use in the industrial sector varies vastly among different countries. An examination of data sets that attempt to disaggregate the energy use of particular economies reveals that the structure of economies and the availability of particular energy sources play major roles in the contribution of greenhouse gases by the industrial sector. A summary of energy-related CO_2 releases for the industrial sectors of the 15 largest CO_2-emitting countries is presented in Table 20-1 (di Primio, 1993).

Clearly, improving the energy efficiency of industrial processes can substantially lower the release of fossil-fuel carbon dioxide; subsequent examples illustrate the potential for substantial

Table 20-1: *Fossil-fuel carbon dioxide from the 15 largest emitters.[1]*

	Total C Emissions (Mt C)	Industrial C Emissions (Mt C)	Industrial % of Total

Mexico[2]	74.17	17.62	23.75
Czechoslovakia[2]	65.63	17.75	27.05

[1] Values are for 1990, unless otherwise noted. Feedstocks are not included in either total carbon data or industrial carbon data; values for electricity inputs into the industrial sector are not included (di Primio, 1993).
[2] 1988 (represents latest available data).
[3] 1985 (represents latest available data).
[4] 1987 (represents latest available data).

reductions. Ultimately, however, thermodynamic free-energy limits preclude further reductions. Any additional lowering of industrial energy emissions can come only by shifting from fossil fuels to non-carbon-based energy sources—such as hydro, nuclear, wind, solar, and geothermal—or by using biomass.

In terms of absolute contribution to global-warming potential, the major sources are CO_2 from fossil-fuel combustion and halocarbons. Cement calcination is the third most important source. Estimates of the quantities of global-warming potential in terms of gigatons of carbon equivalent for these three sources in industrialized, transitional, and developing countries are presented in Table 20-2. It appears that these industrial sources account for close to 30% of total global-warming potential.

20.2.2. Industrial Processes as Sources of Greenhouse Gases

In addition to the release of energy-related greenhouse gases, the industrial sector is responsible for the release of a number of process-related greenhouse gases—although estimates of these gases vary in their reliability. They include halocarbons and hydrohalocarbons, CO_2, CH_4, and N_2O. Whereas CO_2 emissions from fossil-fuel combustion represent the largest portion of industry greenhouse gases, the contribution of process-related

emissions other than halocarbons is less recognized. Changing the production process has the potential to eliminate all greenhouse gases associated with a particular industrial or manufacturing operation. For the United States, process CO_2 emissions in 1991 are estimated to have amounted to 15.6 Mt C (EIA, 1993), or 1.2% of total fossil-fuel releases. In the comprehensive Oak Ridge data set, non-fuel-related CO_2 is estimated explicitly for cement making and implicitly from coal, natural gas, and petroleum that is oxidized in the manufacturing process (Marland, 1994; IPCC, 1991). Examples of process-related GHG releases are presented in Table 20-3; they are discussed under the appropriate industry group in Section 20.3. In some cases—such as the production of cement, lime, and iron—the release of greenhouse gases is intrinsic to the product, so the only option for GHG reductions is material substitution.

Industrial process-related gases include the following:

- CO_2 from the production of lime and cement (calcination process), steel (coke and pig-iron production), aluminum (oxidation of electrodes), hydrogen (refineries and the chemical industry), and ammonia (fertilizers and chemicals)
- Halocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), and hydrofluorocarbons (HFCs) produced as solvents, aerosol propellants, refrigerants, and foam expanders
- CH_4 from miscellaneous industrial processes (iron and steel, oil refining, ammonia, and hydrogen)
- N_2O from nitric acid and adipic acid (nylon) production
- Carbon tetrafluoride or CFC-14 (CF_4) and hexafluoroethylene or CFC-116 (C_2F_6) from aluminum production (electrolysis).

Estimates of the contribution from other minor sources vary considerably. For CH_4 leakages in industrial processes and industrial-fuel combustion, a range of 1–3 Mt of CH_4 for combustion and 3–20 Mt of CH_4 for processing is reported in the literature, reflecting large uncertainties (Berdowski, 1993). Total global anthropogenic emissions amount to roughly 360 Mt of

Table 20-2: *Contribution of industry to global GHG emissions (Gt C-1990).*

	Fossil Fuels[1]	Halo-carbons	Cement Production[2]	Total

CH_4. Estimates of industrial N_2O leakages in nitric acid and nylon production (adipic acid) are equally uncertain but now are considered more important than originally thought. A range of 0.5–0.9 Mt of nitrogen—20 to 50% of total anthropogenic N_2O emissions—is mentioned in the literature (Olivier, 1993). Abatement technologies are available that employ conversion to recoverable nitrogen dioxide (NO_2), catalytic dissociation into molecular nitrogen (N_2) and molecular oxygen (O_2), or improved N_2O destruction in specially designed boilers.

Halocarbons not only cause higher radiative forcing, they also deplete stratospheric ozone. Reduction of many halocarbons, including CFCs, already is occurring in industrial and a few developing countries because of the Montreal Protocol and subsequent amendments. The contribution of halocarbons to radiative forcing will begin to decrease after 2000, although concern over illegal imports into industrial countries is growing (*Scientific American*, 1995). Hydrohalocarbon substitutes for CFCs are expected to grow rapidly in the coming decades and will make modest additions to total warming potential.

20.2.3. Past Trends and Future Prospects for Industrial-Sector GHG Emissions

To discuss the historical and future trends in GHG emissions from industrial energy use, it is convenient to distinguish four essential driving forces. The impact of each driving force on GHG emissions can be influenced by specific policies. These four driving forces and their respective policy domains follow:

- Growth in the volume of industrial production (volume effect—macroeconomic policies), which indicates the quantitative impact of industrial growth
- Changes in the sectoral pattern of industrial growth (structural effect—sectoral policies), which indicate the qualitative impact of industrial growth
- Reduction in energy use for specific products (efficiency effect—energy conservation policies), which is a measure of the impact of energy efficiency improvements

- Changes in energy carrier composition (fuel-mix effect—energy supply policies), which indicate the potential to replace coal and oil by natural gas, renewables, or nuclear energy.

To discuss actual trends and policy opportunities with respect to these four driving forces, it is convenient to distinguish between three regional groups of countries: industrial economies (OECD), transitional economies (Eastern Europe and the former Soviet Union), and developing economies (the rest of the world). The discussion centers on manufacturing, which generally accounts for more than 90% of industrial energy demand. Data on other industrial sectors (energy and mining) are not included.

20.2.3.1. Trends for Industrialized (OECD) Countries

Average manufacturing value in industrialized nations grew from 1973 to 1988 at about 2.3% annually. Nevertheless, energy use decreased by about 1.2% annually. Aggregate manufacturing energy intensity was substantially reduced: in Japan by 45%, in the United States by 43%, and in Europe by 34%. Energy intensities for specific industries in the United States tend be higher than those in European countries, whereas those in Japan tend to be lower.

Schipper and Myers (1992) examined the energy/economic value ratio for a variety of industrial sectors for the United States, Japan, and six European countries. All major industrial sectors recorded gains in measured energy efficiency between 1971 and 1988. For this group of eight nations, energy intensity for chemicals declined by 37%, pulp and paper by 27%, building materials by 32%, ferrous metals by 27%, and nonferrous metals by 26%. Surprisingly, less energy-intensive sectors also declined by an average of 37% during the same period. Ferrous metals and pulp and paper require the greatest energy per value added, followed by nonferrous metals, building materials, and chemicals. The major source of these gains was identified as a combination of 1) better housekeeping practices in operation and maintenance, 2) higher cost investments in process equipment, and 3) replacement of older, less efficient technology with new production processes. In some subsectors such as chemicals, there is also some shift to less energy-intensive products. An excellent case study of how multimillion dollar energy efficiency gains have been achieved in the American chemical industry has been given by Nelson (1994).

Several groups have attempted to assess the potential for future savings from energy efficiency gains in the industrial sector of specific economies. The analysis carried out for the Swedish utility Vattenfall identified major industrial energy savings that would lower CO_2 significantly by 2010 (Johansson *et al.*, 1989).

Statistical analysis of the impact of changes in the sectoral composition of industrial production on energy demand show that in this period structural change generally had a continuous, but relatively small, effect in reducing energy demand. Efficiency

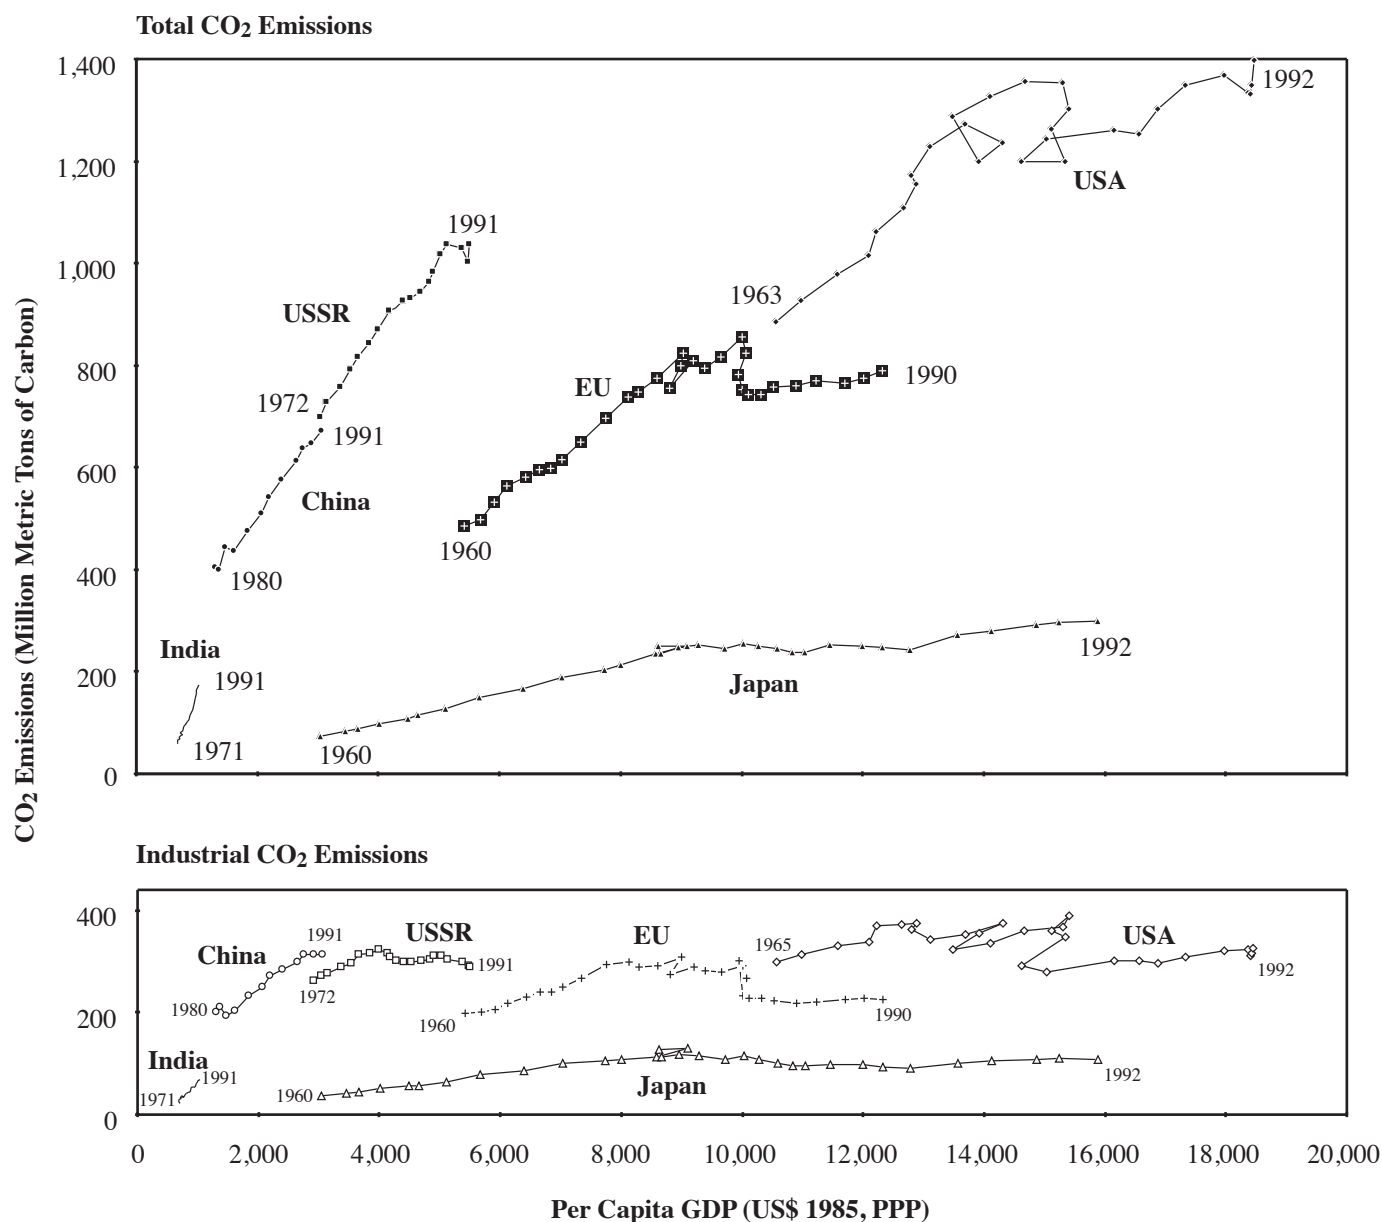
Total CO$_2$ Emissions


Figure 20-1: Fossil fuel CO$_2$ development path for the total economy (upper panel) and the industrial sectors (lower panel) of the United States, the 15 nations that now comprise the European Union (less East Germany), Japan, China, India, and the former Soviet Union. The industrial sector is as defined by OECD, plus CO$_2$ associated with refineries and the fraction of electricity that is used by industry. The CO$_2$ values are from OECD (1994) and the purchasing power parity (PPP) values are from Summers and Heston (1991, 1994).

improvements have been much more important than structural changes in curtailing energy demand, particularly in the period after 1980 when energy prices were very high (Bending, 1987; Schipper, 1992). Cyclical movements complicate this picture considerably because energy-intensive industries, such as the metallurgical and chemical subsectors, are much more sensitive to business cycles than is aggregate industrial production. Moreover, historical trends are different for fuels and electricity. In general, net improvements in electricity efficiency have been lower than in fuel-use efficiency because of the relatively important role of new electricity-using technologies in manufacturing, which offsets efficiency gains in traditional electrical equipment. Given these energy-demand trends and taking into

account the industrial fuel-composition changes toward natural gas, the general trend for GHG emissions from fuel combustion in the manufacturing sector of industrial nations in the past 2 decades has been downward (Torvanger, 1991; Figure 20-1). The overall decrease from 1973 to 1991 was about 15%.

Under business-as-usual conditions, emissions from industrial countries will continue to grow moderately but with a gradual shift away from energy-intensive industries. The materials-producing industries are likely to have slower growth than less energy-intensive industries. This trend is caused partially by saturation effects on the materials demand side (Williams, 1987) and partially by ongoing economic globalization, which

may shift energy-intensive industries to countries with major natural resource endowments (e.g., minerals, fossil fuels, and hydropower) and lower environmental priorities (because of lower environmental loads and urgent poverty problems). Nevertheless, the continuing improvement of bulk transportation technology and the growing integration of quantity-oriented production of bulk materials with quality-oriented production of semifinished products may put a substantial brake on the latter trend. Opportunities for further energy conservation are certainly available, especially for newly emerging industries. Fuel-mix effects may tend to increase emissions by a modest amount because the share of coal may increase after the year 2000. The aggregate impact of all effects leads more or less to a stabilization of GHG emissions in OECD industrial countries.

20.2.3.2. *Trends for Transitional Economies*

Whereas many studies analyze industrial energy demand developments in OECD countries, the historical evidence regarding transitional economies is much scarcer. Data availability and compatibility problems abound. In transitional economies, industry has been very dominant, accounting for approximately half of total energy use. Through the late 1980s, energy demand grew at a rate of about 2% annually, with relatively little progress in energy efficiency or structural change. In the 5 years after it reached a peak in 1988, industrial energy demand dropped sharply from central planning levels, although less so than industrial output. CO_2 is estimated to have dropped by a little more than 25% in the former Eastern bloc between 1988 and 1993 (Brown *et al*., 1995). Thus, manufacturing energy demand and related GHG emissions have been much more directly coupled to aggregate industrial growth and decline (volume effects) and much less affected by structural and efficiency effects than has been the case in OECD industrialized nations. The trend for transitional economies with respect to GHG emissions had been strongly upward until 1989; at that time, a clear break occurred, and the trend has been sharply downward to the present.

For transitional economies, the rate of economic activity is likely to be more fluctuating than for OECD countries. In the short run, a further decrease in aggregate industrial energy demand can be expected because of the ongoing, dramatic restructuring of the industrial sector—which may affect the energy-inefficient heavy industries in particular. Although some Eastern European countries already are recovering from earlier transition difficulties, this is not yet the case for the former Soviet Union, where further declines are expected (Schipper and Martinot, 1993). At least for the period 1990 to 1995, a sharp drop in GHG emissions is fairly certain. Nevertheless, in the long run, these economies may expand again at a high rate, compensating for their earlier performance lapses. By that time, the relatively strong role of heavy industry will not continue under conditions of a market economy, and the development of the sectoral pattern will be toward reduced GHG emissions. Given excessively high current energy intensities, opportunities for energy conservation are very

great. Finally, because of the increasing role of natural gas, the fuel mix is likely to change in a direction favorable for reducing GHG emissions, provided that the high leakage rate of the gas transmission and distribution system can be addressed. The aggregate impact of all effects probably will lead to a small decline in industrial GHG emissions between 1990 and 2020.

20.2.3.3. *Trends for Developing Countries*

Industrial energy use in developing countries is dominated by China, India, and Brazil. Until 1980, China followed national policies focusing on heavy industry; since 1980, however, the emphasis has shifted toward lighter industries. Industrial growth has been very high—14% annually. At the same time, aggregate manufacturing energy intensity declined considerably—30% between 1980 and 1988 (Huang, 1993). However, structural change accounted for only a small part of this reduction; most of the change was caused by efficiency improvements in all industrial sectors. Industrial growth in India has been slower in the same period but still impressive, at roughly 7% annually. India's energy efficiency increased by about 25%. A larger part of this improvement probably was accounted for by structural changes than was the case in China. The picture for Brazil is altogether different because the growth in export-oriented, energy-intensive industries was very high. From 1973 to 1988, industrial production increased by 65% while energy intensity increased by 25%, leading to a doubling of total energy use. Structural changes between and within industrial sectors were the dominating force, more than compensating for efficiency improvements in individual sectors (Keller, 1991). However, part of this growth has been based on hydroelectric developments and, because of the effects of shifts to biomass alcohol fuel, the additions to GHG emissions are less than energy demand growth.

A study of the Indian industrial sector concluded that energy efficiency gains of 8–10% were possible in the metals industries; 10–15% in chemicals, ceramics, and glass; 20–25% in cement and pulp and paper; and 70–80% in sugar refining. These gains would bring Indian industrial energy intensity more into line with energy-efficient modes of production (TERI, 1991).

With respect to other developing countries, few general conclusions are possible—given the widely diverging industrial developments of Southeast Asian economies versus sub-Saharan economies, for example. The developing world as a whole is experiencing an upward and accelerating trend in industrial GHG emissions.

The largest single additive impact in all respects will come from industrial growth in developing countries. Moreover, because the world's most populous countries—China and India—are dependent to a large extent on domestic coal resources, this impact will be reinforced by an additive fuel-mix impact through increased average CO_2 content of industrial energy use. The impact from sectoral shifts (qualitative

structural change) will be additive but relatively small because major expansions in the bulk-materials industries already have taken place. Although the potential for reductions in specific energy use are large, they are likely to meet severe implementation problems, and they will be insufficient to counteract the other effects in a major way. The aggregate effect will lead to a relatively rapid increase in GHG emissions.

20.2.4. Variations Among Regional Groups

It is important to stress that not all economies produce the same levels of greenhouse gases even when they have achieved the same average levels of affluence. An examination of these differences among countries and the particular economic development paths they have followed in getting to their present economic and industrial stage of development can provide useful insights into which policies and strategies may be most effective for producing lower-GHG industrial societies. Figure 20-1 illustrates fossil fuel development paths over the past 30 years for the United States, the 15 nations that now comprise the European Union (less East Germany), Japan, China, India, and the former Soviet Union (Moomaw and Tullis, 1995). These countries accounted for just over 80% of global CO_2 emissions in 1990. Both total and industrial-sector CO_2 emissions are correlated with national GDP, which is expressed as purchasing power parity in 1985 U.S. dollars (Summers and Heston, 1991, 1994). The industrial-sector carbon dioxide data consist of industrial-sector emissions plus refinery emissions and the industrial electricity fraction of each nation's electric power-sector emissions (OECD, 1994). It is clear that different nations have followed very different fossil-fuel trajectories to arrive at their present economic status (Moomaw and Tullis, 1994). The decline in CO_2 in the former Soviet Union is tied to the decrease in industrial output. Whereas total and industrial-sector CO_2 emissions continue to rise for expanding industrializing economies like those of China and India, they have nearly leveled off or decreased for industrial nations. It is important to note that the industrial-sector and total CO_2 emission levels of most OECD countries are below their historic peaks even though their economies and populations have continued to expand.

The expected large impact of volume growth in developing nations does not imply that they will follow the historic industrialization path of industrial nations. Technological developments have changed the optimal scale of production and production-factor requirements dramatically in the past few decades. Moreover, the availability of resources and their relative prices in developing countries are not comparable to historic conditions in industrial countries. Information technology and materials technology have changed industrial processes enormously in the recent past and will continue to do so in the near future. It may well be possible for developing countries to undergo an earlier carbon transition than was the case for present industrial nations.

20.3. Specific Industry Emissions

20.3.1. Basic Metals

The iron and steel, aluminum, copper, and other nonferrous metal industries are extremely energy-intensive (and release process CO_2 and other GHGs, as well). In the United States, they are the leading industrial producers of CO_2, at 63.1 Mt C or 20% of the industrial sector (Marland and Pippin, 1990). Significant efficiency gains have been realized during the past 20 years as new processes have been developed.

20.3.1.1. Iron and Steel

The release of CO_2 from the iron and steel industry in 15 leading industrial nations was estimated to be 151 Mt C in 1990. Carbon inputs are equally divided between energy and chemical feedstocks such as coke. Integrated, primary steel works use approximately 550 kg C per ton of crude steel, whereas electric-arc furnaces using scrap average only 128 kg C per ton of crude steel. The European and Asian steel industries each release approximately 51 Mt C, North America 47 Mt C, and South Africa 2 Mt C. Nationally, the United States leads with 42 Mt C, followed by Japan with 37 Mt C (IISI, 1993).

Iron- and steel-related carbon emissions from the 15 leading producers amount to 2.7% of total global carbon, but their iron and steel production represents only a fraction of the world's total. Several of the largest producers are heavy coal users; they use much-less-energy-efficient technology than that cited above. For example, Japan requires only 19 GJ per ton of steel and the United States 24, but the average for the former Soviet Union is 31, China 38, and India 41 (Chandler, 1985). Additional CO_2 is released in the use of blast-furnace limestone—about 1 Mt C in the United States (Forrest and Szekely, 1991)—and in the removal of CH_4 and other gaseous components from coke. Overall, contributions of the iron and steel industry to carbon emissions could be in the range of 7 to 8% of world totals.

Significant improvements in the efficiency of steelmaking have been made during the past two decades. The Japanese industry has demonstrated a 20% improvement between 1973 and 1990 (IISI, 1993; MITI, 1994). Most of the gains have come about as the result of heat-recovery technologies, although an estimated 40% of process heat is still lost. Improvements have occurred in cokemaking, continuous casting (reducing reheating requirements), and continuous annealing. Top-pressure-recovery turbines also generate electricity from furnace top-gas during iron production. The European coal and steel community is carrying out a research program that suggests that further gains can come from scrap preheating; improved coal and oxygen use; and recycling of coke-oven, blast-furnace, and converter gas (IISI, 1993).

Additional GHG reductions can result from changing iron and steel production processes. Process-related CO_2 for the 15 leading producer countries amounts to 1.3% of global carbon

emissions. The most dramatic improvements have come from the adoption of electric-arc furnaces and the efficient evolution of that technology. Using scrap eliminates carbon releases associated with metal reduction, and total carbon use per ton is only about one-fourth that of an integrated facility. Problems from contamination by impurities may limit this method and suggest that the original metallurgical design of steels should consider their recycling potential. Hydrogen rather than carbon reduction of iron ores would produce a dramatic lowering of carbon emissions if inexpensive carbon-free sources such as hydro or solar electrolysis of water could be developed (IISI, 1993). In the future, carbon for steelmaking may come from used tires or organic chemical wastes rather than from coal (Corcoran, 1994; MMT, 1993).

20.3.1.2. Aluminum

The production of bauxite ore is so localized that the top ten national producers are responsible for 92% of the world total (WRI, 1994). Similarly, aluminum production of 18.194 Mt in 1991 is concentrated in the United States (4.12 Mt), the former Soviet Union (2 Mt), Canada (1.83 Mt), Australia (1.24 Mt), Brazil (1.14 Mt), China (0.86 Mt), Norway (0.83 Mt), and Germany (0.74Mt); India (0.44 Mt) and Venezuela (0.6 Mt) also are major producers (Plunkert and Sehnke, 1991). In 1991, 17.2 Mt of aluminum was consumed, 73% of it in 10 top-consuming nations—led by the United States (24%), Japan (14%), Germany (8%), the former Soviet Union (6%), China (5%), and France (4%) (WRI, 1994).

Aluminum refining from bauxite uses vast quantities of electricity and releases CO_2 whenever coal and other fossil fuels are used. An estimated 280 x 10^9 kWh (Young, 1992) was needed to produce 18 Mt of aluminum in 1990 (Plunkert and Sehnke, 1991). The efficiency of electricity use varies from a low of 13,000–15,500 kWh per ton of aluminum in much of Europe, Brazil, Japan, and the United States to a high of 18,000–20,000 kWh/t in Norway, Russia, and Canada. Aluminum from secondary scrap requires only 1,600 kWh/t (Chandler, 1985). In most market economies, hydropower—which is inexpensive and often subsidized—is used as the source of electricity, but in Australia (the leading producer of bauxite), China, India, and the former Soviet Union, coal is a principle source of electricity. Other countries, such as Brazil, Ghana, and Canada, have large hydro projects tied to aluminum production. The United States, which used 859 PJ of energy in aluminum production in 1989, draws 12.4% from hydropower, 3.5% from nuclear, 49.6% from coal, 26.5% from oil, and 8.1% from gas (Aluminum Association, 1991).

Significant improvements in energy efficiency have been realized by the aluminum industry worldwide. In the United States, efficiency gains in 1989 were estimated at 12.1% since 1972, with an additional 9.2% arising from increases in recycled scrap—for a 21.3% reduction in energy use per ton of aluminum (Aluminum Association, 1991).

CO_2 also is released as a process gas from the destructive oxidation of the carbon anode during electrolysis of bauxite ore. Carbon emissions from this source are estimated to be 0.45 kg of carbon per kg of aluminum [some of which can be as carbon monoxide (CO) (Sadoway, 1990)]—which would imply a total release of 8.2 Mt C, or 0.15% of global fossil-fuel carbon in 1991. This carbon apparently is included in existing emission totals as part of the petroleum coke from which the electrodes are made (Marland, 1994). The use of experimental non-carbon electrodes has been demonstrated (Hryn and Sadoway, 1993), and an alternative chloride-based (rather than oxide-based) process with nondissolving graphite electrodes is claimed to release no CO_2 and to be 30% more efficient (Altehnpohl, 1980).

The second class of important aluminum process GHGs are the perfluorocarbons, carbon tetrafluoride and hexafluoroethylene, which are released during electrolysis of bauxite. These gases have an exceptionally strong absorption in the infrared and an estimated lifetime in the atmosphere in excess of 10,000 years. The range of estimates for perfluorocarbons vary from 0.6 to 2.5 kg per ton of aluminum for CF_4 and from 0.06 to 0.25 for C_2F_6 (Abrahamson, 1992; U.S. DOE, 1994; Haupin, 1987). An estimated 28,000 t of CF_4 and 3,200 t of C_2F_6 were released in 1987 (Fabian *et al*., 1987); CF_4 has been estimated to have contributed 1.7% of the global-warming potential during the 1980s (Lashof and Ahuja, 1990).

Unfortunately, no reliable estimates of total CO_2 release associated with aluminum production exist, but in the United States, the industry accounts for 1.2% of national energy demand and a similar percentage of CO_2 emissions (Aluminum Association, 1991). If this figure prevails worldwide, then aluminum would be responsible for more than 3% of global-warming potential.

20.3.1.3. Copper and Other Nonferrous Metals

In 1992, 9.3 Mt of primary copper was mined worldwide, with nearly 40% coming from Chile and the United States. In addition, 3.4 Mt of lead, 7.1 Mt of zinc, 0.9 Mt of nickel, and lesser amounts of tin and cadmium were produced (WRI, 1994). CO_2 emissions from the U.S. primary and secondary copper industry were estimated at 19 Mt C in 1987, down from 30 Mt C in 1968 (Forrest and Szekely, 1991).

For copper and other nonferrous metals, the major greenhouse gas is CO_2 associated with the energy required for smelting from ore. These metals also are associated with other emissions, such as sulfur dioxide (SO_2). Recycling of metals can greatly reduce the energy required to produce them; substantially lower the CO_2 and SO_2 associated with mining and production; and reduce other air, land, and water pollution. For toxic metals like lead and cadmium, reduced exposure to toxicity is an additional benefit. Nondissipative uses of lead, such as storage batteries, are recycled to a large extent. Large amounts of copper also are recycled, but care must be taken to

ensure that impurities in recycled copper do not reduce electrical conductivity where this is important (e.g., in power-transmission lines).

20.3.2. Chemicals

The chemical industry is extremely energy-intensive because of the source of its raw materials—petroleum and natural gas—and because of the energy required to carry out chemical transformations to final products. In the United States, chemicals accounted for 60.3 Mt or 19.6% of industrial-energy CO_2 in 1985, right behind the primary-metals sector. This sector also accounted for most of the 39.4 Mt of nonfossil-fuel carbon released by the industrial sector (Marland and Pippin, 1990). Since the oil shocks of the 1970s, the chemical industry has redesigned processes, significantly reducing energy use and lowering the production of chemical wastes. For example, the Japanese petrochemical industry reports a decrease of 47% in energy per ton of product from 1976 to 1988 though little change during the succeeding 4 years (MITI, 1994). The U.S. chemical industry reduced its energy per unit of output by 21.8% between 1974 and 1992 (Chemical Manufacturers Association, 1994).

20.3.2.1. Halocarbons and Hydrohalocarbons

Halocarbons and hydrohalocarbons currently are the major greenhouse gases associated with industrial activity. These ubiquitous substances are thought to contribute substantially to direct radiative forcing, but this effect may have been largely offset by their depletion of stratospheric ozone (IPCC, 1992). Most CFCs, halons, and solvents (such as carbon tetrachloride and methyl chloroform) are being rapidly phased out to protect the ozone layer. Proposed substitutes like HCFCs and HFCs, while having less ozone-depleting potential because of their shorter atmospheric lifetimes, have considerable global-warming capability. The United States estimates that the HFCs and fluorocarbons (FCs) released in 1990 have a warming potential equivalent to 20 Mt C, but expects this to grow to 45 Mt C by 2000 (U.S. DOE, 1994).

20.3.2.2. Plastics

Plastics and most organic chemicals are derived from petroleum and natural gas. The latest estimate is very much in need of updating, but Marland and Rotty (1984) suggest that 6.7% of liquid fossil fuels are incorporated into plastics, asphalt, and lubricants that are not immediately oxidized to CO_2. Some plastic wastes and lubricants are eventually burned as fuels, but some of this carbon—perhaps one-third—is sequestered in landfills or products. Worldwide, about 1% of natural gas is used for non-ammonia feedstock (Marland and Rotty, 1984). Energy use for plastics production was about 3% of total energy in the United States in 1988 (Franklin Assoc., 1990). An advantage of using more plastics in transportation and in transported containers is their extremely light weight, although petrochemical production is very energy-intensive. Recycling polymers is advantageous from an energy perspective but is difficult because their low density, high bulk, additives, and the mixtures of plastics in the waste stream make them difficult to reprocess. Moreover, innovation in plastics is important and makes standardization difficult. Some standardization on a smaller number of resins or other policy options might help in this matter.

20.3.2.3. Hydrogen and Ammonia

Hydrogen and ammonia are extremely energy-intensive to produce, and they use CH_4 from natural gas as a feedstock. Hydrogen is stripped from CH_4, and the carbon is oxidized and released as CO and CO_2. Marland and Rotty (1984) estimate that about 2% of global natural gas is oxidized in this way. Ogden and Williams (1989) place the energy content of hydrogen production in the United States at about 2% of total energy, which would imply that 5% of natural gas currently is used for hydrogen and ammonia production plus CH_4 leaks.

In the United States, nearly 340 x 10⁹ m³ of hydrogen are used in ammonia production, 900 x 10⁹ by refineries, and 25 x 10⁹ for methanol production; approximately 5.7 x 10⁹ m³ are produced as merchant hydrogen and by captive users (SRI, 1994). In addition to its main production from CH_4, hydrogen also is produced as a byproduct during oil refining and the electrochemical production of chlorine, sodium hydroxide, and sodium chlorate. Currently, some of this byproduct hydrogen is flared. The current process CO_2 from hydrogen production could be eliminated by using the electrolysis of water as the hydrogen source. At the present time, off-peak hydropower represents the only low-cost electricity supply that is large enough to make a significant contribution toward replacing natural gas as the feedstock. Off-peak power from geothermal, wind, solar (Ogden and Williams, 1989), and ocean thermal energy conversion someday may also be inexpensive enough to produce hydrogen competitively from the electrolysis of water.

20.3.2.4. Other Chemicals

N_2O contributes about 6% to increased radiative forcing, has strong infrared absorption, and has a lifetime of 140 years in the atmosphere. A full understanding of its measured increase in the atmosphere is incomplete. Contributions from fossil-fuel stationary combustion have been shown to be much lower than previously believed (Lyon *et al.*, 1989).

It has been estimated that adipic acid production for nylon accounts for 10% of anthropogenic global N_2O releases (Thiemens and Trogler, 1991), with 3.03 x 10^{-4} kg N_2O released per ton of adipic acid produced (Jacques, 1992). One major manufacturer announced a revised production process that reduces emissions by 98% (*Chemical Week*, 1992). The U.S. production of N_2O associated with adipic acid production has been estimated at 242,000 t, but with the introduction of controls, only 62,000 t is released (U.S. EPA, 1993). Small additional amounts are released in the oxidation of ammonia to nitric acid at a rate of 2 to 20 kg N_2O per ton of ammonia consumed. Controls have been developed and installed in some facilities (*Chemical Week*, 1992). Canada estimates that its annual emissions from this source are only 1 kt and from adipic acid production 30 kt (Jacques, 1992).

A small amount of CO_2 is released in the manufacture and use of lime and soda ash. For the United States, this is estimated to have been 3.26 and 1.14 Mt C, respectively, in 1991 (EIA, 1993).

20.3.3. Pulp and Paper

Because wood and paper are produced from plants that absorb CO_2, they can provide long-term sequestration of carbon in durable products. The major fossil-fuel inputs for paper production are in the harvest and transport of raw materials and in producing the fiber from wood chips. Evaporation of water consumes a very large proportion of the energy in pulp and paper-making. In response to higher energy prices in the 1970s and to comply with clean-air and water requirements in several countries, the paper industry developed efficient cogeneration systems to produce needed steam, hot water, and electricity by burning liquors, bark, and other wood waste. The U.S. paper industry now satisfies 56% of its energy needs by using biofuels in this way (American Forest and Paper Association, 1993). Japan improved the energy efficiency of its pulp and paper industry by 26% between 1980 and 1992 (MITI, 1994). In developing countries, such as Mexico, bagasse from sugar cane provides fiber for papermaking (Gotelli, 1993); China, Japan, and other Asian countries produce paper from rice stalks. Pulp also is used to produce cellulosic textile fibers, such as rayon.

More than 50% of the wood cut in the United States is eventually used for paper and paperboard. Current U.S. paper recycling is 25% (Europe and Japan have achieved rates of more than 50%). A doubling of this rate would reduce the amount of wood cut from U.S. forests by about 17%. Landfills, whose contents are 40% wood and paper products, would benefit similarly in the form of a 13% reduction by weight overall. Thus, paper recycling offers the potential for reducing global warming by increasing forest stands and reducing the amount of atmospheric CH_4 and CO_2 produced from landfills (Zerbe, 1990).

20.3.4. Construction Materials

The production of high-density building materials (such as concrete, glass, brick, and tile) requires high temperatures and hence releases significant quantities of CO_2 during production. Because of their high density, these materials also require large quantities of energy in their transportation.

20.3.4.1. Cement and Concrete

Cement and concrete are key components of commercial and residential construction worldwide. During the past decade, U.S. cement consumption averaged between 75 Mt/yr and 90 Mt/yr (Portland Cement Association, 1990); it is expected to rise to more than 100 Mt/yr by 1997. Worldwide, 1991 cement production reached 1.25 x 10^9 tons (U.S. Bureau of Mines, 1992). Requiring 6.1 GJ per ton of cement (see Table 20-4), cement production is one of the most energy-intensive of all industrial processes.

CO_2 is emitted during cement production in two ways. Approximately 0.75 t of CO_2 is produced per ton of cement from combustion of fossil fuels to operate the rotary kiln. The second source is calcination, in which calcium carbonate ($CaCO_3$) from limestone, chalk, or other calcium-rich materials is heated in kilns to form lime (CaO) by driving off CO_2. This process produces about 0.5 t of CO_2 per ton of cement. Thus, combining these two sources, for every ton of cement produced, 1.25 t of CO_2 is released into the atmosphere—of which 60% comes from energy inputs and 40% from calcination (Griffin, 1987). Worldwide, cement production accounted for approximately 162 Mt of C emissions in 1991, or about 2.6% of total global carbon from oxidation of fossil fuels. The United States annually produces about 9.3 Mt C from cement production, or 6% of global cement-production carbon (CDIAC, 1993).

The carbon intensity of cement is highly dependent on the fuel chosen. Cement production to date has used coal as its primary fuel. As a result, cement production is associated with especially high levels of CO_2, nitrogen oxides (NO_x), and SO_2.

Table 20-4: *Fuel use for cement production (1990).*

Fuel	GJ per Ton of Cement	Percent
Petroleum Products (diesel, gasoline, LPG)	0.06	1.1
Natural Gas	0.5	8.2
Coal and Coke	3.7	60.8
Waste Fuel[1]	0.3	4.9
Electricity[2]	1.5	24.9
Total	**6.1**	**100.0**

Source: Portland Cement Association, 1990.

[1] Waste fuel includes used motor oil, waste solvents, scrap tires, etc.

[2] Electricity figure includes primary energy used to generate electricity.

Producing 80 Mt of cement in the United States in 1992 required about 0.53 EJ, or roughly 0.6% of total U.S. energy use. In terms of its dollar value, however, cement represents only about 0.06% of the U.S. gross national product. Thus, cement production is about 10 times as energy-intensive as the U.S. economy in general. In a number of developing countries, cement production accounts for as much as two-thirds of total energy use.

Process modifications in kiln operation show potential for energy reductions. For example, newer dry-process kilns are more energy-efficient than older wet-process kilns because energy is not required to eliminate moisture. In a modern dry-process kiln, the kiln's exhaust gases are used to preheat the ingredients and drive off moisture. Such a process uses up to 50% less energy than a wet-process kiln (UBC, 1993). Significant reductions in CO_2 emissions from cement production could still be gained by energy-efficiency improvements of cement-kiln operation. Switching to fuels with lower CO_2 content (such as natural gas and agricultural wastes) also can reduce CO_2 emissions; in addition, savings from other techniques (e.g., fly-ash substitution and the use of waste fuels) are possible. Using waste lime from other industries could reduce CO_2 emissions from the calcination process.

20.3.4.2. Brick

Total brick production in the United States has varied recently between about 5×10^9 and 8.5×10^9 bricks per year. In 1992, production was about 6.25×10^9 units. Brick manufacturing constitutes about 96% of total clay-product manufacturing in the United States. Energy estimates for brick production vary widely. In the United States, the most-efficient brick producers, using modern computer-controlled equipment, require between 4.2 and 5.3 MJ/brick. On the other end of the scale, older beehive kilns can consume around 21.1 MJ/brick. Process modifications in brick production could yield large savings in energy use and CO_2 emissions. Technical improvements in burners, air blowers, and "slashing" processes (heating the kiln to excessive temperatures to color bricks for cosmetic reasons) could yield substantial reductions in energy consumption (Brick Institute of America, 1994).

20.3.4.3. Glass

In 1991, the United States produced 20.8 Mt of glass, at 7.4 to 8.4 GJ/t. Of this, 2.2 Mt of flat glass, at 7.4 to 8.4 GJ/t, was manufactured for use in the automotive/transportation and construction industries; 2.0 Mt of fiber glass, at 6.3 to 10.6 GJ/t, was produced for building insulation and a variety of building and product materials. The industry uses mostly natural gas as its energy source, along with some electric furnaces (Ross, 1991).

20.3.4.4. Wood

Wood is a far less energy-intensive building material than steel, concrete, brick, or glass; it provides superior insulating properties; and because of its relatively low density, it has lower transportation-energy requirements. Koch (1992) uses the CORRIM Report (NRC, 1976) to estimate the following embedded energy in residential building materials compared to wood:

- Steel structural building studs (9 x wood)
- Synthetic fiber floor covering (4 x wood)
- Concrete floor (21 x wood)
- Aluminum siding (5 x wood)
- Brick veneer (29 x wood).

An update clearly is needed, to take into account efficiency improvements in each industry.

20.3.5. Food Products and Light Manufacturing

The energy contributions to the food and beverage sector are modest in developing countries but are substantial in industrial nations. Pimintel (1973) has estimated that each U.S. food calorie requires approximately 10 technological calories to grow, transport, refrigerate, and prepare it, partly because the average food travels 2,092 km from the field to the consumer. Significant amounts of energy are expended in refrigeration and food processing, and a large amount of energy is embodied in packaging. For example, in 1991, the United States produced 13.5 Mt of container glass at 7.4 to 8.4 GJ/t, for a total of 114 PJ (Ross, 1994).

In light industry, major GHG reductions are likely to come from improved efficiency in space conditioning and lighting and the replacement of motors and belts with more-efficient ones. In the textile industry, the embodied energy of different fibers suggests that cellulosic fibers may have the lowest values, followed by synthetic petrochemical fibers and conventionally grown natural fibers, which rely heavily on fertilizers and industrial-style agriculture.

20.4. Technical Abatement Options

20.4.1. Fuel Substitution

Fuels with low or zero CO_2-generation potential can be substituted for fuels with high CO_2-generation potential to reduce GHG releases. In general, coal and oil are replaced by natural gas, renewables, and nuclear. For the industrial sector, substitution of coal with natural gas is most relevant. A major study at the International Institute for Applied Systems Analysis (IIASA) on historical trends of energy and fossil-fuel carbon emissions shows that most economies have reduced their energy intensity as industrialization has proceeded and that the carbon content of global energy use has been falling monotonically. The carbon intensity of energy consumed currently is about 0.5 t C/kWyr—down substantially from a value of 0.8 t C/kWyr in 1860 (Nakicenovic *et al.*, 1993).

20.4.1.1. Low-Carbon Fuels

The direct use of low-carbon fuels, such as natural gas, rather than coal in industry can substantially lower carbon dioxide levels. However, the lower price of coal and its much greater abundance have made it the fuel of choice in the absence of incentives or regulations to lower GHGs.

20.4.1.2. Electrification

World economies are becoming more electrified. In the United States, for example, electricity increased from 15.9% of purchased energy in 1974 for six major industrial groups (petroleum and coal products, building materials, paper, chemicals, primary metals, and transportation equipment) to 22.5% in 1988 (GCC, 1993). The implications of this shift for GHG emissions are unclear. Proponents of increased electrification point out that this process often leads to efficiency gains that offset additional CO_2 releases. Additional reductions in GHG emissions are likely to be realized when the direct combustion of fossil fuels is replaced by electrical generating capacity from nuclear, hydro, biomass, or renewable sources. Additional gains can arise when low-temperature industrial process or space heat is supplied by heat pumps rather than by the direct combustion of fossil fuels. Although total energy use in the OECD industrial sector has remained essentially constant during the past 20 years, CO_2 from the industrial sector actually declined by 9.6% between 1970 and 1990 (di Primio, 1993).

On the other hand, electric utilities constitute the largest source of CO_2 in many economies. Di Primio (1993) has identified transformation and distribution losses for electric power production as a principal contribution to CO_2 emissions in both industrial and developing countries, and this percentage has increased with time. The percentage of CO_2 arising from power plants was 22.6% for OECD countries in 1970 but had increased to 29.8% in 1990. For the United States, the increase was even greater: from 23.4% in 1970 to 32.7% in 1990. In the late 1980s, 36.4% of CO_2 came from power plants in India, 19.8% in China, and 32.5% in the former Soviet Union.

In short, the effect of increased electrification on industrial CO_2 releases depends on the particular purpose for which electricity is substituted, the carbon intensity of the source of electric power relative to the direct combustion of fossil fuels, and the structure of a given industrial economy.

20.4.1.3. Biomass

The use of plant material as fuel and feedstock in place of fossil fuels can have a significant effect on the reduction of net CO_2 emissions. Although cellulose releases approximately the same amount of carbon as coal per unit of energy produced, this release of CO_2 is largely offset by the absorption of CO_2 from the atmosphere as biofuel is regrown. Immense potential exists for energy recovery from organic municipal and industrial wastewaters through efficient biomethanation processes (Khanna *et al.*, 1988). Alcohol biomass fuels have played a major role in Brazil (Goldemberg *et al.*, 1993), and plantations could provide significant biofuels in many countries (Hall *et al.*, 1994). A full discussion of liquid fuels and biofuel plantations is included in Chapter 19.

Ironically, although biofuels constitute a major energy source in many developing countries, it is the United States that is the leader in generating electricity from biomass. According to the Electric Power Research Institute (Turnbull, 1993), biomass electric power generation increased from 200 MW in 1979 to 6,000 MW in 1992, plus 1,800 MW of municipal-solid-waste-to-energy facilities. All of the existing generation facilities use conventional steam technology, often at lower temperatures and lower efficiencies than fossil-fuel facilities. Much of this power production from biomass is associated with industries like wood, paper, and food processing that use their own waste. The growth of biomass-fueled facilities in the United States has not been matched in other industrialized countries. This is primarily because of the presence of a regulatory regime in the United States that encourages industrial power production.

Several examples of biomass electric-generating facilities also exist in developing countries. Bagasse is sometimes burned in India, Mexico, and Brazil at sugar refineries for heat and some electricity. A 5-kW diesel generator, modified to burn biomass produced from cow dung and agricultural wastes, produces electricity in Pura, India (Rajabapaiah *et al.*, 1993). The potential for greatly improving the efficiency of biomass power systems lies in the introduction of highly efficient gas turbines coupled to biomass gasifiers, according to Williams and Larson (1993). Their analysis suggests that the 80 cane-growing countries of the developing world have sufficient bagasse and other sugar-cane residues to support such facilities.

20.4.1.4. Renewable Energy Resources

In sunny regions, including many tropical countries, solar drying opportunities exist for grains, specialty fruits and vegetables, sugar cane, and lumber. Solar drying also can be applied to biofuels, whose moisture reduces their effective energy content. For example, approximately half the weight of bagasse from sugar cane is water; when moist, it releases only 9,042 kJ/kg, but when dry, it releases 19,424 kJ/kg (comparable to lignite) (Brown, 1987). In addition, by removing the weight of incorporated water, solar drying can reduce the energy requirements to transport biofuels, lumber, grain, and other products. Existing solar water-heating technology is well-matched to the process-heat levels required by such industries as food processing and textiles and for the curing of plastics, resins, and adhesives.

Few examples can be found of on-site use of solar or wind energy for industrial processes. These intermittent resources would need to be supplemented by grid or conventionally self-generated electricity, used in accord with the availability of

wind or solar power, or disengaged from the demand for power through storage devices (Moomaw, 1991). This suggests that electroplating and other electrolytic chemical manufacturing (e.g., the production of chlorine and sodium hydroxide) might also be suitable for self-generated solar or wind energy. Another possible use of wind or solar energy in manufacturing would be for pumping industrial water that could be stored for use on demand (Lonrigg, 1984).

20.4.1.5. *Hydrogen*

Although hydrogen releases no CO_2 when burned or reacted chemically, it is mostly derived from CH_4, which produces CO and CO_2. Several alternatives are possible for producing hydrogen without carbon emissions. It is estimated that it would cost between \$9 and \$19/GJ to produce hydrogen by off-peak hydroelectric-based electrolysis costing between 1 and 4¢/kWh. Biomass gasification could lower the cost to between \$5.9 and \$8.5 per GJ (Ogden and Nitsch, 1993). Were the cost to drop sufficiently, considerable reductions in GHGs would occur in the primary-metals industry because of the use of hydrogen to reduce oxide ores.

It has been suggested that photovoltaics are ideally suited as low-voltage DC sources of electricity for the electrolysis of water to produce merchant hydrogen where it is needed (Ogden and Williams, 1989; Ogden and Nitsch, 1993). The auto manufacturer BMW has built a 600-kW photovoltaic test facility with Siemens and the Bavarian government to produce hydrogen automotive fuel.

20.4.2. **Energy Efficiency**

Energy efficiency in industrial plants can be improved through opportunities on the end-use side (such as variable-speed electrical drives and insulation) and opportunities on the conversion side (such as cogeneration applications and advanced boilers).

20.4.2.1. *Efficient Electrical End-Use Devices*

Electrical motors are major consumers of industrial electricity. Several studies in the United States conclude that approximately two-thirds of electricity is consumed by electrical motors, with the industrial sector accounting for between 26 and 30% of the total. These motors are used primarily to drive pumps, compressors, and fans. Major opportunities exist to improve the efficiency of the motors themselves and the systems, connecting shafts, and belts they drive (U.S. DOE, 1980; Baldwin, 1989).

Standard motors operate with an efficiency of 70% for small devices of a few kilowatts, to 92% for large motors of 100 or more kw. High-efficiency motors operate in the range of 83 to more than 95% (Baldwin, 1989). One analysis of an industrial pumping system showed that only 49% of the energy output of

the electric motor actually was converted into work to move the liquid (Baldwin, 1989; U.S. DOE, 1980). Optimizing system design rather than simply choosing components can lead to improvements of 60% using existing technology (Baldwin, 1989). A study of Indian industrial efficiency found that replacing traditional power-transmission V belts with modern flat belts could improve efficiency from 85 to 98% (NEERI, 1993). This study, along with Baldwin's, also demonstrates the potential for adjustable-speed electronic drives to better match mechanical load, substantially reducing electricity use.

The U.S. Environmental Protection Agency (EPA) has estimated that 12% of U.S. utility CO_2 emissions—55 Mt C—could be eliminated by replacing existing lighting systems with cost-effective lighting technology (U.S. EPA, 1993). Industry represents one of the largest users of lighting. The voluntary Green Lights program had enrolled more than 1,255 corporations, institutions, and state and local governments by early 1994, all of whom are committed to replacing 90% of their lighting with cost-effective, efficient substitutes within 5 years (U.S. EPA, 1994). Computers are estimated to consume approximately 5% of U.S. electricity; EPA has developed the Energy Star program, which has produced significant declines in the electricity use of new computers and other office equipment now entering the market. The average power demand of different types of computer printers was found to range from as little as 3 to as much as 129 W in one study (Norford *et al.*, 1989). Although these ancillary devices represent a small fraction of total industrial energy use, there is substantial room for significant savings. The surprising success of voluntary programs in the United States suggests that this approach should be more widely utilized in other countries.

20.4.2.2. *Cogeneration and Steam Recovery*

In cogeneration facilities, fuels are burned and the heat produced is used both for generating electricity and for process heat. Cogeneration schemes are of two kinds: topping-cycle and bottoming-cycle. In topping-cycle cogeneration, primary energy (the high-temperature energy, generally about 1,500°C) is used to produce electricity, and the low-temperature heat that emerges from the generator is used for process or space heating (e.g., to dry pulp in a paper mill). In bottoming-cycle cogeneration, primary energy is used to produce heat (e.g., to anneal steel), and the leftover heat is used to generate electricity.

Cogeneration facilities generally use as much as 80% of the heat content of fuels, significantly reducing the amount of CO_2 produced compared to facilities where electricity and heat are produced separately. A variety of technologies now are employed that continue to improve the overall efficiency of cogeneration. Conventional steam turbines that recover a portion of waste heat are being displaced by higher-efficiency and less-costly gas-turbine cogeneration systems and combined-cycle systems that use some of the heat from the gas turbine to run a lower-temperature steam turbine as well as to provide process steam (Williams and Larson, 1989). In the United

States and many European countries, many small-scale cogeneration facilities have been developed in the industrial sector as the result of new technological developments and changes in the laws governing electrical utilities. Industries are now permitted to sell surplus electricity to the utility grid, and utilities are required to purchase it at favorable prices. Since the change in legislation, a majority of the new electric-generating capacity constructed in the United States has been from manufacturing, pulp and paper, and other industrial or independent cogenerators rather than large utilities. The U.S. Office of Technology Assessment has estimated that industrial cogeneration could reduce industrial energy demand by 140 TW/yr in the United States by 2015 (OTA, 1991).

Substantial cogeneration is carried out in Western Europe, especially in Finland, Denmark, the Netherlands, Sweden, and Germany. Because of regulatory constraints and climatic conditions (large air-conditioning demand), Japan was slow to adopt cogeneration relative to other industrial nations. The Japanese electric utility industry law was revised in 1995 and may now facilitate the spread of cogeneration in that country. Because of the large amount of heavy industry and extensive district-heating systems already installed in the former Soviet Union, an enormous potential for major reductions in CO_2 also exists there through the adoption of industrial cogeneration.

20.4.2.3. Waste-Heat Utilization

Even in countries where high levels of industrial energy conservation have already been achieved, a large potential still exists for further industrial heat recovery. Data from a survey conducted in 556 representative factories in Japan indicate that almost half of the surplus heat that currently is discarded has potential for use. From a total of 1.8 EJ surplus energy generated by these factories, about 0.5 EJ already has been used effectively as steam, process gases, or electricity—a 2.7% decrease in primary energy consumption. Unexploited-energy figures for the four main energy-consuming industries in Japan are shown in Table 20-5. The unexploited surplus energy from these industries amounts to almost 1 EJ, of which about 48% has a potential for economic use (Kashiwagi, 1991).

The first step in planning energy utilization is to carefully map the flow of energy in each industry, from primary energy or electricity input to the lowest-temperature waste-heat output. Once these flows are known—including the quantity (e.g., kilowatts) and quality (e.g., temperature levels, voltage, and frequency)—industrial processes can be integrated, initially within each industry, to minimize the input of primary energy and/or electricity.

Cascaded energy use involves fully harnessing the heat produced by fossil-fuel combustion, from its initial 1,800°C down to near-ambient temperatures, with a thermal "down flow" of heat analogous to the downward flow of water in a cascade. If a water flow were to be used to generate electricity, for example, a dam would first be built on a mountain; then a succession of power-generation plants would be set at strategic points down the river to use up heads of water. Once the river water had flowed to sea level, it would have become useless for electricity generation. The heads of water at each generation plant are analogous to temperature gradients in thermal energy; sea level corresponds to ambient temperature. As in the case of river water reaching sea level, heat that has cooled to ambient temperature no longer is usable. Currently, even in the industrial sector, there are extremely few cases of heat being used in multiple stages (cascaded) akin to hydroelectric power generation.

Based on the ideal energy flow among industrial processes classified by their temperature levels, Kashiwagi (1992) suggests a representative example of ideal exergetic utilization of fossil fuel resources in a temperature cascade that utilizes combined heat and power and renewable energy, as shown in Figure 20-2.

In an effort to construct district-heating systems using unexploited energy sources, several countries have been promoting

Table 20-5: *Unexploited energy of the largest energy-consuming industries in Japan (joules).*

			Paper Pulp[2]	Chemical Industry[3]	Cement	Iron and Steel[4]	Total
Energy Flow	**Energy Input**		4.2 x 10^17	1.5 x 10^18	2.6 x 10^17	1.8 x 10^18	4.0 x 10^18
	Unexploited Energy[1]	Usable	1.1 x 10^16	–	2.6 x 10^15	4.9 x 10^17	0.5 x 10^18
		Unusable	1.2 x 10^17	1.9 x 10^16	5.1x 10^16	3.3 x 10^17	0.5 x 10^18
		Total	1.4 x 10^17	1.9 x 10^16	5.4 x 10^16	8.2 x 10^17	1.0 x 10^18

[1] Amounts of unexploited energy are estimates based on models for the four industrial sectors, thus may differ in precision depending on the model adopted.

[2] Estimates for the paper and pulp industries presuppose increases in effective use of black liquor.

[3] For the chemical industry, even if supply and economic conditions are fulfilled, there are almost no prospects; unexploited energy for the chemical industry refers to the ethylene sector only.

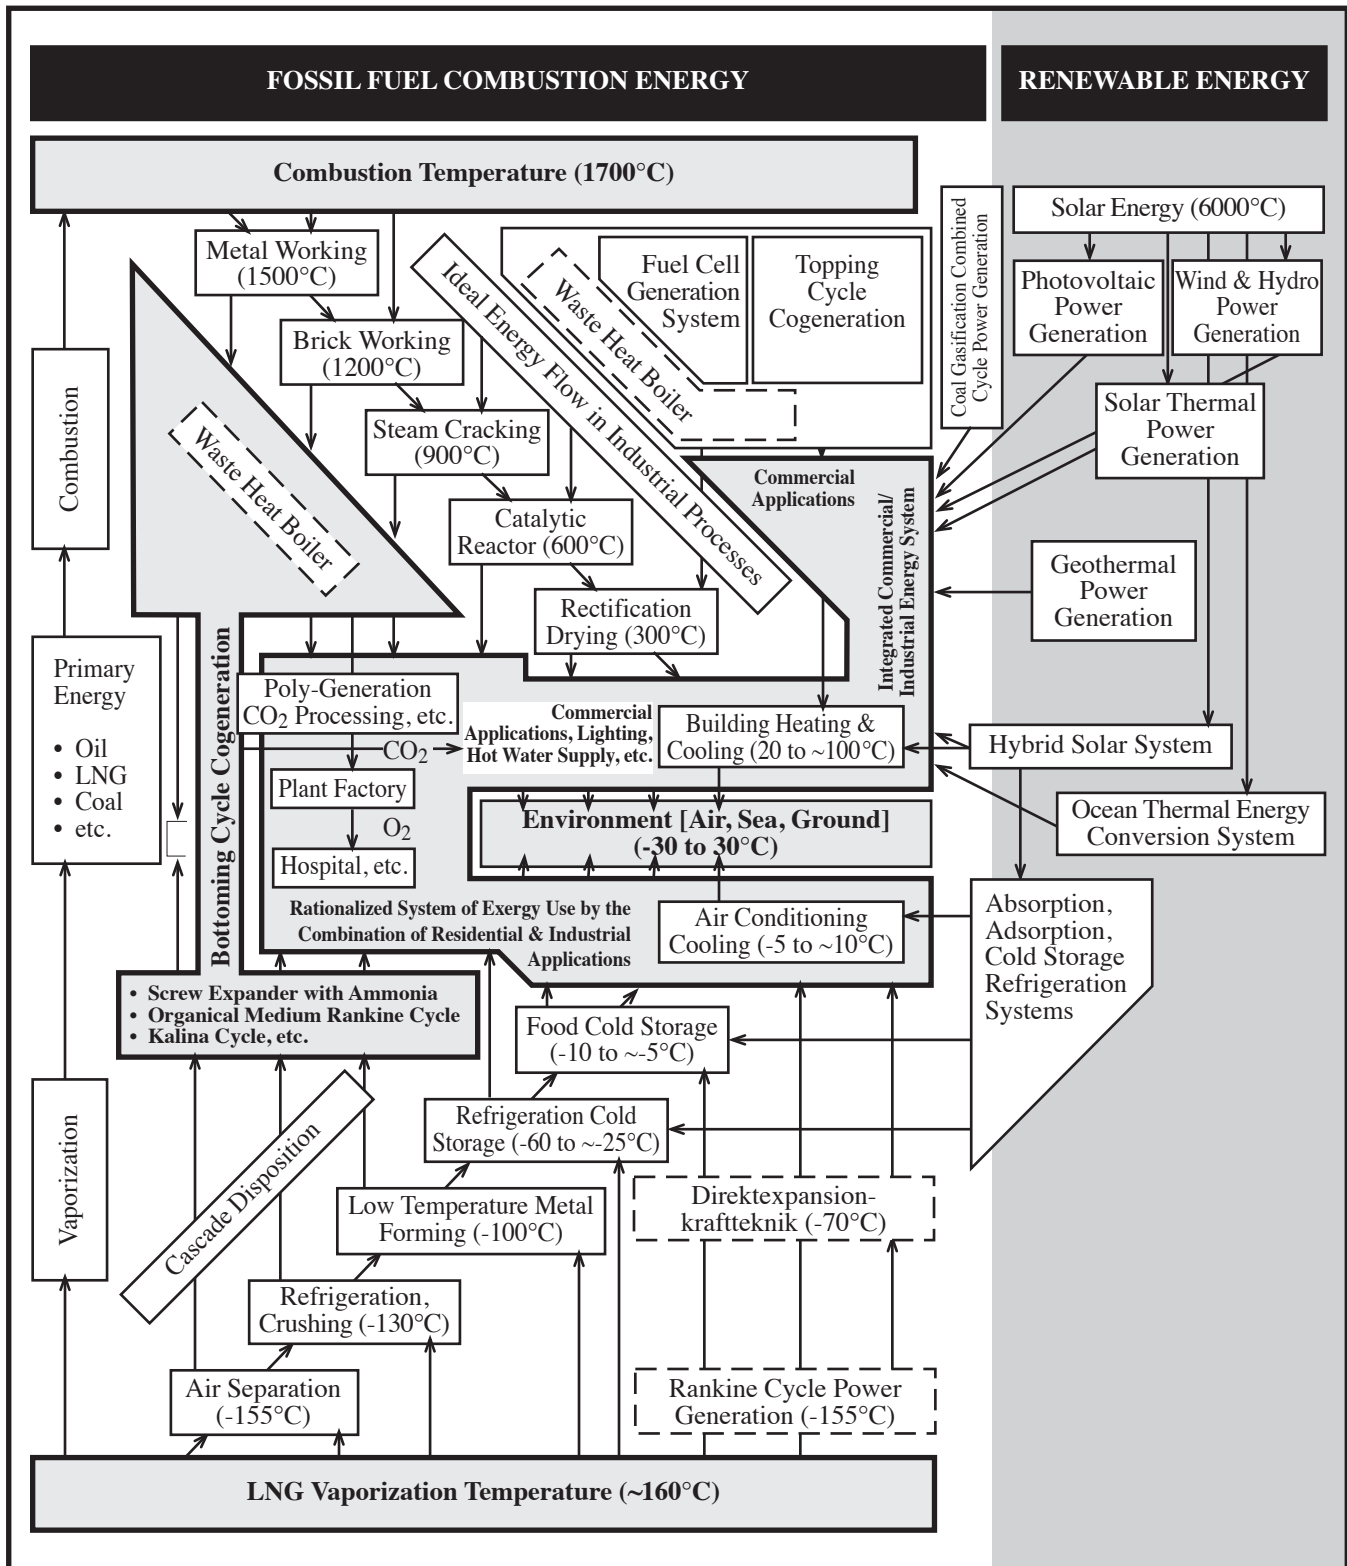
[4] Values of energy input and unexploited energy for iron and steel industries based on examples of combined steel and iron manufacturing.


Figure 20-2: Cascaded energy utilization concept in an integrated industrial/urban system.

research and development (R&D) on large-scale, high-effi-ciency machines; heat-transport technologies; large-scale heat storage; and optimized systems combining these technologies. Expansion of district-heating systems brought on by dramatic increases in the efficiency of unexploited-energy utilization systems is expected to reduce and optimize energy consumption—and, hence, to help shave off the peak of electric power demand.

Thyssen Stahl AG produces 10 Mt of steel each year in Duisburg, Germany, where demand for space heating is high and district-heating systems are well developed. Heat is recovered from its high-temperature furnaces as steam at 480°C and 1.4 MPa for driving electric-power-generating turbines and also as hot water (150°C) for supply to 15,000 of 45,000 nearby households served by the local district-heating system. Because the point-of-use temperature of the hot water must be kept between 90 and 95°C, the operating company of the district-heating system has installed natural-gas boilers to make up for fluctuations in heat demand and/or temporary stoppage of the high-temperature furnaces.

The conception of the Onahama hot-water supply system in Japan dates to the 1960s. A coke factory owned by the Nihon Kasei conglomerate in Onahama, Fukushima Prefecture, had been using seawater to cool high-temperature process gases in its facilities. A feasibility study conducted by Nihon Kasei in 1965 showed that this industrial surplus heat could potentially be used in the nearby Onahama area. Encouraged by these results, the city mayor formed a preparatory committee for the establishment of a hot-water supply company in Onahama, which was run by local associations of commerce, tourism, fishing, and inns. The heat-supply system included a pipeline of more than 10 km, pumps, heat-storage tanks, high-speed filters, and chlorination facilities. Freshwater now is supplied to the factory as a process-gas coolant, with a hot-water output of 10^5 m³/h at 63°C. After filtering and chlorination, the hot water is pressurized by pumping so that the return pressure always exceeds 10^6 kg/m². The point-of-use temperature of this hot water always is maintained at or above 50°C. Monthly water-quality tests carried out by Fukushima Prefecture sanitary

	Half-Million People City	Four-Million Ton Scale Iron Works
Power Consumption	2.0×10^8 W	2.5×10^8 W
Drainage	1.5×10^5 t/day	1.5×10^5 t/day
Gas Use (at 41.9 MJ/N m³)	2.4×10^5 Nm³/day	2.7×10^6 N m³/day
Heat and Hot Water Supply	7.95×10^{12} J/day	32.2×10^{12} J/day
Figure 20-3: Urban-level energy system with industrial waste-heat utilization.

authorities have consistently shown this hot water to be on par with potable water, which makes it suitable not only for bathing and washing clothes but also for dishwashing.

Large-scale energy conservation will require the establishment of urban-level energy systems supported by industries. Figure 20-3 provides a schematic of this concept, in which a city of 500,000 people would use waste heat from a 4 Mt/yr iron works. An air-conditioning plant and energy center would provide heating and cooling to the city using heat received from the iron works and from a garbage-incineration plant.

The figure indicates that the urban demand for energy could be met by using waste heat from the factory. Factories with high energy consumption can use that energy more effectively by conserving energy and using waste heat.

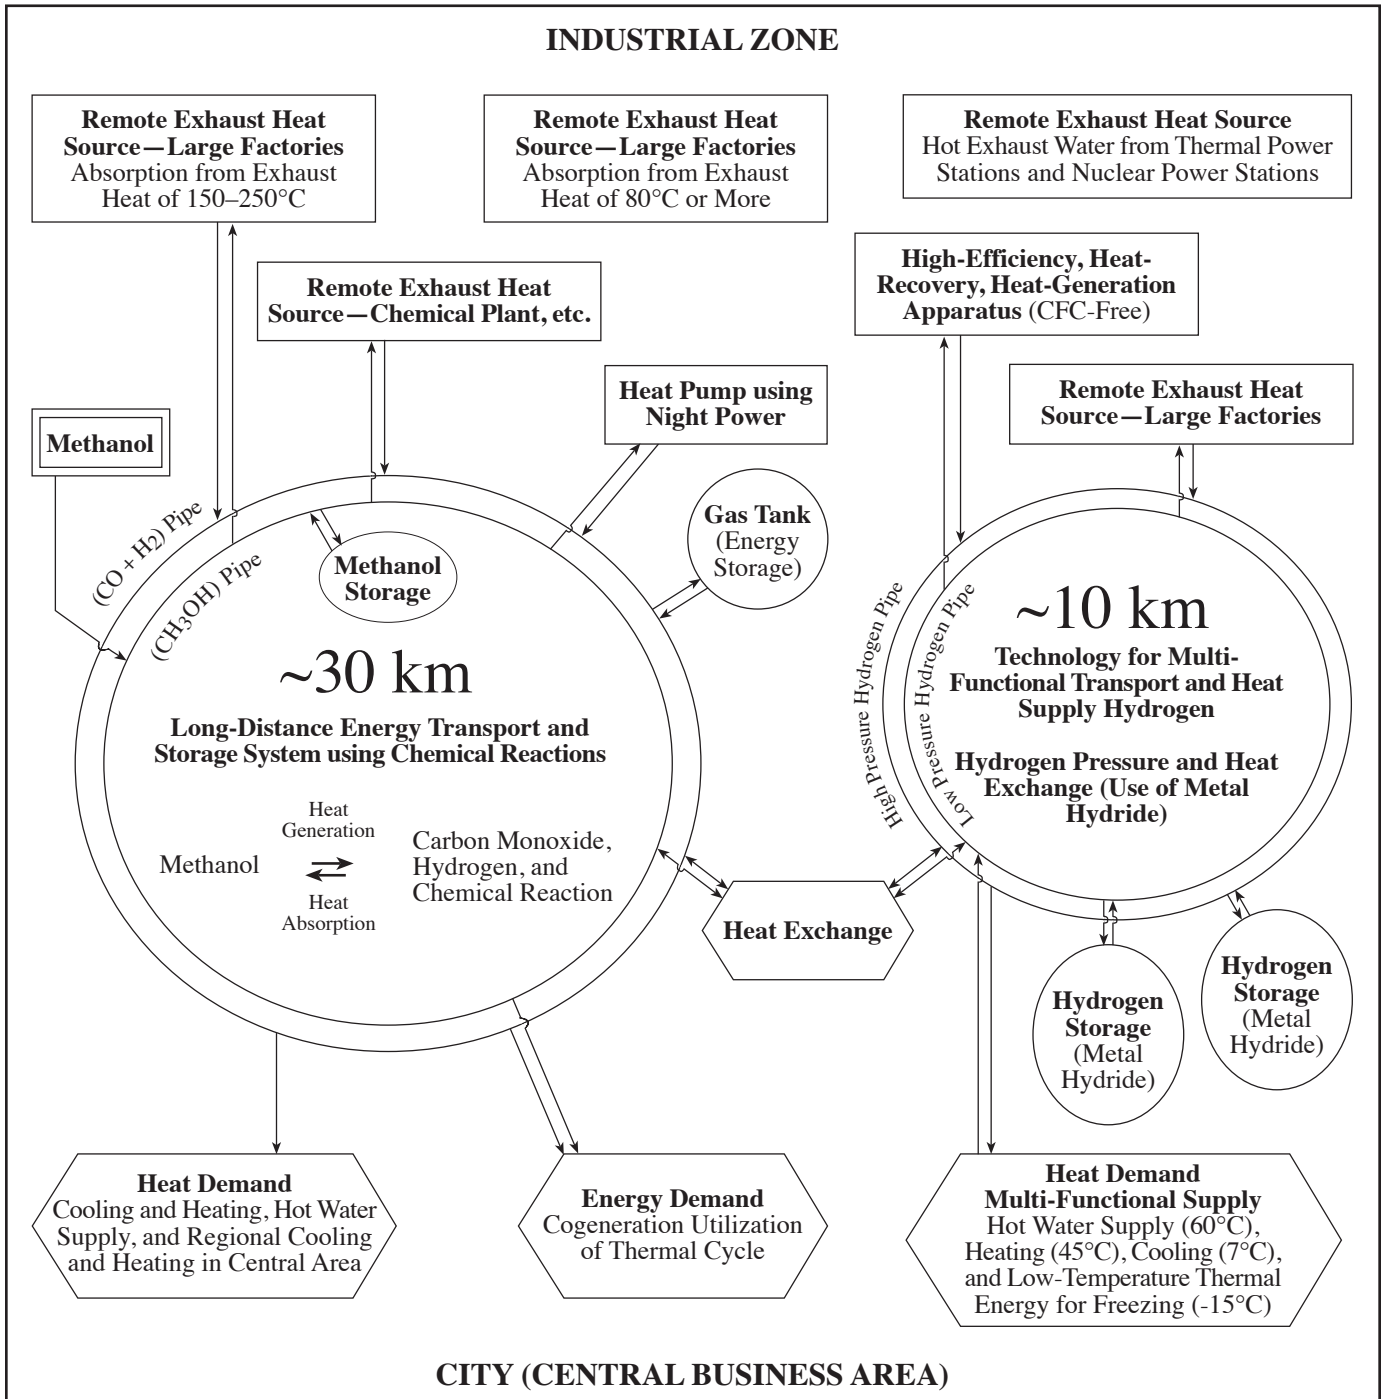
The future technology of broad-area energy utilization systems would involve an advanced cascaded and combined thermal energy-recirculation system based on innovative technology that recovers waste heat from facilities and transports the recovered energy efficiently to remote urban areas. This concept is illustrated in Figure 20-4.


Figure 20-4: Schematic of the area-wide energy utilization network.

To implement this concept, major breakthroughs would be required in two main areas. First, key technologies would have to be developed: heat recovery with a maximum utilization of sensible heat and with a temperature-lifting capability; heat transport and storage technology that employed chemical reactions; and multifunctional heat supply technology. Second, the total system would have to be structured and optimized by matching multiple and wide-area heat sources to the energy demand, which would be supported by industrial energy centers as seen in Figure 20-5.

One estimate for Japan indicates that if unexploited energy in coastal industrial regions near major urban areas were used to the maximum extent, national energy consumption would be reduced by 6% and CO_2 emissions would be reduced by 9% (Kashiwagi, 1992). A system that utilizes high-temperature heat from electric power-producing gas turbines to boost the lower-temperature heat from municipal waste incineration to run steam turbines and provide district heat has been described (Lindemann, 1992; NEDO, 1993). Industrial centers based on sound land-use planning and industrial ecology principles—where waste materials and heat from one production process are utilized by nearby industries—have been attempted only in a few places, such as Kalundborg, Denmark (Frosch, 1995).

20.4.2.4. Materials Recycling and Reuse

When goods are made of materials whose manufacture consumes considerable amounts of energy, the recycling and reuse of those goods can save not only energy but GHGs released to the atmosphere. However, recycling usually involves complex tradeoffs. For example, a car with an aluminum frame is lighter than a car with a steel frame—and thus consumes less energy for the same transportation service—but its own energy content is higher because the energy content of aluminum is higher than that of steel. Using returnable glass bottles instead of plastic bottles for mineral water (i.e., artifacts with a much longer lifetime—the average returnable glass bottle being used 18 times, for example, in Europe) reduces the amount of energy embodied in the materials needed for the same service but increases the energy embodied in collecting, transporting, and washing the bottles. Moreover, lengthening the lifetimes of durable goods may hinder the diffusion of new generations of goods or techniques that emit less CO_2. Assessing the emissions benefits of such actions, therefore, requires careful life-cycle analysis.

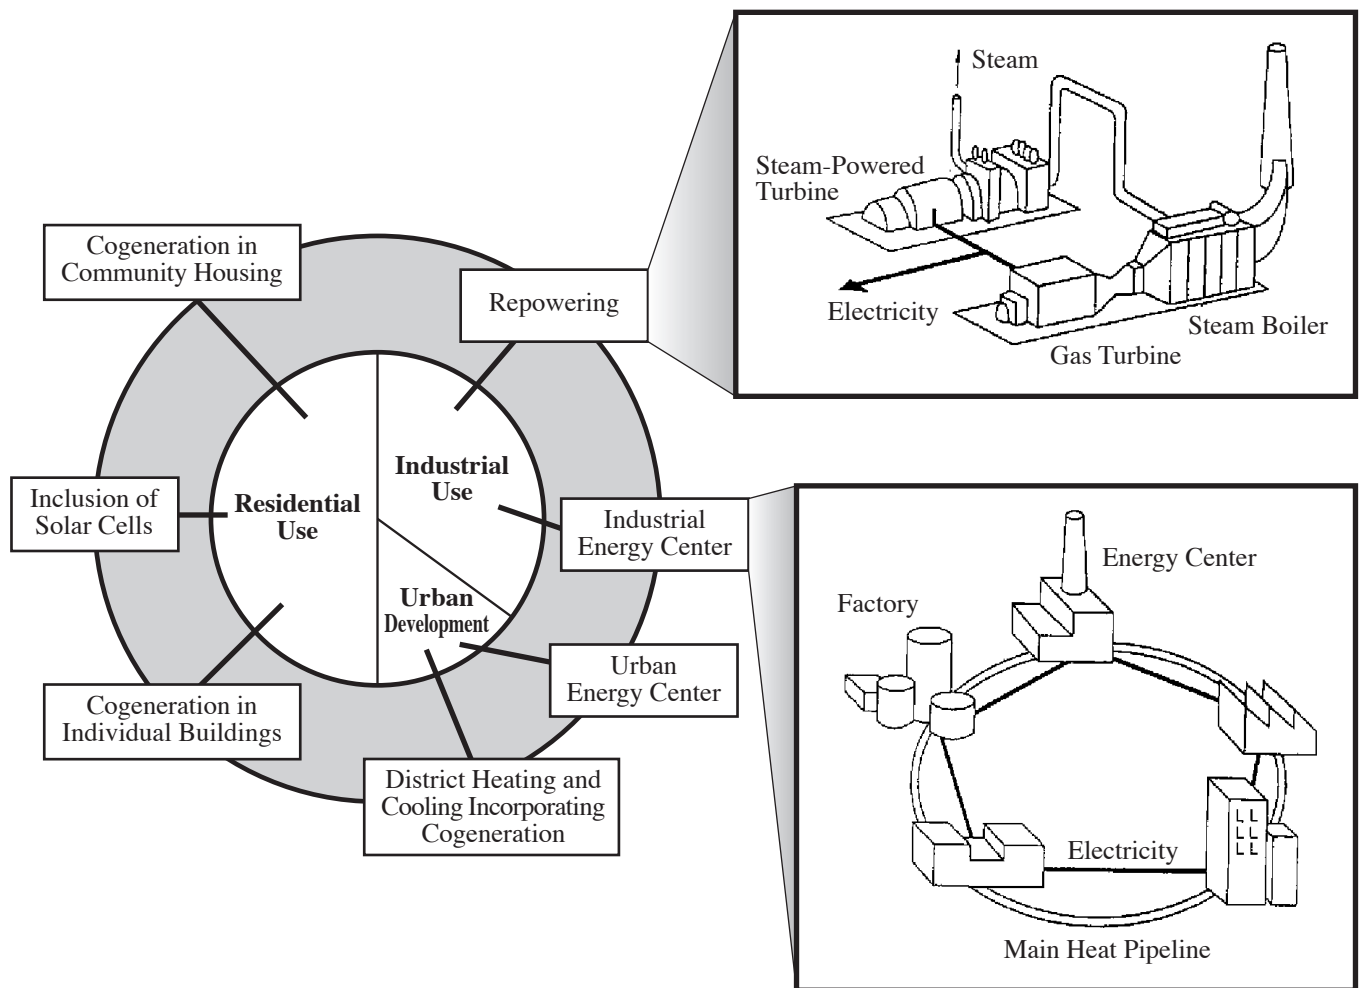
Recycling of energy-intensive materials undoubtedly has increased during the past 10 years, mostly in industrialized


Figure 20-5: The structure of industrial energy centers.

countries. Data on present recycling rates, however, are diverse. The rate of rough steel produced from scrap is about 43% worldwide (IISI, 1993). In OECD countries, the recycling rates of nonferrous metals are 30% for aluminum, 35% for copper, 48% for lead, 25% for zinc, and 20% for tin (Metalgesellshaft, 1988). The recycling rate for paper is estimated to be 30% at the world level, which also is the rate estimated for the present recycling of glass bottles in OECD countries (IIASA, 1993). Reliable rates for plastics are difficult to arrive at, though they seem to be increasing. Recycling data for developing countries are scarce. In some developing countries, such as India, recycling is significant—a great proportion being carried out by the "informal sector" (Konishi, 1995).

Differences in recycling rates among countries yield a first approach to the existing potential. In Japan, for example, rates for paper and glass bottles were expected to reach 55% by 1994 and rates for steel and aluminum cans to reach 60% in 1995. In Europe, voluntary agreements between administrations and business organizations have been signed to reach recycle rates of 60 to 70% for packaging materials and about 75% of the material content of automobiles before the end of the century. All of these figures are well above world averages. Public measures to improve recycling of materials also must strike the right balance among collection, sorting, and reusing activities. This balance is rather unstable at present and has led in extreme cases to a collapse of secondary-materials markets, thus frustrating further developments.

One must recognize that returning the secondary resource into virgin-grade material is not always necessary or desirable. By analogy to heat recovery of lower-temperature heat through cascading processes, materials recovery can be envisioned as a materials-cascading process in which secondary materials may be used most efficiently for different purposes than are virgin materials. To optimize recycling and reuse potential, materials and products must be designed for recovery as well as for their initial intended purpose.

A summary of carbon emissions from primary and secondary materials production for OECD countries is presented in Table 20-6. Primary materials release about four times the CO_2 of secondary materials for all substances except aluminum (where the figures are substantially higher). Carbon savings of 29 Mt

for a 10% increase in OECD recycling of each of the materials also is listed.

20.4.4.5. Dematerialization and Materials Substitution

A number of possibilities for reducing industrial greenhouse gases arise from the management of materials rather than of energy. Dematerialization (decreasing the amount of a material or substituting lighter-weight material for it) can play a major role in lowering GHG emissions (Grubler *et al*., 1993; Herman *et al*., 1989). Energy-related CO_2 also can be reduced in manufacturing by substituting less energy-intensive materials for more energy-intensive materials. Materials that release significant quantities of process GHGs during production can be replaced with materials that release fewer process GHGs (e.g., replacing aluminum with plastic lowers carbon and fluorocarbon emissions). Developing fundamentally new processes that use intrinsically less energy or are dependent on completely different feedstocks such as dry process for paper making, also can lower CO_2 releases.

The use of plants as a source of chemical feedstock also can reduce CO_2 emissions. Many large wood-products companies already produce chemicals in association with their primary timber or paper production. In India, a major effort to develop a "phytochemical" feedstock base has been underway at the National Environmental Engineering Research Institute. The production of chemicals such as acetone, butandiol, butanol, and isopropanol utilizing water hyacinth, grass, and industrial waste as feedstocks has been demonstrated to be technically feasible. The same institution also has been working to develop processes to improve the production of CH_4, as well as microbial conversion of CH_4 to methanol (Motwani *et al*., 1993; Juwarkar *et al*., 1994; Sharma *et al*., 1994).

20.5. Policy Options

Industrial GHG reductions can be achieved by good housekeeping (operational performance), additional investments in energy-efficient technologies (both conversion and end-use equipment), or redesigning the manufacturing process itself (process innovation and integration). Clearly, the technical and

Table 20-6: *Tons of carbon saved and released in primary and secondary materials production.*

	OECD C Reduction for 10% Increase in Recycling (Mt C/yr)	Primary	Secondary	Primary/ Secondary
Steel	18.9	0.65	0.15	4.33
Aluminum	5.0	3.52	0.09	40.04
Copper	0.44	1.08	0.22	4.96
Glass	0.68	0.20	0.04	4.92

Investment in Energy Conversion End-Use Equipment	Product information Specialized courses	Investment subsidies Trade tariff exemptions Market pricing of energy	Performance standards DSM-oriented utilities Demonstration projects
Process Innovation and Integration	Pinch technology Exergy analysis Life-cycle analysis	Internalization of environmental costs	Voluntary agreements R&D programming Land-use planning

financial consequences of these approaches become increasingly important and the role of management becomes correspondingly pervasive. Most industrial facilities and processes have a relatively short lifetime—on the order of a decade or, at the most, 20 years. Hence, there is plenty of opportunity to introduce low-GHG-emitting technology into the manufacturing process as part of normal capital-stock turnover. Unfortunately, under present circumstances, there are no compelling incentives for companies to choose a lower-GHG-emission strategy over a higher one when they are planning new processes or products. Hence, there is a need for additional policy instruments and incentives, some of which are described in this section.

Even when efficiency improvements and greenhouse gas reductions are feasible from a technical perspective, there remain a number of barriers that still may prevent the realization of such improvements. First, a company must be aware of the opportunities that are available. Second, there may be capital constraints such as unfavorable pricing of energy or recycled materials. Third, institutional and legal measures may be necessary where financial and economic incentives remain weak and markets for efficient equipment are just emerging. In some cases, additional research may be needed to develop appropriate energy-efficient technologies, material-efficient applications, or nonpolluting manufacturing processes. Table 20-7 provides a survey of implementation measures according to the type of barrier encountered.

20.5.1. Providing Information and Training

Reduction of greenhouse gases from industrial sources can be promoted by a variety of information-related policy steps on the part of individual firms, industry groups, or governments. Technical guidance can be provided to industrial managers to help identify opportunities to alter techniques of managing energy and materials in the manufacturing process, toward the goal of reducing energy use and GHG emissions.

Consumers often lack information about the environmental consequences of their purchases and seldom consider energy and other life-cycle costs in their purchasing decisions. Energy-efficient appliances, for example, may have higher purchase prices but during their lifetimes cost less for the consumer to operate. The economic disincentive of higher purchase prices might be overcome by better information and labeling about the life-cycle costs and environmental impact of manufactured goods.

20.5.2. Fostering Technology Transfer

Because future global industrial growth will take place largely in the developing and transitional economies, the early transfer of advanced energy-conservation technology may be crucial to curb worldwide GHG emissions. Developing countries might even jump from an early stage of industrial development to an advanced stage in one step. Such leapfrogging makes sense only if the new technology is economically superior to the old technology over its life cycle and if capital is available to purchase it. This may be the case only for isolated, large-scale, turn-key projects that usually are associated with multinational corporations or multinational lending agencies. The applicability of the concept across the spectrum of efficiency options needs careful scrutiny. In many cases, judicious adaptations may be called for, particularly to enable the manufacturing of major components by local industries.

In regard to technology transfer, two issues are still unclear. One is trade barriers in the form of import tariffs and legal barriers for the protection of intellectual-property rights. Such barriers affect the adoption of high-tech components of energy-efficient equipment. A balance must be struck between the interests of developing nations and the interests of industrial firms elsewhere. Ongoing economic globalization and the increasing involvement of foreign investors in many developing countries—including, in the recent past, both China and India—may be symptomatic of changing attitudes on both

sides. This development follows in the wake of economic liberalization and shows the importance of institutional aspects for effective technology transfer.

The other issue is the establishment of mechanisms for financial transfers, in particular within the framework of the Global Environmental Facility and Joint Implementation. Energy efficiency is high on the list of priorities in this respect. At present, the future of political modalities for technology transfer still is not clear. Political controversies surrounding joint implementation involve complicated issues regarding responsibilities and credits and are far from resolved.

Nevertheless, joint implementation could potentially be viewed as a mechanism to make private capital available for the transfer of energy-efficient technology. This possibility is particularly true for the industrial sector, where multinational firms are keen to avoid the increasingly steep costs of GHG emissions in some countries if attractive alternatives are available elsewhere. In some cases, utilities from industrial nations are already actively exploring potential opportunities.

There also needs to be a better mechanism for making available new industrial ecology management systems, like that used in Sweden (Graedel *et al*., 1994), that encourage lower GHG emissions.

20.5.3. Financial and Economic Policies

Conservation opportunities may not be profitable from the perspective of the private investor due to unfavorable pricing of energy or lack of capital. Financial and economic measures are then required.

20.5.3.1. Subsidizing Energy Audits

The first step toward energy improvement requires managerial awareness of the potential benefits of saving energy and an accurate overview of how and where energy is used in the factory and at what costs. Tax credits for plant audits and consulting may help to initiate energy-saving programs by identifying opportunities for good housekeeping and by indicating where energy-saving investments would be technically possible and financially profitable.

20.5.3.2. Providing Fiscal Incentives for the Purchase of Energy-Efficient Equipment

The next step requires a proper market for energy-efficient equipment (cogeneration systems, efficient boilers and furnaces, heat exchangers, electric drives and pumps, insulation materials, and advanced control systems). Fiscal incentives in the form of tax credits may help an emerging market for such equipment to mature. Adequate performance standards and active involvement from utilities will create legal and institutional support at

this stage. Finally, in order for decisions about new processes and factories to be guided by energy-cost considerations, attention to plant energy costs will be stimulated by a firm government commitment to long-term energy-demand policies, correcting market distortions from environmental externalities, researching demand-side priorities, and land-use planning (where system-integration aspects are crucial).

Implementation problems for energy-efficiency improvements in developing and transitional economies are more severe than those in industrial countries. In addition to problem areas already indicated, key problems in both developing and transitional economies concern the economy-wide lack of capital, foreign exchange, and industrial energy prices and tariffs that often are below those of the world market. Because energy-saving investments often are characterized by capital and foreign-exchange intensity rather than by labor and resource intensity, their cost-effectiveness tends to be less in those countries than in the industrialized countries. Moreover, developing and transitional economies, in general, are characterized by lower overall productivity, including energy productivity. One should not attempt to solve energy-efficiency problems in isolation from other efficiency problems. Problems related to vintage equipment, scarcity of management skills, small-scale production, or poor technological infrastructure will not be solved by addressing climate-change or energy goals alone.

Market-oriented energy pricing is the first step in raising energy-efficiency priorities in all economies, regardless of their state of development, and already is receiving attention in most developing and transitional economies. The problem of capital and foreign-exchange scarcity has a more permanent and pervasive character. Although taxing environmental externalities is desirable, many industries operate on an international level, so the introduction of such taxes requires international action. Unilateral correction of national market prices can lead to a loss of international competitiveness.

20.5.3.3. Examining Taxation as a Tool

The "material content" of economic growth and its resulting greenhouse effect results from a huge number of interrelated decisions made by economic actors (e.g., business firms and households). Therefore, economic instruments—such as taxes that internalize externalities—seem to be most appropriate policy tools. However, although some assessments have been carried out on the effect of a carbon tax on energy efficiency in different sectors, little work has been done on the effect of such a tax on recycling or material substitutions. We must therefore admit that we do not know the efficiency of economic instruments in this field.

Preliminary results (ADEME, 1993; Gielen, 1993) tend to demonstrate that a carbon tax would mainly influence waste management (increased recycling and/or incineration) and would promote little in the way of material substitutions within products—unless it reaches very high levels and except for

products whose material composition has a significant impact on energy consumption in the end-use phase.

Carbon taxes on fuels have been proposed as one way to lower CO_2 emissions from fossil-fuel burning. Interestingly, although the use of carbon taxes on fuels to internalize climate-change costs from that source have been the topic of major discussions, little attention has been given to applying a "greenhouse tax" to process-related releases. In some countries, such as the United States, an "ozone depletion tax" has been applied to CFCs and halons to improve the price competitiveness of substitutes. Such a strategy might be considered for goods whose manufacture produces GHGs.

Internalizing environmental costs in energy prices and tariffs through ecotaxes is particularly problematic for the industrial sector because of the consequences for national competitiveness on international markets. Taxes that are not levied on a global scale may provoke industry relocation, which may adversely affect emissions efficiency as well as international competitiveness. Most countries are hesitant to embark on policy ventures that might endanger their international market position and their attractiveness as industrial locations. Although tax exemptions for specific industries are possible, policymakers are wary about the administrative feasibility and costs of such exemptions. On the other hand, little empirical evidence points to any actual dangers of industrial relocation resulting from ecotax burdens. Because only new investment is affected, the impact of taxation may not be immediately apparent, although the impact may be more pronounced in the future because industries are becoming more international.

Systems of internationally traded emissions permits, carbon taxes, and opportunities for joint implementation are options that require international cooperation. It is difficult for a single nation to impose full environmental cost accounting and remain competitive unless other nations do the same.

20.5.4. Supporting Technical Innovations through Research and Development

During the past two decades, many energy-saving technologies—such as compact fluorescent light bulbs—have been developed with government research support and have successfully penetrated the market. To reach further reductions in energy intensity, more-expensive and less-proven technologies must make a contribution. Energy-conservation programs, therefore, need to devote more attention to research, development, and demonstration than in the past. An appropriate balance between energy-supply R&D budgets and energy-conservation R&D budgets has not yet been achieved. Additional R&D needs to be encouraged in the private sector through appropriate tax incentives.

In several cases, secondary materials similar in quality to primary materials will be available during the coming 10 to 20 years. In these cases, the steady-state rate of recycling will depend mostly on the cost of collecting and sorting. Hence,

regulations and policies favoring economic efficiency at the collecting and sorting stage are crucially important. However, for some materials, like plastics, the situation is more problematic. With these materials, obtaining high-quality recycled products or finding uses for recycled low-grade materials seems to remain rather difficult. Hence, public intervention can be essential to promote R&D activities in this field and expand the market for recycled products.

20.5.5. Organizing and Supporting Recycling

Increasing recycling rates is linked to the following measures: limitation of dissipative uses; product design allowing easy-to-treat structures and easy disassembly; standardization of materials to produce more homogeneous scrap; more cost-efficient collecting and sorting; and technical innovation to increase the quality of secondary materials and/or lower their quality requirements in volume markets.

Regulations banning dangerous dissipative uses have been implemented in many OECD countries, particularly for heavy metals. The primary goal obviously was not to limit the greenhouse effect, but the impact on recycling rates was additive. Industrialized countries are putting increasing regulatory pressure on recyclability, mostly driven by solid-waste concerns. This trend is illustrated by recent French and German initiatives concerning packaging wastes. The producers of packaging materials have been made responsible, through voluntary agreements, for setting up organizations (DSD in Germany and Ecoemballage SA in France) to collect, sort, and recycle their materials.

As another example, an ongoing regulatory process within the European Community is aimed at drastically reducing the volumes of industrial and domestic wastes dumped in landfills. The general purpose is to ban the dumping of any type of "unprocessed" waste, thereby limiting landfilling to "ultimate" wastes. Waste "processing" may be recycling and/or incineration with heat recovery and/or power generation—the former being preferred, although it is not clear that clean incineration is always worse for the environment than recycling. For industry, the cost of producing wastes will therefore rise, leading to "material-efficiency" improvements (including internal recycling) within industrial plants.

In many locations, policies dictate that households use different types of receptacles to separate papers, glass, plastics, and organic matter. Such behavior significantly lowers the cost of sorting, improves the homogeneity of scrap, raises the quality of secondary materials and lowers their treatment costs, and ultimately increases the potential rate of recycling. Successes have been reached by several pilot experiences.

Manufacturing materials from scrap tends to be less expensive than from primary raw materials, but secondary materials often cannot be used in all of the applications that primary materials can. Therefore, the maximum rates of recycling depend on the

costs of collecting and sorting scrap, as well as the opening of wider markets to secondary materials.

20.5.6. Creating Voluntary Organizations and Agreements

Broad voluntary agreements have been fashioned between industry and government to curb energy demand. Such voluntary agreements free governments from the regulatory burden of setting up complicated and inefficient systems of industrial-equipment efficiency standards and operating norms, and enable industries to choose strategies and technologies that are most efficient from the point of view of industry-specific conditions and opportunities. However, the effectiveness of such arrangements clearly depends on the financial conditions facing the industry. When profit positions become less favorable, through internal or external circumstances, the incentive to honor voluntary agreements is likely to suffer.

20.5.7. Underwriting Demonstration Projects

Seeing is believing. Often, the amount of uncertainty associated with a new technology being applied to a new situation with untested goals and techniques is too great to convince managers to invest in it—even if theory indicates not only that the investment will be safe but also that it will return dividends throughout its lifetime. However, if those same managers see the technology successfully applied to a test bed under conditions that resemble their company's situation, they might be more convinced that it would work for them. Such demonstrations can be offered by government agencies, trade groups, developers of the technology, utilities, corporations, or other institutions. Cooperative efforts often are most effective.

20.5.8. Creating Legal and Institutional Instruments

20.5.8.1. Developing and Enforcing Standards

A final approach to reducing GHG emissions from the industrial sector is the development and imposition of standards. This strategy already has been used in such applications as automotive emissions and the energy efficiency of buildings. Such standards can be written by industry groups and incorporated into regulations or legislation. Such standards ensure that feasible goals are set, that the technology to achieve those goals is available or under development, that a level playing field is provided for all participants, that the information needed to comply with the standards is disseminated, and that monitoring and enforcement mechanisms are in place. One of the advantages of such an approach is its flexibility; the standards and the technologies they prescribe can change over time in response to technical advances, economic conditions, and the perception of social and political needs.

20.5.8.2. Expanding Land-Use Planning

Opportunities for efficiency improvement through system integration are substantial in densely populated areas of the industrial world, where sources of waste heat and materials and demands for low-temperature heat and waste materials as inputs often are located close together. Such opportunities, however, pose additional implementation barriers because the organizational and regulatory complexities of system-integration projects are particularly demanding. A positive attitude from local authorities and utility planners and an innovative approach in regional planning have proved essential in the few cases in which this approach has been successfully followed.

20.6. Conclusions

The worldwide industrial sector contributes a large percentage of GHGs to the atmosphere. The bulk of this is CO_2 associated with energy use, but significant quantities of process GHGs—including CO_2, CH_4, N_2O, CFCs, and other halo- and hydrohalocarbons—also are released. OECD industrial economies contribute the bulk of fossil fuel CO_2 emissions, but these have remained relatively constant over the past 2 decades. Transitional-economies emissions have declined sharply since 1988 with the contraction of economic output, while developing-economies emissions have grown as their industrial sectors have expanded. A number of opportunities have been identified in the most energy- and GHG-intensive industrial subsectors for more efficient use of energy and materials. Creating industrial ecosystems that make maximal use of recycled secondary materials as feedstocks and take advantage of cascaded lower-temperature heat can lead to substantial reductions in greenhouse gas releases. The use of low-carbon fuels, renewable energy technologies, less energy-intensive materials, and dematerialization can lead to lower GHG emissions in all economies. Shifting industrial practices to reduce GHG emissions (and other environmental pollutants) can occur as part of the regular replacement of capital stock, but information and a variety of economic incentives and other policies are likely to be needed to assure that replacement technologies and processes are chosen that lower GHG releases.

CONTENTS

EXECUTIVE SUMMARY

The transport sector—including passenger travel and freight movements by road, rail, air, and water—was responsible for about 25% of 1990 world primary energy use and 22% of CO_2 emissions from fossil-fuel use. It is one of the most rapidly growing sectors. Energy use in 1990 was estimated to be 61–65 EJ. Without new measures, this might grow to 90–140 EJ in 2025. Confidence in this range, and in the outlook for relative contributions of different countries, is low, and future transport energy use will be influenced by government policy. Nevertheless, industrialized countries are expected to continue to contribute the majority of transport-related greenhouse gas emissions until 2025. After 2025, the majority of transport-related emissions may be from countries that are currently developing rapidly or that have economies in transition.

Transport activity increases with rising economic activity, disposable income, access to motorized transport, and falling real vehicle and fuel costs. Societies are becoming increasingly dependent on the car for routine travel, aircraft for long distance travel, and the truck for freight transport. Transport activity, the development of urban and other infrastructure, lifestyles, and patterns of industrial production are all closely interrelated. As well as being linked to economic development, the transport sector imposes burdens on society, including the effects of traffic congestion, accidents, air pollution, and noise. Climate change is currently a relatively minor factor in decisionmaking and policy in the sector, although this could change in the future.

Greenhouse gas emissions could be reduced in all transport modes through changes in vehicle energy intensity or energy source, stimulated by research and development as well as by changes in current patterns of intervention in the markets for vehicles and fuels:

- Improved vehicle energy efficiency might reduce greenhouse gas emissions per unit of transport activity by 20 to 50% in 2025 relative to 1990 without changes in vehicle performance and size.
- If users were prepared to accept changes in vehicle size and performance, transport energy intensity could be reduced by 60 to 80% in 2025.
- With energy-intensity reductions, the use of alternative energy sources could, in theory, almost eliminate greenhouse gas emissions from the transport sector after 2025. A complete transition to zero greenhouse gas emission surface transport is conceivable but would depend on eliminating emissions throughout the vehicle and fuel-supply chain.

In all cases, there is medium confidence in the ranges for these technical potentials, which depend on government policies and decisions made by vehicle and energy suppliers.

The use of motor vehicles might be reduced by changing land-use patterns and lifestyles to reduce the need for goods transport and travel; restrictions on the use of motor vehicles; and fiscal or other measures to discourage motor vehicle use and to encourage the use of nonmotorized transport. No confidence can be placed in estimates for the ultimate potential mitigation through these measures. A few city authorities have used packages of such measures to control traffic and have reduced energy use by 20 to 40%.

Travel-mode switching from car to bus or rail can reduce primary energy use by 30 to 70%, while switching container freight traffic from road to rail can reduce primary energy use by 30%. The percentage of greenhouse gas emission reduction is more than this value if railways are powered with electricity from nonfossil sources. Confidence in the potential for mitigation through mode switching is low because human behavior and choice play a central role, and these factors are poorly understood.

Experts may not agree on the best approach among these options and sometimes give conflicting advice. Nevertheless, there is an emerging consensus that attempts to move traffic to less energy-intensive modes depend on using well-integrated strategies designed specifically for local situations. Measures to encourage nonmotorized transport and public transport tend to work only when combined with measures to reduce the distances people need to travel and discourage energy-intensive vehicle use. Several cities in Latin America, Southeast Asia, and Europe have succeeded in stemming the growth in car use by such combined strategies.

In many circumstances, strategies may not be implemented if they might reduce the benefits provided by transport systems to individuals and firms. Greenhouse gas mitigation strategies will have to address this issue and find ways to meet or change the needs and desires currently met by energy-intensive transport. Preferences in travel behavior are driven by social and cultural factors, as well as by cost-effectiveness in meeting needs.

Policies with a wide variety of social, economic, and environmental objectives—especially those of reducing traffic congestion, accidents, noise, and local air pollution—also can reduce greenhouse gas emissions from transport. Conversely, greenhouse gas mitigation strategies are likely to be more acceptable

and successful if they are integrated into wider strategies in transport, urban development, and environment policy.

Appropriate mixes of policies will vary between cities and countries. In small towns with relatively simple infrastructure, provision for nonmotorized transport and alternatives to transport may be particularly important. Cities with rapidly developing infrastructure have an opportunity to manage transport-system development, ensuring the viability of nonmotorized and public transport modes. In countries and cities with highly developed infrastructure and technical capability, changes in the transport system are likely to be slower but may hold more potential to influence vehicle technology and energy sources.

When considering transport-sector mitigation options in engineering, economic, or planning terms, it is important to recognize that there are simplifying assumptions in these three frameworks, so each gives an incomplete picture. None incorporates an accurate understanding of human behavior and choice, although these are essential determinants of greenhouse gas emissions from the sector. Policymakers can address these issues by developing mechanisms and institutions to inform and educate transport stakeholders and involve them in the design and implementation of mitigation strategies.

There are several factors that lead to inertia in the development of transport systems: Technologies and fuels now in the laboratory can require several decades for commercialization; transport infrastructure is developed slowly and has an influence that can last for centuries; stakeholders may be reluctant to change their practices; and transport user behavior and choice also may develop slowly in response to a changing environment. Once transport systems are developed to service the car, truck, and airplane, it is very difficult to reverse the shift away from nonmotorized and public transport. Some immediate actions can be taken to facilitate future mitigation strategies; for example, new infrastructure can be designed to allow for nonmotorized transport. Greenhouse gas mitigation strategies could take some years, even decades, to deliver results and will have to be implemented long before anticipated greenhouse gas reduction needs.

21.1. Introduction

This chapter addresses options for mitigation of greenhouse gas emissions in the transport sector, which includes all types of travel and freight movement by road, rail, air, and water. Fluids—mainly petroleum and natural gas—are moved by pipeline, but greenhouse gas mitigation in pipeline systems is treated in Chapter 19.

Section 21.2 analyzes current emissions of greenhouse gases from transport and their trends, looking at road, rail, water, and air; the contribution of non-CO_2 greenhouse gases; and the patterns in different countries and regions. Section 21.3 reviews the potential for emission reductions through changes in vehicle maintenance and new vehicle design, through changes in vehicle operating practice, and through the introduction of alternative fuels. It also discusses the long-term potential for electrically powered transport and identifies key areas where research and development are needed. Section 21.4 reviews the effects of fiscal, regulatory, planning, and other measures in the transport sector and aims to clarify some of the differences of opinion among experts on the desirability and feasibility of measures.

21.2. Transport and Greenhouse Gas Emissions

21.2.1. Current Emissions

Greenhouse gas emissions from transport result mainly from the use of fossil fuels; the main greenhouse gas produced is CO_2. The transport sector was responsible for about 25% of 1990 world primary energy use and 22% of CO_2 emissions from energy use (including energy use in fuel production; based on IEA, 1993c). These shares are growing in almost all countries. Rising incomes and steady or declining fuel costs have encouraged a 50% growth in world energy use in the sector between 1973 and 1990—an average of 2.4% per year (Orfeuil, 1993). The 65 EJ consumed by transport, including
Figure 21-1: Transport-fuel sales, 1990, EJ (IEA, 1993c; Pischinger and Hausberger, 1993).

marine bunker fuel, in 1990 represented 58% of all oil products consumed (IEA, 1993c).

In 1990, about 23 countries' transport sectors are thought to have consumed more than 0.42 EJ in final energy, excluding marine bunkers. Figure 21-1 shows transport-fuel sales, excluding marine bunkers, in the 20 of these countries for which detailed data are available (IEA, 1993c, 1993d). In these countries, road traffic uses roughly 80% of total transport final energy consumption, air traffic 13%, rail 4.4%, and inland water transport 2.6%.

Given the large road-transport share of energy use, greenhouse gas mitigation options discussed in this chapter will focus on this subsector, although some options for air transport also will be addressed.

While CO_2 is the main greenhouse gas emitted by the transport sector, emissions of non-CO_2 greenhouse gases add to the radiative forcing of vehicle emissions. In addition to nitrous oxide (N_2O), methane (CH_4), and chlorofluorocarbons (CFCs), vehicles emit large quantities of carbon monoxide, volatile organic compounds (VOCs), and nitrogen oxides (NO_x) for which global warming potentials (GWPs) are not currently available (see IPCC Working Group I volume, 1995). N_2O contributes about 10% to the radiative forcing of tailpipe emissions of gasoline cars equipped with three-way catalytic converters (based on CEC, 1992; Prigent *et al*., 1991). Greenhouse gas emissions during car manufacture and disposal add a further 10 to 15% relative to tailpipe CO_2, while releases of CFCs (used mainly in air conditioning) add between 10 and 50%. CO_2 and CH_4 emitted during oil exploration, extraction, processing, and transport contribute 10 to 20% of overall life-cycle forcing caused by vehicles using petroleum products (IEA, 1993a; CEC, 1992; DeLuchi, 1991).

The radiative-forcing effect of non-CO_2 emissions from aircraft engines is very uncertain. In particular, the impact of NO_x emitted at altitudes where subsonic aircraft fly could be more important than equivalent NO_x emissions at the Earth's surface. The effect of aircraft NO_x is uncertain: It could be of similar magnitude or smaller than the effect of CO_2 from aircraft (see Chapter 2.2, *Other Trace Gases and Atmospheric Chemistry,* in the IPCC Working Group I volume). Aircraft also emit carbon monoxide, water vapor, soot and other particles, sulfur gases, and other trace constituents, which have the potential to cause radiative forcing, but the impact of these emissions has not yet been properly assessed.

21.2.2.   *Projections of Transport Greenhouse Gas Emissions*

At least until 2025, CO_2 is likely to remain the main greenhouse gas produced by the transport sector, and emissions will depend mainly on energy use in the sector. Several scenarios of transport energy use to 2025 have been developed; some are shown in Figure 21-2. All of these projections are produced based on some set of assumptions regarding the continuation of historical relationships between transport fuel consumption

and variables such as gross domestic product (GDP), fuel prices, and vehicle energy efficiency.

International comparisons reveal a strong correlation between transport energy use and GDP. (The data plotted in Figure 21-3 indicate a GDP elasticity of 0.89, with $R^2 = 0.93$.) Nevertheless, at a given level of GDP, energy use can vary by a factor of two. The growth of transport with income and time is faster for middle-income countries than for very-low-income countries (Button, 1992). Button developed a model for car ownership that has been used by Orfeuil (1993) to indicate that, by 2020—assuming current GDP growth trends continue—developing countries will have a third of the world's car fleet, compared with 14% today.

Many analysts have found a close correlation between road-freight traffic (tonne-km) and GDP (Bennathan *et al*., 1992), whereas rail freight appears to be almost independent of GDP but is very closely related to country surface area.

Figure 21-4 plots national average road-transport energy use per unit of GDP against fuel prices. It shows that prices may help to explain some, but by no means all, of the variation in energy use per unit of GDP. Variations also may be explained partly by geographic, cultural, and other factors.

Many analysts have criticized the use of historical relationships between the economy and energy use to produce projections. Although car ownership is growing very rapidly in Europe and Asia, Grübler and Nakicenovic (1991) suggest that it may saturate at lower per capita levels than in North America. In this case, global car energy use may not be much higher in 2010 than it was in 1985, assuming that fuel economy continues to improve at historical rates.

21.2.3. The Role of Transport

Transport is needed for basic survival and social interaction as well as cultural and economic activity and development. Transport systems develop with the socioeconomic situation and the land-use patterns in which they are embedded (Dimitriou, 1992). Climate change is a new concern to be added to the many influences and interests in the transport sector; some of these influences and interests may support the aim of reducing greenhouse gas emissions, while others may be in conflict with it.

People use transport to travel between homes, workplaces, shops, and services; to socialize; and to take vacations. As travel becomes quicker, more flexible, and cheaper, people's options (where to live, work, shop, and socialize) broaden. Some people can use increasing mobility to improve their economic situation and quality of life. For others, especially the poor—particularly those in rural areas—the lack of affordable transport remains an economic and social constraint.

Producers of goods use transport systems to gain access to raw materials and to their markets. As the quality of transport improves and costs fall, the production and distribution of goods becomes cheaper and more efficient. Firms have increasing flexibility in their sources of raw materials and the markets for their products; they have a greater choice of production locations and employees; they also can become more

specialized, achieving economies of scale and taking advantage of local conditions suited to their activities.

Transport systems can become an end in themselves; this is perhaps most obvious in the case of the automobile, which has become a symbol of wealth and social status. Tengström (1992) explores the extent to which this technology has shaped modern culture and provides a review of the related literature.

The uses to which transport services are put evolve as incomes rise, costs fall, and priorities change. A number of stages in the use of transport systems can be identified, corresponding roughly to Maslow's hierarchy of needs (Maslow, 1954):

1) Essential survival needs: movement of food, fuel, water, and travel for health care and to escape danger
2) Needs relating to economic security: movement of traded goods—mostly primary commodities—and travel to work and for education
3) Needs relating to social involvement: visiting family and friends, travel to entertainment, and family vacations; goods transport moves beyond essentials to include more manufactured goods
4) Needs relating to self-expression and exploration: tourism and more distant vacations; goods transport moves toward very high value-added goods.

This pattern is reflected in transport statistics and travel surveys, which indicate that, as societies become wealthier, social and leisure travel become more important. The car has been an essential element in this process, allowing increasing flexibility, especially in social relationships. The development of air travel has allowed tourism to flourish.

Transport demand was, until recently, seen in most countries as a social and economic need to be met. At the same time, growing motorized transport use has long been recognized to have negative consequences for society. The most important of these include:

• Traffic congestion
• Accidents
• Noise, vibration, and air pollution
• A wide range of social problems related to the use of land, reduction in nonmotorized transport use, reduction in availability of local services, and so forth, contributing to a declining quality of life for non-car owners.

Measures designed to address these issues provide the main opportunity at present to reduce greenhouse gas emissions from transport. Greenhouse gas mitigation policy is more likely to succeed if it addresses concerns such as these.

21.2.4. Activity and Energy Use in the Transport Sector— Travel Behavior

Table 21-1 shows information from a number of city travel surveys in Asia and Africa. The variation in travel patterns

Table 21-1: *How people travel—percentage of trips by mode in Asia and Africa.*

Country/City	Survey Year	Non-motorized	Private Motorized	Public Transport and Taxi

Low Income		55	3	41
Middle Income		27	19	54
High Income		5	57	38

a large proportion of mobility and access needs in many countries.

Several observations can be made based on the European data. First, the variation among countries in distance traveled per day (standard deviation 16% of mean) is about twice as large as that in the number of trips and the time spent traveling (8 and 9%, respectively). It might be concluded from this type of data that (1) people travel to satisfy a certain number of access needs (for work, services, etc.) that do not vary significantly as the transport system changes, and (2) people operate with a time budget and will spend roughly the same amount of time traveling during each day, regardless of the average speed of the transport system. This would imply that measures that make travel faster will tend to increase the distance traveled by people.

Second, in most countries (with the exception of the United Kingdom), public transport is used for longer trips than cars: The public-transport share of trips is smaller than the share of distance. This has been confirmed by other studies (e.g., Birk and Bleviss, 1991). Walking, cycling, and moped trips, not surprisingly, are shorter on average than public-transport and car trips in all countries.

Third, although the car dominates the distance traveled in all countries, the car share of trips is about equal to the share of trips on foot, bicycle, or moped. Thus, although cars appear to dominate European transport according to the distance traveled, they are about equal in importance with travel on foot and on two-wheelers according to the number of trips.

among cities in Asia, even at similar income levels, is quite striking and is much greater than the variation among countries within Europe, for which survey results are provided in Table 21-2. Despite the upward trends in most motorized forms of transport, walking and cycling continue to provide

Global road-vehicle fleets grew 140% between 1970 and 1990 (OECD, 1993a). The vehicle population could increase by anything from 60 to 120% by 2025, and 140 to 600% by 2100 (Walsh, 1993b; see Table 21-3). The current annual percentage growth is highest in Southeast Asia, Africa, Latin America, and

Table 21-2: *Daily travel of Europeans according to travel surveys (Salomon et al., 1993).*

2030	910–1300	60–90	180–250	5.8–8.2	1.1–1.5	0.5–0.7
2100	1200–3800	110–380	250–800	8.1–24.3	2.0–6.7	0.7–2.2

some central and eastern European countries. Much of the fleet growth in these countries comprises second-hand vehicles imported from the Organisation for Economic Cooperation and Development (OECD) countries, which still have the largest markets for new vehicles. Developing countries account for only 10% of the world's cars (Birk and Bleviss, 1991).

Light-duty vehicle traffic has risen rapidly in recent years with rising incomes and falling real costs of vehicle ownership and use, including fuel costs. The fastest growth has been in Southeast Asia, Africa, Latin America, and most recently in Central and Eastern Europe (Suchorzewski, 1993). Most countries have seen an increase in travel by bus and train from 1965 to 1991, although the growth has been less rapid than that in car traffic (ECMT, 1993; Schipper *et al.*, 1993).

Two-wheelers, especially mopeds with two-stroke engines, are one of the most rapidly growing means of personal transport in parts of South and East Asia and Latin America (Dimitriou, 1992; IEA, 1994c). India has about four times as many two-wheelers as cars (UNESCAP, 1991), and the ratio is expected to increase. Three-wheelers are important means of transport in several Asian cities, where they often are used as taxis.

OECD countries have four cars to every goods vehicle; in non-OECD countries, the ratio is nearer to two cars to every goods vehicle. Goods transport by road rose more during the 1980s than did personal travel. An increasing share of goods transport in industrialized countries has been carried by smaller trucks, as high-value-added goods account for an increasing proportion of production and as the service sector, including retailing, grows faster than the rest of the economy. At the same time, bulk freight is becoming increasingly concentrated in very large trucks (around 40 tonnes gross vehicle weight).

The breakdown by type of vehicle of the 46 EJ of energy used for road transport in 1990 is poorly documented, but Walsh (1993a) estimates that goods transport is currently responsible for about 27% (see Figure 21-5).

Rail freight traffic has increased or remained fairly steady in most countries. Because rail freight is less flexible than road freight, it has tended to become confined to conditions where costs per tonne-km are lower than for road freight; rail terminals exist at, or good road/rail transfer facilities exist near, both the origin and the destination; speed is relatively unimportant;

and shipments are regular. Rail freight is most important in large countries where long hauls are more frequent (Bennathan *et al.*, 1992), including the United States, the former Soviet Union, and China. Its market has declined in many small countries. It also has declined as industries have moved toward "lean" manufacturing requiring fast, flexible, "just in time" transport systems. In central and eastern European countries, the process of economic reform also has brought about a large shift of freight from rail to road (GUS, 1993). Meanwhile non-motorized goods transport, which makes a negligible contribution in OECD countries, is important in developing countries, especially in rural areas.

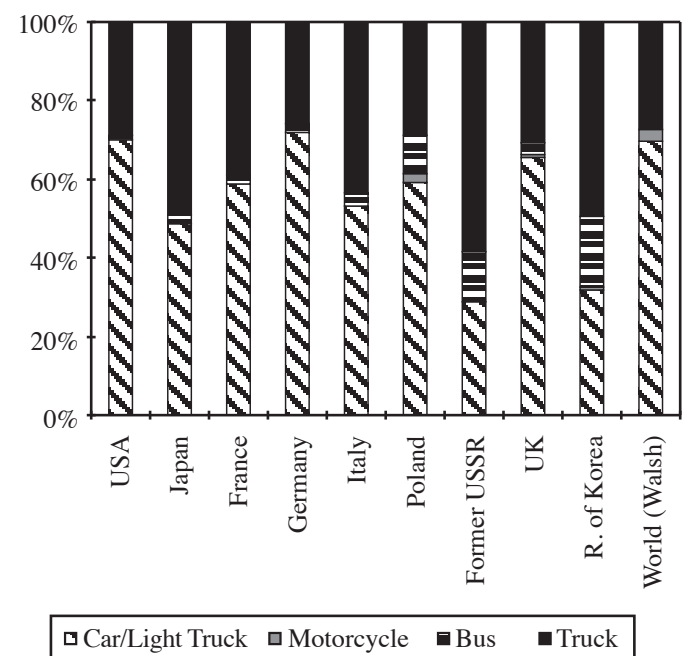
Growth in air travel (passenger-km on scheduled services) has been much greater than economic growth but has been closely linked with it. The growth rate has declined, from 13.4% per year during 1960–1970 to 9.0% per year during 1970–1980 and 5.7% per year during 1980–1990 (ICAO, 1992). An increasing share of air passenger traffic is for leisure purposes. Air freight traffic (tonne-km on scheduled services) has grown


Figure 21-5: Shares of energy use by road vehicles, various years (Schipper *et al.*, 1993; Pischinger and Hausberger, 1993; Walsh, 1993a; Kang, 1989).

more rapidly, at 11.7% per year during 1960–1990 (ICAO, 1992). Half of passenger traffic and about 80% of freight traffic is international (ICAO, 1994a).

Waterborne transport volumes—mostly bulk marine freight—have fluctuated with international trade in bulk commodities. Bulk marine freight grew from 25.3 billion tonne-km in 1981 to 28.8 billion tonne-km in 1991 (OECD, 1993b). Most traffic in 1991 was made up of crude oil and oil products (46%), coal (11%), iron ore (11%), and grain (6%).

21.2.5. Trends in Transport Energy Intensity

So far, this chapter has discussed trends in traffic by different transport modes. Greenhouse gas emissions from transport depend mainly on energy use, which is the product of the energy intensity (energy use per passenger-km or tonne-km) and the level of activity (passenger-km or tonne-km).

Table 21-4 provides estimates of the range of national averages of energy intensity for travel by car, bus, and train in various parts of the world. Differences between countries may be explained by a variety of interlinked factors, including age and design of the vehicle fleet, share of larger or higher-powered cars, quality of maintenance, and level of traffic congestion. All of these variables may be influenced by geographical, social, economic, and other factors.

There are competing influences on energy intensity. High-income countries in North America and Scandinavia have efficient technology but use it partly to provide a higher standard of transport services; vehicles of most types, including buses and trains, tend to be larger, heavier, and more comfortable. Low-income countries, such as China and India, tend to have less-efficient technology—but occupancies are relatively high, leading to low energy intensity. Indeed, average two-wheeler occupancy in Delhi, at 1.6 (Bose and Mackenzie, 1993; UNESCAP, 1991), is higher than car-occupancy levels in many industrialized countries, which can be as low as 1.2. Countries between these two extremes where transport activity is currently increasing rapidly (including southern and eastern European countries, Korea, and Japan) tend to have efficient technology that is used for lower standards of transport service, resulting in quite low energy intensities.

Car-occupancy levels in industrialized countries have declined with rising car ownership. Whereas buses and trucks in developing countries often are overloaded, leading to safety concerns, those in industrialized countries tend to have low occupancies or load factors, so operators and policymakers are concerned to find ways to increase loading.

For cars, there is an estimated 10 to 20% differential between national average on-road fuel economy and the results from official fuel economy tests (IEA, 1993a; Martin and Shock, 1989; Schipper and Tax, 1994). Differences arise because,

Table 21-4: *Passenger transport energy intensity—estimated national averages (Chin and Ang, 1994; Davis and Strang, 1993; Faiz, 1993; Grübler et al., 1993b; CEC, 1992; Schipper et al., 1993; Walsh, 1993a).*

[a]Estimated gasoline-equivalent fuel consumption per vehicle-km for the national car fleet.
[b]Electricity as primary; efficiency of conversion from primary energy to electricity supplied to locomotives assumed to be 30%.
[c]Very uncertain.

among other things, cars usually are not tested with auxiliary equipment, such as air conditioning, in operation, and some tests do not include cold starts, which can result in excess fuel consumption as high as 50% for short trips in cold weather (Hausberger *et al.*, 1994). In some regions, poor road quality may increase fuel consumption; that increase is an estimated 50% in Russia (Marchenko, 1993).

Car mass and engine size are closely related to energy intensity (Ang *et al.*, 1991). An upward trend in these factors has been observed in several European countries and in Japan (IEA, 1991a; Martin and Shock, 1989). In the United States, a downward trend in engine size and car mass (Difiglio *et al.*, 1990) has been reversed in recent years (NHTSA, 1994).

A more important factor in some countries is the expanding use of "light trucks"; these include small pickup trucks and minibuses. Light trucks accounted for 32% of the personal private vehicle market in the United States in 1990, and their fuel consumption per kilometer is about 36% higher than that of cars (Greene and Duleep, 1993).

The on-road mean fuel consumption per kilometer driven of light-duty passenger vehicles in North America fell by nearly 2% per year between 1970 and 1990, to about 13–14 L/100 km, but remains 30 to 40% higher than that in Europe or Japan (Schipper *et al.*, 1993). In other industrialized countries, changes during the period were quite small (see Figure 21-6), although new-car fuel economy in official tests improved by about 20% during the period (IEA, 1993a).

Most of the cars sold worldwide are either new cars made to designs originating in the OECD or second-hand cars exported

from the OECD. Any changes in vehicle technology, therefore, tend to be driven by the requirements of OECD new-vehicle markets.

While car energy intensity in the OECD has fallen during the past 20 years, the energy intensity of car travel has increased in many countries as a result of declining car occupancy. Meanwhile, the more recent trend is toward higher energy intensity in new cars in countries including the United States, Germany, and Japan (IEA, 1991a, 1993a), and global average fuel economy will not necessarily improve in the near-term future. Nevertheless, projections often incorporate a reduction of 1 to 2% per year (Davidson, 1992; Grübler *et al.*, 1993; IEA, 1991a, 1993a). This can vary considerably within regions: Davidson (1992) gives projections for African countries between 1985 and 2025 ranging from 0.6% per year in Sierra Leone to 1.8% per year in Nigeria.

Few estimates are available of energy intensity in aviation. Flights of 1,000 km or more typically have energy intensity in the range of 1.5 to 2.5 MJ/passenger-km. For short-haul flights, energy intensities can be higher than 5 MJ/passenger-km (ETSU, 1994). World civil air traffic (tonne-kilometers) increased by 150% between 1976 and 1990, while energy consumption rose by only 60%. This situation represents about a 3–3.5% per year reduction in energy intensity (Balashov and Smith, 1992), which is a result of improved aircraft energy efficiency and rising utilization of available seats and cargo capacity.

Walking and cycling only result in greenhouse gas emissions if people eat more food to compensate for the energy they use. This is of the order of 150 kJ/km for walking and 60 kJ/km for cycling (Banister and Banister, 1994; Hughes, 1991). Fossil-fuel use in agriculture, food processing, transport, storage, and cooking is highly variable but on average is of the same order of magnitude as the energy content of the food.

Data on the energy intensity of road freight traffic are hard to obtain and interpret in most countries. Energy use is typically in the range of 3 to 4 MJ/tonne-km on average and 0.7 to 1.4 MJ/tonne-km for heavy trucks (Schipper *et al.*, 1993; CEC, 1992). In countries where services and light industry are growing faster than heavy industry, the share of small trucks or vans in road freight increases; these have high energy intensity compared with large trucks. Along with the increasing power-to-weight ratios of goods vehicles, these trends offset—and in some cases outweigh—the benefits of improving engine and vehicle technology (Delsey, 1991a). The energy intensity tends to be lower in countries with large heavy-industry sectors, where a high proportion of goods traffic is made up by bulk materials or primary commodities.

Average truck energy use per tonne-kilometer of freight moved has shown little sign of reduction during the past 20 years in countries where data are available (Schipper *et al.*, 1993). Although vehicle technology has improved, this improvement has been used partly to increase the power-to-weight ratio of vehicles rather than to reduce energy use. The structure of the
Figure 21-6: Light-duty passenger-vehicle energy intensity (MJ/vehicle-km) (Schipper *et al.*, 1993).

road-freight market has shifted in many OECD countries away from medium-sized trucks toward very large trucks for bulk freight and small trucks for retail distribution and high-value goods. Much of the recent growth has been concentrated in small trucks, which can have very high energy use per tonne-kilometer—although perhaps it would be more helpful to measure the goods movements in value rather than weight.

Rail freight often is viewed as a very energy-efficient way of moving goods. Average rail-freight primary energy intensities, at around 0.7–1 MJ/tonne-km, are a quarter of those of average road-freight intensities (CEC, 1992; Schipper *et al.*, 1993; Tanja *et al.*, 1992). However, it is important to compare similar types of goods movements. The energy intensity of rail container freight, at 0.4–0.9 MJ/tonne-km, may not be much smaller than that of road container freight, at 0.7–1.0 MJ/tonne-km (Martin and Shock, 1989; Rigaud, 1989; CEC, 1992).

Marine transport, on average, is the most efficient means of bulk international goods movement, with energy intensities below 0.2 MJ/tonne-km (Bremnes, 1990). Dry bulk goods (e.g., iron ore, cereals, coal, bauxite, and phosphate rock), crude oil, and oil products make up 60 to 70% of goods movements by sea and are moved in the largest, most efficient vessels. There has been a strong trend toward larger vessels (up to 170,000-tonne capacity) to capture economies of scale in both investment and operating costs of ships (Doyle, 1986).

21.3. Reducing Transport Greenhouse Gas Emissions

Greenhouse gas emissions from the transport sector and its energy supply chain can be reduced by policies and measures aimed at:

- Reducing energy intensity through vehicle downsizing, lower power-to-weight ratios, more efficient vehicle technology, changes in vehicle use (load factor, driving style, traffic management, etc.), improvements in infrastructure, or changes in transport mode
- Controlling emissions of carbon monoxide, VOCs, NO_x, N_2O, and methane
- Switching to alternative energy sources with lower full-fuel-cycle greenhouse gas emissions
- Reducing the use of motorized vehicles through switches to nonmotorized transport modes, substitution of transport services with other services (e.g., telecommunications), or reduction in the services consumed.

Section 21.3 provides a review of the potential for technical change to reduce transport greenhouse gas emissions. Section 21.4 addresses the role of policy in changing technology and its use.

21.3.1. The Technical and Economic Potential for Vehicle Changes

Studies of the potential for technical change can give a huge range of results even for a single technology in a single country.

For example, in the United States, estimates of potential new-car fuel economy for the late 1990s range from 4.8 to 8.4 L/100 km (DeCicco and Ross, 1993; NRC, 1992; OTA, 1991). Analyses differ partly in the assumptions made but also in the type of potential being considered. It is helpful to distinguish among the *technical potential* (the reduction in greenhouse gas emissions that would result from application of the best available technology), the *economic potential* (the reduction in emissions that can be achieved cost-effectively), and the *"policy" potential* (the reduction in emissions that can reasonably be achieved as a result of policies and measures).

The technical potential usually improves with time as new fuels, prime movers, materials, design techniques, and operating systems become available. The economic and policy potentials do not necessarily improve; they depend on the economic and other priorities of the providers and users of transport services. The extent to which these potentials are achieved depends on a complex interaction among technology, the economy, and choices made by consumers, producers, and policymakers. It is this interaction that most needs to be understood and addressed if policymakers wish to reduce greenhouse gas emissions from the transport sector.

21.3.1.1. Energy-Intensity Potential in Road Vehicles

Reductions in energy use per vehicle-kilometer can be achieved through changes in maintenance practice, vehicle-body design changes, more energy-efficient engine and drive-train designs, and changes in operating practice.

Vehicle maintenance may be inadequate because spare parts and servicing are too expensive or unavailable (Davidson, 1992) or because maintenance is a low priority for drivers. Regular checks on tire pressure, engine oil, and tuning can save energy. Studies on cars have shown a 2 to 10% fuel saving immediately after engine tuning (Davidson, 1992; Martin and Shock, 1989; Pischinger and Hausberger, 1993). Some countries—including Mexico, Korea, and some European countries—and some American states have introduced regular vehicle emission tests, with remedial action when necessary, usually including engine tuning.

Vehicle mass affects energy use for acceleration and in overcoming resistance or friction in the axles, wheels, and tires. In most types of road vehicle, acceleration and rolling resistance each typically account for around a quarter to a third of the useful mechanical energy from the engine, although these shares are larger for city buses and delivery vans. Vehicle mass can be reduced by using advanced materials, improving component design and joining techniques, and reducing vehicle size or engine size. Concept cars have been demonstrated with masses 30 to 40% below those of conventional cars of similar size and performance (Chinaglia, 1991; Delsey, 1991b; Lovins *et al.*, 1993). The technical potential in 2010 for mass reductions without compromising comfort, safety, and performance is probably in the range of 30 to 50% for most vehicle types; this

is the target of the United States' Partnership for a New Generation of Vehicles (PNGV). Such a mass decrease would lead to reductions in energy intensity in the region of 15 to 30%, provided engine size is reduced to keep performance constant (ETSU, 1994).

The technical potential in 2010 for reducing *rolling resistance* is probably around 30% for cars but rather less in buses and trucks (ETSU, 1994; DeCicco and Ross, 1993). For most road-vehicle types, a 10% drop in rolling resistance reduces energy intensity by roughly 2 to 3%, provided engine size is reduced (ETSU, 1994).

Air resistance, or drag, accounts for a third to a half of the energy required to move most types of vehicles, although the share is lower for city buses and delivery vans. Changes in vehicle design can reduce it by about 50% for most vehicle types without sacrificing performance—offering a 15 to 30% reduction in energy intensity, provided engine size is reduced (ETSU, 1994). The ultimate limit on drag reduction without reducing vehicle size is probably 70 to 80%, but this would involve radical changes in vehicle shape and performance.

Improved *transmission designs* can reduce energy use by allowing the engine to operate closer to its optimum speed and load conditions. Complete engine load/speed optimization can be achieved with electronically controlled continuously variable transmissions (CVT), although these may be more expensive than conventional gearboxes and currently are available only for small cars. Energy savings in the range of 3 to 10% are possible relative to automatic transmissions (DeCicco and Ross, 1993; Tanja *et al.*, 1992; NRC, 1992).

The three-way *catalytic converter*, combined with electronically controlled fuel injection into the engine air-intake manifold, is rapidly becoming standard for new gasoline cars in medium- and upper-income countries. This technology reduces emissions of carbon monoxide, unburned hydrocarbons, and NO_x from gasoline cars by approximately 60 to 90% relative to a car with a carburetor and no catalytic converter. N_2O emissions are raised approximately fivefold but depend strongly on the age of the catalyst and driving pattern (Ybema and Okken, 1993). The overall effect on radiative forcing of adding a catalytic converter to a gasoline car is small and uncertain; there may be a reduction in some circumstances (CEC, 1992; Pischinger and Hausberger, 1993; Wade *et al.*, 1994).

In *heavy-duty diesel engines*, the main needs for exhaust-gas pollution control relate to particulate and NO_x emissions. Controls such as particulate traps and filters tend to reduce energy efficiency and increase CO_2 emissions, without any compensatory effect from reductions in other greenhouse gases. However, other approaches to reducing engine emissions, such as the use of electronic fuel-injection systems, can lead to reductions in both engine pollution emissions and fuel consumption.

Changes in *gasoline-engine technology* have resulted in gradual improvements in energy efficiency. This progress is likely to continue. Energy-intensity reductions in the range of 15 to 30% are thought to be available with current technology (Bleviss, 1988; CEC, 1992; DeCicco and Ross, 1993; ETSU, 1994; NRC, 1992; Pischinger and Hausberger, 1993). These reductions could arise from a combination of many changes, including improvements in component design and lubrication, improvements in materials, increased use of electronic control systems, and changes in engine design such as the use of three or four valves per cylinder.

Car manufacturers have worked intensively on advanced two-stroke engines with the aim of reaching the noise, emission, and durability standards of existing four-stroke engines. The two-stroke engines would have higher efficiency and power-to-volume and weight ratios than four-stroke engines, allowing for more flexibility in car design and potentially for improvements in fuel economy of around 10%, provided the efficiencies realized were not used to raise power.

Another engine concept is the gasoline direct-injection engine, which might have fuel requirements 10 to 25% lower than those for a conventional engine (Schäpertons *et al.*, 1991); such engines remain far from commercialization however. Lean-burn gasoline engines also may offer 10 to 20% energy savings, but further development will be needed in the engines, or in the development of a lean-burn engine NO_x reduction catalyst, to meet future NO_x emission standards.

Diesel engines in heavy-duty vehicles are already very efficient. The energy efficiency of a large truck engine can approach 40% in use. The potential for further energy savings is probably no more than 10 to 20% in the long term.

Diesel-engine cars, taxis, and vans are widespread in Europe, the Middle East, and Southeast Asia, although they cannot meet some strict U.S. emission standards. Most of these cars have indirect-injection diesel engines and offer 5 to 15% lower fuel consumption (in energy terms) than gasoline cars. Cars with direct-injection diesel engines consume about 10 to 20% less fuel than indirect-injection diesel engines.

Alternative engine designs, including gas turbines and Stirling engines, have received attention from governments and manufacturers over the decades. These engines are cleaner than Otto or diesel engines and are also fuel-flexible, but in the 50 to 300 kW range required for road vehicles, they are currently inefficient and expensive and have poor load-following characteristics. By 2025, improved materials and precision engineering could make these engine types viable for road vehicles. Hybrid engine/electric drivetrains could be used to avoid the need for the engine to match the load on the drivetrain. These are discussed in Section 21.4.

21.3.1.2. Cost of Energy-Intensity Improvements

Several studies (DeCicco and Ross, 1993; Greene and Duleep, 1993; NRC, 1992) use cost models to estimate the potential for

reducing the energy intensity of car use in the United States. However, as DeCicco and Ross (1993) observe, it is hard to predict which technical changes will raise manufacturing costs and which will lower them. Changes in materials and manufacturing technique, in particular, frequently result in reduced costs. It is also difficult to carry out cost-effectiveness analysis on changes in vehicle design because many changes have some effect on the appearance if not the performance of a vehicle, and this can influence purchasers' willingness to pay for the changes.

21.3.1.3. Energy-Intensity Potential for Aircraft

Balashov and Smith (1992) estimate that fuel intensity in scheduled air passenger services will improve at an average of 3% per year during the 1990s and 2.5% per year from 2000 to 2010. With traffic expected to grow at 5.5% per year in the 1990s and 5% per year from 2000 to 2010, total fuel consumption could be about 65% higher in 2010 than in 1990. Beyond 2010, fuel-intensity improvements would have to come from the introduction of new engine concepts. An example might be the use of lightweight heat exchangers to provide charge cooling and recuperate exhaust heat from the engine. If such technologies could be applied in aviation, they might, in theory, provide a 20 to 25% energy savings (Grieb and Simon, 1990).

If a new generation of supersonic aircraft is successfully developed and commercialized, it would likely lead to an increase in the average energy intensity of civil air traffic and possibly an increase in traffic.

21.3.1.4. Energy-Intensity Potential for Ships

The energy efficiency of existing ship engines can approach 50%, and only small improvements (5 to 10% savings in fuel used) are anticipated in the future. Hull and propeller design improvements could reduce energy use by a further 10 to 30% (CEC, 1992).

Some existing ships use sails to assist their engines, and one option that has been claimed to save 10 to 20% of ship energy is the use of wind assistance by means of vertical-axis wind turbines (CEC, 1992). These have the added advantage of improving ship stability.

21.3.1.5. Summary of the Potential for Vehicle Energy-Intensity Improvements

By 2010, it may be technically possible to reduce energy intensities for new vehicles of most types by 25 to 50% without

Table 21-5. *Potential for energy efficiency.*[a]

Mode	National Average Load Factors (pass. per seat or tonne load per tonne capacity)[b,d]	National Averages of 1990 Intensity (MJ/pass-km or MJ/tonne-km)[d]	Trend[c,e]	Economic Reduction Potential at Constant Performance[c,e]	Technical Reduction Potential at Constant Performance[c,e]	Technical Reduction Potential: Reduced Speed and Performance[c,e]

[a] Actual potentials depend strongly on vehicle load factors and patterns of use.
[b] Load factors exceeding 1.0 indicate overloading.
[c] 2010 new stock, 2025 fleet average.
[d] Bose and MacKenzie, 1993; CEC, 1992; Davidson, 1992; Hidaka, 1993; Rigaud, 1989; Schipper *et al.*, 1993; UNESCAP, 1989 to 1992, various.
[e] Much of the literature on trends and potentials is focused on cars from 2000 to 2005 (e.g., Difiglio *et al.*, 1990; Greene and Duleep, 1993; DeCicco and Ross, 1993; IEA, 1993a). Values here are the authors' estimates, revised following expert review, based on these and on longer term estimates covering various transport modes in Bleviss (1988), CEC (1992), ETSU (1994), Lovins (1993), Martin and Shock (1989), Pischinger and Hausberger (1993), and Walsh (1993a).

reducing vehicle performance or the quality of transport provided (see Table 21-5). However, the economic potential—the energy-intensity reduction that would be cost-effective—is likely to be smaller than the technical potential. As Table 21-5 indicates, the economic potential for energy savings in cars might be about two-thirds the technical potential. Meanwhile, the trend is for less energy saving than the economic potential; for some key vehicle types, including cars and heavy trucks, it is possible that the fleet average energy intensity might not decrease between 1990 and 2025. Substantial reductions in energy intensity would require new government measures and might entail reductions in vehicle performance.

If the vehicle energy-intensity trends in Table 21-5 are combined with road traffic projections from Walsh (1993b) and air traffic trends from Balashov and Smith (1992) extrapolated to 2025, energy use in the transport sector in 2025 could be 90–140 EJ. This assumes no significant changes in energy use by rail and marine transport. The adoption of energy-efficiency improvements—to achieve the technical potential in energy use at constant performance—would result in energy use in 2025 reduced by around a third to 60–100 EJ.

21.3.1.6. Life-Cycle Greenhouse Gas Emissions

Land-based transport. Several analysts have estimated greenhouse gas emissions from road vehicles on a life-cycle basis that includes vehicle manufacture, vehicle operation, and fuel supply (CEC, 1992; DeLuchi, 1991, 1993b; IEA, 1993a; Pischinger and Hausberger, 1993). CEC (1992) also includes estimates of emissions associated with vehicle disposal and addresses emissions from trains, shipping, and aircraft. All of these sources estimate emissions of CO_2, CO, VOCs, CH_4, NO_x, N_2O, and CFCs, converted to CO_2-equivalents with a variety of GWP estimates. These GWPs all have been superseded by more recent values. Chapter 2.5, *Trace Gas Radiative Forcing Indices* in IPCC Working Group I volume, estimates GWPs as follows for a 100-year time horizon: CH_4, 24.5; N_2O, 320; CFC-12, 8500; HFC-134a, 1300. These values have been used by the authors to recalculate the life-cycle greenhouse gas emissions from various transport modes. GWPs for NO_x, VOCs, and CO are not estimated but are all expected to be greater than zero (Chapter 2.5, *Trace Gas Radiative Forcing Indices* in IPCC Working Group I volume).

The principal greenhouse gas emissions in a vehicle life cycle are CO_2 in the vehicle exhaust, during vehicle manufacture, and in the process of fuel supply; CFCs, primarily as a result of leakage from air conditioning and refrigeration systems; CH_4 emitted during oil extraction and from vehicle disposal where organic wastes are placed in landfills; and N_2O produced during fuel combustion and in the catalytic converters currently used for gasoline engines in many countries.

Vehicles are the main source in some countries of CO, NO_x, and unburned hydrocarbons. Although these are precursors of ozone—and hence are indirect greenhouse gases, GWPs cannot be reliably estimated for them (Chapter 2.5, *Trace Gas Radiative Forcing Indices* in IPCC Working Group I volume). The increasing use of catalytic converters on gasoline-engine cars during the coming 10 to 20 years will reduce emissions of ozone-forming gases and increase emissions of N_2O. The overall greenhouse-forcing impact of this change is likely to be small or neutral.

Air conditioning is likely to be installed in an increasing proportion of cars, although HFC-134a is likely to be used as the main refrigerant instead of CFC-12. At current rates of refrigerant loss, HFC-134a would add about 10% to the life-cycle greenhouse forcing caused by a passenger car. Improved equipment design and maintenance could reduce this loss, perhaps to near zero.

Car air-conditioning systems are powered by electricity generated from the engine alternator at very low efficiency. When operating, they add to vehicle fuel consumption, further increasing greenhouse gas emissions.

For diesel or electric-powered vehicles, emissions of non-CO_2 greenhouse gases contribute a smaller proportion of overall emissions than they do for gasoline cars. Buses, trucks, and trains have much higher utilization rates (distance traveled per year and in their lifetimes), so emissions associated with operation (tailpipe and fuel-supply emissions) dominate life-cycle emissions (CEC, 1992).

Aircraft. Besides CO_2, emissions of NO_x at high altitudes may make a similar contribution to climate change. While CO_2 is emitted in proportion to fuel consumption, factors influencing NO_x emissions from aircraft engines are more complex, and there may be some tradeoff between NO_x emissions and engine efficiency. During the past decade, manufacturers have developed several approaches to reducing aircraft engine NO_x emissions without compromising energy efficiency. New, more complex combustion systems are currently being developed that are anticipated to provide a 30 to 40% reduction of NO_x emissions. These targets appear to have been achieved by one medium-size engine that entered service in 1995, but not by a larger model, owing to major materials and cooling limitations. For the latter, the potential and time scale for achieving the anticipated 30 to 40% reduction are open to question. Research also is underway—primarily aimed at a second generation of supersonic civil aircraft—on systems to achieve greater than 80% reductions. Such systems could start entering service between 2005 and 2010 (Grieb and Simon, 1990).

21.3.2. Operational Influences on Vehicle Greenhouse Gas Emissions

The energy intensity of travel and freight transport is influenced by several factors other than vehicle technology. One of the single strongest influences is the load factor or occupancy of the vehicle, but other factors—including driving style (or speed profile), routing, and traffic conditions—also are important.

Differences in driving style can explain about 20% of variations in energy use by cars, buses, and delivery vans in urban areas (Martin and Shock, 1989; Tanja *et al.*, 1992). The potential for energy saving by "gentler driving" has been estimated to be about 10% in urban areas and 5 to 7% overall (Tanja *et al.*, 1992).

Energy use also can be reduced by traffic-management measures, such as computerized traffic-light control and network and junction design, to reduce congestion and unnecessary stops. Introduction of a traffic-control system in Los Angeles is estimated to have yielded a 12.5% reduction in energy use (Shaldover, 1993). However, energy-use reductions resulting from computerized traffic control may be rapidly reversed because the increase in road network capacity is likely to produce additional traffic.

For commercial vehicles, computerized routing systems can be used to optimize payloads and minimize the time spent and fuel used on the roads. For many haulage firms in industrialized countries, such systems pay for themselves through increased revenue. Some studies indicate that reductions of 25 to 30% in energy use per tonne-kilometer are technically possible (O'Rourke and Lawrence, 1995).

A variety of computerized routing aids are being developed for drivers in general, some providing real-time information on congestion and the availability of alternative modes and routes. Energy-saving potentials in urban road passenger transport could range from a few percent in small towns with little congestion to 30% in large, congested conurbations with effective public-transport alternatives (Shaldover, 1993).

For aircraft, while present flight patterns seek to minimize costs—particularly fuel consumption—there might be scope for operational changes, including alternative routings to avoid greenhouse gas precursor emissions at sensitive altitudes (such as the tropopause), latitudes, and longitudes, or changing seasonal or diurnal patterns that might reduce the impact on atmospheric processes. Civil airlines operate increasingly sophisticated computerized booking systems with multiple tariffs, and the resultant increase in seat occupancy has contributed to falling energy intensity. Further increases in occupancy are likely (Balashov and Smith, 1992).

Speed is an important influence on energy use by all types of vehicles. For road and rail transport, speed limits and vehicle speed limiters are mainly used for safety reasons. Moderate reductions in average road vehicle speed (e.g., from 90 km/h to 85 km/h) can lead to energy savings on the order of 5 to 10% (Tanja *et al.*, 1992). In ships and aircraft, speed is routinely controlled to manage energy costs. Because fuel constitutes 20 to 30% of shipping costs, operators plan voyages using shipping cost models that take account of energy use in choosing the optimum speed. An oil price of $30/barrel can produce optimum speeds 25% lower than a price of $15/barrel; the result is a 33 to 40% energy saving (Doyle, 1986).

21.3.3. Alternative Fuels

Alternative fuels are an important complement to measures that improve fuel economy as a means of reducing greenhouse gas emissions. In the past, alternative-fuel vehicles (AFVs) have been developed as a means of reducing oil consumption; they currently are being promoted as a means of reducing urban air pollution. Some types of AFVs can contribute to meeting both of these goals.

21.3.3.1. Alternative Fuels in Light-Duty Vehicles

For gaseous fuels and alcohols, engine emissions of carbon monoxide are generally lower than with gasoline, and particulate emissions are much lower. Engine NO_x emissions are generally similar to or lower than those from conventional fuels (Gover *et al.*, 1993; IEA, 1993a; OECD, 1993c; Wang, 1995). Emissions of unburned fuel and certain other pollutants, such as formaldehyde, on the other hand, can be higher than for gasoline or diesel fuel. In the short term, some of the main applications for alternative fuels are likely to be in situations where they can substitute for conventional gasoline additives, such as methyl tertiary butyl ether (MTBE), in helping to meet reformulated gasoline requirements (IEA, 1994b).

On a full fuel-cycle basis, alternative fuels from renewable energy sources have the potential to reduce greenhouse gas emissions from vehicle operation (i.e., excluding those from vehicle manufacture) by 80% or more (CEC, 1992; DeLuchi, 1991; IEA, 1993a).

Estimated life-cycle greenhouse gas emission ranges for several fuels, based on a variety of sources, are shown in Table 21-6, which also shows cost estimates for using some of the alternative-fuel vehicles. Some of the fuels listed are already cost-competitive with gasoline in some circumstances. These include diesel, liquefied petroleum gases (LPG), and compressed natural gas (CNG), all of which are in current use. Vehicles operating on these fuels may have full fuel-cycle greenhouse gas emissions about 10 to 30% lower than vehicles operating on gasoline, as shown in Table 21-6. These alternative fuels are used preferentially in high-mileage vehicles, where low fuel costs compensate for high engine and fuel-storage costs. Methanol from natural gas also may be cheaper to use than gasoline in some circumstances and might offer slight greenhouse gas-emission reductions. Methanol from coal also could be cost-competitive with gasoline, but with a 10 to 75% increase in greenhouse gas emissions (DeLuchi, 1991).

Alcohol fuels can be produced in a variety of ways from any of several sources. Life-cycle greenhouse gas emissions depend on the source and conversion technology (DeLuchi, 1993; IEA, 1993a), as Table 21-6 shows. Ethanol is produced from sugar cane for transport use in several countries, including Brazil, Zimbabwe, and Kenya. Full fuel-cycle greenhouse gas emissions are estimated to range from 30 to 50% of those that would be obtained with gasoline where bagasse (crop waste) is

used as fuel for conversion facilities to around 80 to 90% where coal is used (estimates based on Goldemberg and Macedo, 1994; IEA, 1994b; Rosenschein and Hall, 1991). N_2O emissions from agriculture form a substantial but uncertain component of these estimates.

Ethanol is produced from corn on a large scale in the United States, where it provides about 0.5% of gasoline demand in energy terms. It is produced from wheat and sugarbeet on a small scale in Europe. Cars using ethanol produced from these food crops would have life-cycle greenhouse gas emissions ranging from 20% of those from gasoline cars when crop waste is used as the conversion fuel (not the current practice anywhere) to nearly 110% where coal is used (Table 21-6; IEA, 1994b).

Hydrogen can be used either in internal combustion engines or in fuel cells. Where hydrogen is produced from renewable sources—either by gasification of biomass or by electrolysis of

Table 21-6: *Life-cycle greenhouse gas emissions and costs for alternative fuel and electric cars (based on DeLuchi, 1992, 1991; IEA, 1993a[a]; CEC, 1992; Pischinger and Hausberger, 1993; Goldemberg and Macedo, 1994; DOE, 1991, 1990, 1989).*

[a] Both the work of the IEA and that of Pischinger are based on a model developed by DeLucchi (1991, 1993).

[b] Average driving cycle based on gasoline car consuming 7 L/100 km; GWPs are for 100-year time horizon (CH_4, 26; N_2O, 270; CO, 3; VOC, 11; NO_x, 0). These differ from the latest IPCC values (IPCC, 1995), but the effect on total life-cycle emissions estimates is negligible.

[c] Based on Renault Clio 1.4 liter, 13800 km/year, 10-year life, 10% d.r.; levelized cost calculations based on IEA, 1993.

[d] Assumes current industrial practices. Ranges reflect differences between regions.

[e] Ranges reflect differences between primary energy sources and conversion technologies.

[f] Ranges reflect differences in vehicle technology, maintenance, and operation.

[g] Emissions based on urban cycle, consuming 200–300 Wh/km from mains (IEA, 1993a; CEC, 1992; DeLucchi, 1993; Eyre and Michaelis, 1991).

[h] DeLucchi (1991) and IEA (1993) ignore emissions associated with electricity-generating plant and electricity-grid construction. In fact, some CO_2 emissions will occur during plant construction, both from energy use and from cement manufacture. Emissions also may result from the flooding of land for hydroelectricity production.

Box 21-1. Ethanol in Brazil

Brazil has used small amounts of ethanol for decades as an octane enhancer in gasoline and as a byproduct market for the sugar industry. However, in the late 1970s, rising oil prices combined with high interest rates and a crash in the world sugar market to create a foreign-debt-servicing crisis. This compelled the Brazilian government to look at ways of reducing petroleum imports.

From 1975 to 1979, the government-sponsored program, Proalcool, increased the ethanol percentage in gasohol to 20%. From 1979 to 1985, Proalcool promoted the use of dedicated ethanol vehicles. In 1986, ethanol vehicles constituted 90% of new car sales, but a further expansion of the program was mothballed because of the drop in the price of oil. In the first phase of the program, the government provided up to 75% subsidies for ethanol-producer investments and assured a 6% return on the investments. At this stage, however, car manufacturers were unwilling to produce ethanol-only vehicles. In the second phase, consumer incentives were introduced for vehicle purchases, and the pump price of ethanol was guaranteed to be no more than 65% that of gasoline. The car industry was encouraged by the government's commitment and started producing ethanol vehicles. Despite initially poor redesign of engines, the consumer take-up was massive.

In late 1980, the world sugar market was improving, and the government began to increase the ethanol price from 40% of the of gasoline price toward the 65% limit. Credit subsidies for distilleries also were suspended. The result was a rapid fall in ethanol-vehicle purchases. The government later regained public confidence by restoring incentives.

Costs of ethanol production in Brazil are around 25 to 28¢/L of gasoline displaced, compared with world market prices of gasoline on the order of 17¢/L (pump costs are usually about 10¢/L higher). The government's current limit on the pump price of ethanol is 80% of the gasoline price.

---

water with electricity from renewables—life-cycle greenhouse gas emissions can be very low. The method of hydrogen storage aboard the vehicle can affect life-cycle emissions. If hydrogen is liquefied for storage, the energy input is about one-third of the energy content of the hydrogen; emissions, of course, will depend on how this energy is supplied (DeLuchi, 1993; ETSU, 1994).

Several trials have been carried out, with varying success, of hydrogen cars with Otto-cycle engines. Fuel consumption could, in theory, be 15 to 20% lower than that of gasoline engines on an energy basis (Brandberg *et al*., 1992; DeLuchi, 1991; ETSU, 1994). Considerable technical development will be required in the various stages of hydrogen production, distribution, storage, and use before it is economical to use in cars and its safety can be fully demonstrated.

21.3.3.2. Alternative Fuels in Heavy-Duty Vehicles

Buses have been operated on LPG, CNG, alcohols, and vegetable oils, and there are several demonstration programs and commercial operations throughout the world. Fewer studies have been carried out into life-cycle greenhouse gas emissions from heavy-duty vehicles than from cars. However, Figure 21-7 shows results from one study (DeLuchi, 1993; IEA, 1993a). This study shows that most of the immediately available alternative fuels for heavy-duty vehicles are unlikely to offer life-cycle greenhouse gas emission reductions. The main reason for this conclusion is that CNG and LPG are used in spark-ignition engines with lower efficiency than existing diesel engines. Alcohols can be used in compression-ignition engines, but expensive fuel additives are required, and spark ignition engines usually are preferred.
Figure 21-7: Life-cycle greenhouse gas emissions from heavy-duty vehicles with alternative fuels (DeLuchi, 1993; IEA, 1993a).

Box 21-2. CNG in New Zealand

The New Zealand government launched a compressed natural gas (CNG) program in 1979, aiming for 150,000 post-assembly vehicle conversions to CNG by the end of 1985. The main motivations for the program were to enhance New Zealand's energy security and improve its balance of payments. Incentives were provided in the form of grants and loans for vehicle conversion and filling-station development. The cost of car conversion at the time was about NZ$1,500 (US$750 in 1984 prices); the government provided NZ$150. Initial take-up was poor, but it was improved in late 1980 by an increase in the grant to NZ$200 and increased subsidies to fueling stations, along with tax benefits to consumers.

A large increase in government support in 1983 included a low-interest loan for conversions. By 1986, 110,000 vehicles (11% of all cars and light trucks) had been converted, and New Zealand had 400 filling stations; CNG comprised 4.6% of road-transport fuel.

The rise in conversion rate was halted in 1985 when the government reduced support for the program because of perceptions that CNG was sufficiently favored by its low price relative to gasoline, the CNG industry was sufficiently well-established and no longer required government support, and world oil markets were more stable and less emphasis was needed on the development of indigenous energy sources.

The vehicle conversion rate fell from 2,400/month in 1984 to 150/month by 1987. By 1993, CNG sales fell to 42% of their peak level in 1985, contributing only 2% of road-transport fuel. In addition to the withdrawal of government subsidies to CNG, a number of factors may have contributed to this demise. One is the increase in CNG prices from less than half to about two-thirds of the gasoline price, at a time when oil markets have been quite stable. Another possible factor is a negative public perception of CNG resulting from a number of faulty installations in the early 1980s, a cylinder explosion in 1989, the poor performance of dual-fuel vehicles that were not optimized to operate on CNG, and the realization that carrying CNG cylinders substantially reduces luggage space. A third possible factor is a lack of industry enthusiasm for marketing the fuel, bearing in mind that most of the retail outlets are oil-company-owned filling stations.

Sources: Sathaye *et al*. (1989); New Zealand Ministry of Commerce (1994).

In the long term, alternative fuels, such as methanol and ethanol from wood, could be used in heavy-duty vehicles, producing life-cycle emission reductions of more than 50% relative to diesel vehicles. Meanwhile, developments in direct-injection, compression, or spark-ignition engines operating on CNG, LPG, and alcohols could lead to substantial improvements in efficiency with these fuels (CEC, 1992).

Another option not shown on Figure 21-7 is the use of synthetic diesel produced from renewable sources, such as wood. This strategy would allow existing, efficient diesel engine technology to be used with a fuel with very low full-fuel-cycle carbon emissions.

21.3.3.3. *Alternative Aviation Fuels*

Aircraft carry a large amount of fuel in proportion to their total weight (around half of the takeoff weight for a Boeing 747). In view of this, any alternative fuel has to have a high energy content per unit of mass. LNG and liquid hydrogen fit this requirement, and trials have been carried out with both (Grieb and Simon, 1990; Schäfer *et al*., 1992). In principle, both LNG and liquid hydrogen aircraft could have lower fuel consumption than conventional aircraft because of the lower weight per unit of energy in the fuel. Energy use depends on the additional weight of the fuel tanks, the design changes

required in the aircraft, and the energy required to liquefy the fuel. Overall greenhouse gas emissions from the use of these fuels, including emissions of NO_x and water vapor, cannot yet be predicted. The implications for climate change depend on the GWPs of high-level NO_x and high-level water vapor, which remain uncertain—as do the safety implications of using cryogenic methane and hydrogen in aircraft.

If low-carbon fuels are required for aviation, a safer alternative might be synthetic liquid hydrocarbons from biomass, although even these fuels may have drawbacks, such as poor thermal stability. It will be necessary to demonstrate the safety and reliability of aircraft engines that use synthetic hydrocarbons before they can be adopted for civil aviation purposes.

21.3.4. *Electrically Powered Transport Systems*

Many analysts believe that the most promising route for the development of transport systems, along with the rest of the energy economy, would be toward the use of either electricity or hydrogen as energy carriers (MacKenzie, 1994; Sperling *et al*., 1992; Sperling, 1995). This strategy would effectively make final energy use independent of the primary source of energy, allowing renewables such as photovoltaics, wind power, and biomass to be used interchangeably as the electricity or hydrogen source.

Emissions can be eliminated at the point of vehicle operation by the use of some form of electric drive. Power can then be supplied by oxidation of hydrogen in a fuel cell, from an electrical storage device, or directly from the public electricity supply. Electric motors have the advantage of high efficiency at part-load, no fuel consumption when stationary, and the potential for regenerative braking (where the motor is used as a generator to return power to the source or a storage device).

Battery electric vehicles have aroused interest mainly for their potential to reduce urban air pollution. Electric-vehicle technology has been reviewed in detail by several authors (CEC, 1992; DeLuchi, 1991, 1993; ETSU, 1994; IEA, 1993b; MacKenzie, 1994; Sperling, 1995). Life-cycle greenhouse gas emissions depend not only on the primary energy source but also on many aspects of the vehicle technology and the way it is used.

Electric-car technology has been intensively developed in several countries in recent years, mainly as a result of legislation in California. Batteries have so far provided the best combination of energy and power density, along with low cost for on-vehicle electricity storage. Battery-powered cars, buses, and light vans are in use, but they have high costs and poor performance compared with gasoline vehicles, and most types of battery would need replacing several times in the life of a vehicle. The future evolution of this technology and of the market for electric vehicles is very uncertain, depending on factors such as the extent of cost reductions that can be achieved in batteries, electric motors, and control systems; the extent to which battery-recharging rates, energy densities, and power densities can be improved; and market factors, including consumer preference and future legislation to reduce air pollution.

Alternatives to the battery are under development. Whereas batteries store energy in the form of chemicals that react to produce electric power, supercapacitors store energy in the form of electric charge, and flywheel storage devices store energy in the kinetic energy of a rapidly rotating flywheel. These devices may have the potential for much higher power density than batteries, with similar energy-storage density.

Some recent studies in California (Bunch *et al.*, 1993) indicate that, in choosing between conventional and alternative vehicles, car purchasers are likely to be particularly sensitive to the extra cost and shorter range of battery-powered and other alternative-fuel vehicles. Other studies in California (Sperling, 1995) have found that consumer preferences can be modified and that a substantial proportion of drivers might purchase electric vehicles to use for local trips and commuting, keeping their gasoline vehicles for other trips.

The range and durability limitations of batteries are avoided with fuel cells, which produce electric power directly from the oxidation of a fuel carried in a separate storage vessel. The fuel normally is hydrogen, although some fuel-cell types can use methanol or other fuels. Alternatively, methanol can be used to make hydrogen on board the vehicle. Of the various fuel-cell types, the solid polymer fuel cell (SPFC) is probably the strongest near-term candidate for an on-vehicle power source (Appleby and Foulkes, 1989; DeLuchi, 1993; ETSU, 1994). SPFCs have been tested in a van and a bus in Canada, with hydrogen from high-pressure cylinders. They are preferred over other fuel-cell designs because of their robustness, long life, low operating temperature, quick startup, and reasonably high power density.

Currently available SPFCs cost well over $1,000 per kW of output, although some analysts predict future costs as low as $20 per kW (Sperling, 1995). For comparison, gasoline engines cost $20 to 40 per kW. A fuel-cell vehicle probably would use the fuel cell to provide a constant power output, with a battery to store power for peak-load requirements. Costs per kilowatt for such systems would be lower than those for a fuel cell sized for peak loads. Nevertheless, given the technical and cost improvements required, fuel cells are unlikely to be in widespread use for cars before 2025. They will face institutional and other challenges similar to those confronting alternative fuels in general. However, if the various barriers to their use can be overcome, fuel-cell cars could be the predominant mode of motorized travel by 2050.

Many hybrid concepts have been suggested and demonstrated, combining the advantages of electric drives and internal-combustion engines. One approach involves using a low-powered fuel-burning engine to run a generator that provides a constant supply of electric power (see, e.g., Lovins *et al.*, 1993). This is either used directly to power electric motors or fed to a peaking storage device, which might be a battery or flywheel. A major theoretical advantage of such a system is that the engine can operate under its optimum speed and load, and braking energy can, in principle, be recovered and stored. In principle, energy savings in urban driving could amount to 40 to 60%. However, with current technology, energy savings are likely to be very small because efficiency is constrained by energy losses in the electric generator, storage device, and motor; matching the engine and electrical storage device to real on-road power requirements is difficult; and existing batteries are unable to recharge at the rates required to store a useful portion of energy from the engine and from braking. Flywheels may be more appropriate for this purpose, and the concept is under development. Hybrid technology is not likely to achieve substantial market share in the short term without government intervention, in view of the high overall cost of an electric motor, control system, and battery or other storage device. It might be feasible to produce hybrid vehicles on a competitive commercial basis some time between 2005 and 2025.

Direct electric power has long been used in light-rail systems and trolleybuses, as well as in electric trains. Urban bus and light-rail routes involve low speeds and frequent stops. In these circumstances, the features of electric drives are very attractive—in particular the capability for regenerative braking, the avoidance of energy use when stationary, and the absence of emissions at the point of use.

Trolleybuses are in use in numerous cities throughout Europe. They are lighter than battery buses because they do not have to

carry an electricity source. They also allow for a more efficient use of grid electricity and a better capability for regenerative braking. Whereas the overall efficiency from grid electricity to motive power for a battery-powered vehicle is about 55%, that of a trolleybus is about 75 to 85%.

Several proposals exist for personal passenger-vehicle systems based on direct electric power. These range from cars supplied with electricity via induction coils placed under the road surface to monorail systems with vehicles powered by linear motors. Some designs involve the use of computer-controlled vehicles for public use. Others provide for the use of private cars off the system using batteries or other power sources. Such systems are potentially an efficient means of using electric power for personal transport.

21.3.5. High-Speed Trains

High-speed trains can have higher energy use per seat-kilometer than traditional trains but much lower energy intensity than cars or aircraft at typical load factors. Their role in greenhouse gas emission reduction is subject to debate and will depend heavily on the situations in which such trains are used: They may attract passengers without reducing the use of other modes, resulting in higher overall energy use and greenhouse gas emissions. Nevertheless, high-speed rail lines between Paris and Lyons in France and between Madrid and Seville in Spain have been remarkably successful in attracting business from the roads and the airlines, and have been profitable.

An alternative to the high-speed train is "maglev": trains that are levitated on a magnetic field rather than having wheels in direct contact with tracks. The only existing maglev systems in use are small-scale local shuttle or transit systems. Maglev trains may have some energy-efficiency advantage compared with wheeled trains at a given speed, but analyses differ on this (Schäfer *et al*., 1992). Rolling resistance (25% of energy use in a normal high-speed train) is avoided, but energy is required to power the magnets. The main advantage of maglev trains is that they can operate at higher speeds than wheeled trains; the Transrapid line to be built from Hamburg to Berlin will operate at up to 450 km/h. This means that they can compete with air travel over longer distances than existing high-speed trains—potentially as far as 1,500 km. Maglev trains have the disadvantage compared with high-speed trains that, unless provided with auxiliary wheels, they cannot use existing stretches of track to penetrate urban areas and serve destinations without new infrastructure.

21.3.6. National and International Technology Policy

Governments can take various kinds of action to influence technology development and deployment. Some, such as basic research and development, are aimed at bringing technology to the point where industry can further develop it to produce new products and sell them in the market. Others, such as fiscal and regulatory incentives and funding for demonstration programs, are aimed at encouraging industry to carry out its own research or to market different products and encouraging consumers to buy them.

Research and development is usually difficult to plan on a rational, economic basis. Scientific breakthroughs are inherently unpredictable, and even if a technology is successfully developed its market success is also unpredictable. Fundamental research often depends for its existence on some form of government intervention, whether this is direct funding, tax exemptions for firms undertaking research and development, or information brokering. Meanwhile, national investment in research may be justified on cultural grounds as well as on economic grounds. Contributions to international scientific ventures often are motivated by international relations as well as by an interest in cost-effectiveness.

Important areas for fundamental research relating to transport technology include recyclable materials for cheap, robust, lightweight vehicles; materials with special properties for high-efficiency engines, turbines, flywheels, and so forth; advanced conversion technology for liquid fuels from biomass; electrochemistry for batteries and fuel cells; power electronics for electric-propulsion-system management; power-transmission technologies for vehicles powered directly from the mains; and information technology for vehicle and traffic optimization. There is also a need for social and economic research—for example into consumer behavior and choice, including attitudes toward new technology.

Interventions in the market may have the advantage that government does not necessarily have to attempt to "pick winners" among technologies or bear the risk of investment in research that may not bear fruit. However, this risk does have to be borne by manufacturers that wish to remain in the market and have to respond to the government's intervention. One example of a technology-forcing intervention is the California Air Resources Board's strategy for encouraging the development of zero-emission vehicles (see Box 21-3). Meanwhile, a strategy of announcing a timetable for gradually tightening standards or increasing fiscal incentives, aimed at reducing greenhouse gas emissions, will encourage industry both to introduce currently available technology and to develop new technology.

21.4. A Transport-Policy Perspective on Greenhouse Gas Emissions

While technical changes can, in theory, reduce greenhouse gas emissions by 80% or more for a given transport activity, such changes are not occurring under current market conditions. Meanwhile, in most countries, transport-activity growth is faster than the rate of energy-intensity improvement.

Section 21.4 explores different viewpoints that influence policymaking, identifies areas of transport policy that can influence

---

Box 21-3. CARB Strategy for Encouraging Zero Emissions Vehicles

California's urban air-quality problems have long been recognized as more severe than in other regions of the United States. The California Air Resources Board (CARB) introduced the Clean Fuels and Vehicles Plan in September 1990. The plan imposes progressively lower emission standards on vehicles from 1994 onward. VOC emissions must be cut 80% below 1994 levels by 2000.

Under the legislation, vehicles are given one of four new emission classifications: transitional low-emission vehicle, low-emission vehicle, ultra-low-emission vehicle, or zero-emission vehicle. Manufacturers' sales-weighted VOC emissions calculated from their sales of each vehicle type must not exceed a prescribed level in a given year. A banking and trading system permits manufacturers to earn marketable low-emission credits.

CARB's specifications for reduced summer gasoline volatility, elimination of lead, and the use of detergent additives came into force in 1992. Further tightening of gasoline specifications is expected.

Alternative fuels are being promoted by CARB and through the federal California Pilot Vehicle Program. The fuels are expected to help satisfy low-emission requirements. They include M100, M85, CNG, and LPG. At least 90 Southern California filling stations must supply alternative fuels by 1994, rising to 400 by 1997. From 1994 onward, 200,000 new low-emission vehicles per year (about 10% of the state's new-car fleet) must be sold in California. Alternative-fuel use is also being encouraged through tax exemptions.

Electric vehicles will be required to satisfy the zero-emission-vehicle requirement from 1998 onward. They will have to make up a minimum of 2% of annual new-car sales by companies selling more than 30,000 cars per year in California; the share is scheduled to rise gradually to 10% by 2003. Electric-vehicle use in California is likely to result in greenhouse gas emissions significantly lower than those associated with gasoline-vehicle use because much of the power generation in the state is from non-fossil-fuel sources or natural gas.

---

greenhouse gas emissions, and examines policy options for emission reduction.

Transport policymakers' central aims are usually to maximize mobility and access to services, enhance economic activity, and improve safety. These aims have to be balanced with energy and environment goals, especially those of reducing urban air pollution and greenhouse gas emissions. At the same time, policymakers have to consider the political acceptability of their measures, as well as their ease of implementation and their effects on equity and social welfare generally.

21.4.1. *Stakeholders and Viewpoints in Policymaking in the Transport Sector*

Policymakers and other stakeholders typically are involved in the transport sector in several different ways:

- Local public-transport authorities or firms make decisions regarding public-transport scheduling and investment, aiming to maximize fare revenue, minimize costs, and in some instances to provide a minimum level of service.
- Local or municipal authorities make many decisions regarding transport policies, urban road layout, parking facilities, urban traffic management, and facilities for walking and cycling. Their objectives include improving access; reducing road congestion, accidents, and noise; and, more recently, reducing air pollution—all within a fixed budget.
- Decisions regarding the development of highways, railways, and other transport infrastructure are usually made by national transport ministries, which often define the parameters within which local transport authorities work and provide funds for infrastructure and services. Transport ministries have traditionally aimed to maximize mobility and access for both freight and motorized passenger transport in a cost-effective manner, sometimes including social costs associated with congestion, accidents, noise, and air pollution.
- Vehicle emission standards are often negotiated between government departments of environment, transport, and industry. Emission standards for road vehicles and aircraft (ICAO, 1993) are, in many instances, agreed between governments—in consultation with industry and other interest groups—with the mediation of intergovernmental organizations.
- Vehicle and fuel taxes are of interest to transport, industry, and energy departments, but they often are determined by finance ministries.
- Transport research and development is undertaken by a range of interests, including various government departments, universities, and other research institutes, as well as vehicle manufacturers and transport-system operators.

- Transport-system users make day-to-day decisions regarding vehicle purchase and utilization but normally have limited influence on transport policy.

Differences in the priorities of decisionmakers have much to do with differences in training, approach, and worldview associated with the professions most involved in each area of policy. Dimitriou (1992) provides a characterization of fields of expertise:

- Engineers often emphasize the operational efficiency of transport systems and usually offer solutions based on technology or the design of infrastructure.
- Economists usually emphasize economic efficiency, aiming to maximize the benefits minus the costs of the transport system. Their solutions tend to focus on improving the functioning of the market.
- Other social scientists, such as sociologists, political scientists, anthropologists, and development planners, are less likely than engineers or economists to use formalized concepts of optimization. Their solutions are likely to focus on institutions, community involvement, and consultation.
- Physical planners (architects, city planners, and transport planners) tend to view transport issues as part of a wider picture of urban development. Their solutions tend to relate to the spatial organization and design of infrastructure.

Politicians, environmentalists, and other interest groups (including transport-user associations) may draw on a variety of these viewpoints and solutions in identifying their preferred transport strategies. To bring transport policy to bear on the aim of reducing greenhouse gas emissions, it will be important to bring the different professions and viewpoints together to develop robust strategies that satisfy all of their criteria and make use of all of their insights and techniques.

21.4.2. Planning, Regulation, and Information Measures

Traditional approaches to transport planning have concentrated on providing sufficient roads to carry projected volumes of traffic and on smoothing the traffic flow. Many planners now recognize that it is impossible to provide sufficient roads to carry unrestrained projections of traffic in urban and perhaps some interurban areas, and that extra road provision can stimulate traffic growth, leading to congestion elsewhere (Goodwin *et al.*, 1991). Increasingly, the objectives of transport are seen as moving people and providing access to services, jobs, and homes rather than moving vehicles. The planning emphasis is on alternatives such as improving the traffic flow, encouraging the use of public transport and nonmotorized transport, and discouraging car use.

Improving the traffic flow in cities to reduce stop-start driving can reduce the energy use per vehicle-kilometer as well as emissions of local pollutants (Ang *et al.*, 1991; Hausberger *et*

al., 1994; Joumard *et al.*, 1990; Tanja *et al.*, 1992). Many measures to improve traffic flow, such as computerized traffic-signal control, actually increase the capacity of the road network so that traffic volumes may increase unless traffic levels are restrained in some way. Provided that traffic is restrained—for example, by limited parking provision, tolls, or fuel taxes or through constraints on vehicle access—the introduction of computerized signal control may lead to energy savings of 10 to 15% (Ang, 1992).

Encouraging public-transport use and nonmotorized modes. Travel by bus, train, foot, or bicycle usually involves lower greenhouse gas emissions per km than travel by car (see Section 21.2.5) and also can reduce wider social and environmental damage. People's willingness to use low-energy-intensity transport modes depends partly on the quality of travel by those modes. Planners can influence this by providing infrastructure, such as pedestrian and cycle paths, bus lanes, and railways. Public-transport use can be increased by providing better information about services, reducing fares, and improving the quality of the service. Flexible services, such as shared taxis and "dial-a-ride" minibuses, can play a role. Improvements in public transport rarely have proved to be an effective means of stemming the rise in private-transport use unless combined with measures to limit the attraction of car travel, such as access and parking constraints. Experience in Hannover, Zurich, and other cities indicates that such combined approaches can be successful (Brög, 1993; Goodwin, 1985; Ott, 1993). Lessons learned in these cities may have particular relevance for cities in Central and Eastern Europe (Suchorzewski, 1993).

A UK study in the 1970s found that the degree of hilliness and perceived safety were the main determinants of the share of trips by bicycle in a number of towns (Rowell and Fergusson, 1991, quoting Waldman, 1977). While it is hard to modify hills, safety and security are important keys to maintaining and promoting levels of cycling and walking. Safety for cyclists can be improved by providing physically separated cycle lanes on and off roads and by giving cyclists priority over motorized traffic at junctions. Security against cycle theft can be improved by providing appropriate parking facilities. Safety for pedestrians can be improved by providing and maintaining footpaths, providing lighting at night, and ensuring safe means of crossing roads. For rickshaws and carts, similar facilities are effective—in particular separated lanes on roads so they do not have to compete for and disrupt traffic.

Discouraging car use. Cities that have succeeded in promoting nonmotorized and public-transport use have done so partly by making car access more difficult. This has been accomplished in two main ways: pedestrianization of town centers, and "traffic calming"—most frequently in residential streets—with a combination of engineering, design, psychological, and architectural methods to slow vehicles down, alter the "balance of power" away from vehicles and toward pedestrians, and restrict car use.

Approaches include the conversion of existing road space to cycle and bus lanes or "high occupancy" lanes for shared cars;

restrictions on parking; limits on vehicle access to certain city areas or on movement between parts of a city; and motor vehicle-free zones. Restrictions on vehicles can result in evasive actions by drivers that lead to higher levels of traffic, energy use, and pollution in other parts of the city. However, if measures are planned well, residents and local businesses frequently are pleased with the results (Ott, 1993). The best schemes have resulted in increased safety, a more pleasant street environment, and improved retail trade (Hass-Klau, 1990, 1993). Poorly designed schemes can make emissions worse (for example, speed bumps that are too far apart encourage acceleration and deceleration), but in general these policies are seen as reinforcing the attractiveness of public transport and deterring traffic growth. The effectiveness of a strategy may hinge on consultation with the local community on its preferred approaches. Flexibility also can be an essential component: Counterproductive effects cannot always be anticipated, and it is important to monitor the results of measures to identify necessary changes.

Urban structure affects the distance people travel to meet their needs. Travel patterns may be influenced by many factors, including the size of settlements, proximity to other settlements, location of workplaces, provision of local facilities, and car ownership. Changes to settlement planning and regulation have been proposed as means of reducing car use and encouraging public transport and nonmotorized travel (Newman and Kenworthy, 1989). However, the link between settlement patterns and energy use for transport is controversial, and analysts have produced conflicting recommendations (Banister, 1992). While there does appear to be an inverse correlation between urban density and transport energy use (Armstrong, 1993), experts disagree on the desirability and effectiveness of densifying existing dispersed populations to reduce energy use. The trend toward lower urban density may result from people purchasing homes in locations with lower land prices where they have an improved quality of life. Attempts to reverse this trend may depend on addressing the welfare implications directly through measures to improve the physical and social environment in high-density areas. Policies that directly discourage the use of energy-intensive transport modes are likely to be more effective in reducing energy use.

In the short term, the greatest potential for urban planning to affect transport energy use is in rapidly developing cities where the car is still a minority transport mode. In such cities, infrastructure development focused on provision for cars and trucks could accelerate the growth in use of these modes and the decline in use of less energy-intensive modes. Provision for nonmotorized modes in new infrastructure is an important enabling factor for policies to encourage the use of these modes and discourage car use.

In the long term, around 2025 to 2050 and beyond, changes in travel culture and lifestyle combined with changes in urban layout might lead to substantial reductions in motorized travel in North American and Australian cities. The potential reduction in European cities is smaller because a higher proportion of access needs already are met by walking and cycling.

21.4.3. National Transport Policy

National transport policymakers influence the decisions taken by local transport and urban authorities through regulations, grants, planning guidelines, provision of information, and other means. National governments can contribute to local initiatives by providing coordination, information, and encouragement to local authorities considering measures that affect energy use and greenhouse gas emissions.

National governments may have a responsibility for a variety of regulatory measures that can influence vehicle fuel economy and greenhouse gas emissions. These measures might include speed limits, vehicle emission standards, and maintenance checks, as well as more direct measures, such as vehicle fuel-economy standards (see Box 21-4).

Drivers are more likely to change their vehicle choices and driving behavior in ways that reduce environmental impact if they understand that impact and are motivated to reduce it (Jones and Haigh, 1994). National measures can include advertizing and information campaigns, as well as the incorporation of energy- and environmental-awareness elements in the school curriculum and driver training. Standards in advertizing also are normally set at a national level. Information-based policies are likely to be most effective if they are maintained over long periods and are linked to changes in fiscal and regulatory policy.

National governments may have a direct involvement in the provision of rail and bus services through ownership, subsidies, franchises, and regulation. Many of the means of encouraging passengers to use these services are similar to those that apply to urban public transport; the most effective measures are likely to be those that discourage car use.

National transport policymakers can influence freight-transport patterns through measures applied to road-freight vehicles and their use. Vehicle licensing fees are often a significant element in road-haulage costs and can be used as a measure either to discourage road freight or to encourage the use of vehicles with lower power-to-weight ratios. Vehicle standards, including safety requirements, weight limits, and emission standards, also can influence vehicle choice and mode choice.

Where goods can be shifted from road to rail, the energy saving per tonne-kilometer can be zero to 50%. A variety of approaches have been developed to allow freight to be transferred easily between road and rail. The greatest energy savings are likely to be obtained with multimodal containers that can be moved between truck trailers and flat rail wagons. Cost savings can be significant for very long trains (100 wagons or more) traveling long distances because driver costs are greatly reduced.

21.4.4. Alternatives to Travel

Many of the needs that are met by the transport system could, in principle, be met by other means. Telecommunications, for

Box 21-4. Fuel-Economy Standards

In theory, the most economically efficient way of reducing car fuel consumption is through fiscal measures (which are discussed in Section 21.4.5). Higher fuel taxes tend to lead drivers to economize through driving more carefully, reducing the distance they drive, and choosing more energy-efficient vehicles. However, fuel taxes are difficult to impose in some countries. Consumers often have inadequate information about the cars they are buying and may not respond optimally to the price change. More complex price-based measures, such as taxes (or subsidies) linked to vehicle fuel economy, may be more effective in the long term, because they give consumers a direct incentive at the time of purchase to choose an energy-efficient vehicle.

An alternative or complement to taxation is to use regulations to require car manufacturers to sell more energy-efficient cars. There are advantages and disadvantages to this approach. Standards avoid the large transfer payments that might be required with a tax approach, given the low price elasticity of transport-fuel demand. On the other hand, improving fuel economy can lead to reduced driving costs and increased travel (the "rebound effect"), so that, while energy use and greenhouse gas emissions may be reduced overall, other environmental and social impacts of transport may be increased. Vehicle standards are sometimes criticized because they provide industry with insufficient flexibility to find the best technical solutions to complex problems. In the U.S. Corporate Average Fuel Efficiency (CAFE) program, this problem is partly addressed by allowing manufacturers freedom to determine the fuel economy of individual models, provided that the average fuel economy of their total sales of cars meets the standard. Companies that do not meet the required average fuel economy have to pay fines. Meanwhile, very-high-consuming cars are subject to a "gas guzzler tax," which is effective in limiting the fuel economy of cars sold (DeCicco and Gordon, 1995). A "sipper rebate" for very-low-consuming cars has been discussed, though never enacted. Manufacturers of alternative-fuel vehicles can claim credits against their corporate-fuel-economy average, allowing them to produce cars with higher fuel intensity.

While CAFE has generated considerable debate in the United States, Greene (1990) finds that the policy was a real constraint on vehicle manufacturers from 1978 to 1989 and that it had twice as much effect on car fuel economy as fuel price. However, the rebound effect was such that somewhere between 5 and 30% of the fuel-economy gain was lost through increased mileage (Berkowitz *et al.*, 1990; Greene, 1992; Jones, 1993).

example, might allow many trips to be avoided. The growth in service industries and associated office-based employment means that many types of work could be carried out in the home or in small regional offices connected to central offices via computer systems, faxes, and telephones. Similarly, an increasing number of transactions can be carried out through telecommunication systems. Much of the existing transport infrastructure in Europe and the United States was developed before such possibilities existed. Thus, culture has developed around travel to work, to shop, and for other purposes. Conversely, in many developing countries, telecommunication infrastructure is likely to precede efficient transport infrastructure. This offers opportunities for cheap access to employment and services that would not otherwise be available.

Telecommunications are likely to substitute for travel only to a limited extent. Indeed, improved communications may encourage more travel, as people develop closer working and social relationships over longer distances. At the upper end of the income scale, mobile telephones and electronic mail allow executives to maintain communication with their offices wherever they are, giving them freedom to travel while keeping in touch. However, at the other end of the scale, telecommunication systems may provide a means to economic growth without the traditional associated costs in infrastructure and the social and environmental burdens of rising levels of transport activity. In the long term, virtual-reality-based communication might

replace business and other travel, although the extent of this possible substitution cannot now be predicted.

21.4.5. *Economic Influences and Fiscal Measures*

Roads in most countries are built and maintained by governments and are available, subject to regulations mainly related to safety, for anyone who wishes to use them. While the costs of road provision are recovered through fuel or vehicle taxes in some countries, in others taxes are insufficient to cover the costs. MacKenzie *et al.* (1992) estimate that road users in the United States pay only 60% of infrastructure costs through taxes and fees. Apart from tolls for special kinds of infrastructure (bridges, tunnels, and motorways), direct payment for road use, or "road pricing," occurs only in a few, mostly experimental, situations.

In Europe, vehicle purchases constitute about 90% of total investment in road transport, with infrastructure investment only 10% (ECMT, 1992). Infrastructure in rail transport accounts for 65 to 80% of total investment, with rolling stock only 20 to 35%. There is no straightforward way to allocate infrastructure costs between freight and passenger transport, but indicative costs for roads in Europe would be US$0.015 to 0.025 per passenger-km and US$0.1 to 0.2 per tonne-km (based on ECMT, 1992). These represent about 5 to 10% of

passenger transport costs and a third of freight transport costs, respectively. In Western Europe, direct government expenditures on infrastructure related to car use are usually fully recovered from users through fuel or other taxes, although these taxes may not be explicitly intended to provide for a "road fund" as in the United States. Infrastructure costs for road-freight transport in some countries may not be fully recovered through taxes and fees. Charges reflecting these costs might add 10% to 30% to road-freight costs (Blok, 1991).

Most studies find that, when social and environmental damage are included, the costs not paid in money outlays by car and truck users have about the same order of magnitude as the costs paid (Button, 1990; DeLuchi *et al.*, 1994). Table 21-7 shows results based on several studies in OECD countries. The work by Button (1990) is based on earlier work by Quinet.

From the point of view of transport and environment policy, it is important to understand which of the costs of transport are born by users and which are not. Where users do not bear the full cost of transport, they are likely to make more use of transport services than is economically efficient (Button, 1994). DeLuchi *et al.* (1994) find that, in the United States, motor-vehicle users bear about 70% of the overall cost of vehicle use (see Table 21-8). Most of the remainder relates to free parking provision and accident damage not paid for by insurance.

Environmental external costs amount to $0.02 to $0.1 per km driven by cars (Bleijenberg, 1994; DeLuchi *et al.*, 1994; IEA, 1993a; Kågeson, 1994; MacKenzie *et al.*, 1992). Kågeson (1994) gives total external costs for Germany in 1993 of 0.012 European Currency Unit (ECU) (US$0.015) per tonne-km in trucks. External costs for trains are about 0.005 ECU (US$0.006) per passenger-km and 0.004 ECU (US$0.005) per tonne-km.

Table 21-7: Estimates of total social cost (as percentage of GDP) of transport in OECD countries.

Cost Item	Road[a]	Other Modes[a]	All Transport[b]
Noise	0.10	0.01	0.3
Local Pollution	0.40		0.4
Total Pollution			1–10[c]
Accidents	2.00		1.5–2
Total Travel Time	6.80	0.07	8.5
			(of which 2–3 is due to road congestion)
Use Expenditure	9.00	0.30	–
Total	**18.30**	**4.71**	**–**

[a] Button, 1990.
[b] Quinet, 1994.
[c] This depends on the assumed damage costs associated with global climate change.

Table 21-8: Costs of motor vehicle use in the United States (DeLuchi et al., 1994).

Cost Item	Percentage of Driving Costs
Money Costs of Driving	**40–45**
Paid by user	30
Public roads and services	5
(not recovered through taxes and fees)	(2)
Private sector costs not paid by user	
(mostly unpriced parking)	5–10
Non-Money Costs of Driving	**55–69**
Borne by user (includes travel time)	40
Not borne by user (mostly accidents)	15–20
(environmental effects on health)	(2–10)
Subtotal—due to road dust	1–7
Subtotal—due to fuel/exhaust emissions	1–3

The incorporation of nonmoney costs of driving as user fees or taxes is one of the most commonly discussed measures to reduce traffic congestion and pollution. The response of transport energy demand to costs, especially fuel prices, has been extensively studied since the early 1970s. Researchers find that:

- A 10% increase in fuel prices results in a 1 to 6% short-term reduction in demand, according to most studies (Dahl and Sterner, 1991; Fowkes *et al.*, 1993a; Tanja *et al.*, 1992), although the effect of price increases is not symmetrical with the effect of price decreases (Dargay, 1993). In the long term, fuel-price increases encourage the use of more energy-efficient vehicles, and a 10% increase in gasoline prices can lead to a 5 to 16% reduction in demand. The response to fuel price falls as incomes rise, all else being equal (Goodwin, 1992; Greening *et al.*, 1994). Where several fuels compete and can be used in the same vehicles, small relative price changes can have a large effect on fuel choice (Greene, 1989; IEA, 1993a).
- A 10% increase in car price leads to a 1 to 5% reduction in total fuel consumption (Tanja *et al.*, 1992), but there is a complex interaction between the price of fuel, the prices of new and second-hand cars of different sizes, car ownership, and car use (Mogridge, 1983). Differential vehicle taxes related to energy efficiency can be one of the most economically efficient means of encouraging the use of energy-efficient vehicles (DeCicco and Gordon, 1995).
- Car and truck use is not affected noticeably when the costs of other transport modes fall, although rising public-transport and rail costs may encourage users to switch modes. Rail and bus travel do depend strongly on the cost of car travel. Studies of the effects of transport costs have been carried out for different transport modes in many situations (Oum *et al.*, 1990;

Fowkes *et al*., 1993a, 1993b). In the United Kingdom, these studies indicate that a 10% increase in bus or urban metro fares reduces patronage by 3 to 4% in the short term and around 7% in the long term.

- Various factors in addition to transport costs and income affect travel activity, including household size, the occupation of the head of the household, household makeup, and location (Hensher *et al*., 1990; Jansson, 1989; Walls *et al*., 1993). People in higher-skilled occupations, requiring higher levels of education, are more price- and income-responsive in their transport energy demand than people in lower-skilled occupations (Greening and Jeng, 1994; Greening *et al*., 1994). Families are more price- and income-responsive in the early years of childrearing than in the later stages.

Road-use charges can, in theory, help allocate available road space in the most economically efficient way. Road-use fees can be used to reduce both the explicit subsidies for road building and maintenance and the implicit subsidies associated with the externalities of driving. By increasing the variable cost of driving, such changes can encourage travelers to share vehicles, travel shorter distances, or use alternative modes. They are expected to be most effective when charged to the driver at the time and point of use. Polak *et al*. (1994) have analyzed the long-term impact of the Area Licensing Scheme in Singapore and found that a 10% increase in the cost of peak-period travel resulted in a 7% reduction in peak traffic in the short run and a 12% reduction in the long run. Toll rings in the Norwegian cities Oslo and Trondheim have reduced traffic by 4 and 8%, respectively (Polak and Meland, 1994; Ramjerdi, 1992).

Parking fees can be an important component of any transport strategy. In many cities, employees are provided with free car parking at work. Studies in the United States (DOE, 1994) indicate that offering people in large cities the cash value of their parking place as an alternative would raise the effective cost of their trip to work by 116%. Of those offered the "cash-out," 23% would accept it in the long term and choose alternative transport modes to commute to work.

Many other market-based strategies have been proposed, ranging from "pay at the pump" insurance charges collected through filling stations to fuel-consumption permits that would be tradable between manufacturers.

Revenues from charges imposed on cars and trucks can be used to subsidize transport modes with lower social costs and greenhouse gas emissions. Nevertheless, while keeping fares low may maintain existing ridership, it is unlikely to attract many additional users from private transport without other measures.

21.4.5.1. Vehicle Taxes

Vehicle taxes are traditional sources of government revenue and controls on imports. Cars usually are taxed at a higher rate than

buses or trucks—a policy that promotes commercial activity as opposed to private car ownership. Many countries base purchase taxes or license fees on engine size or vehicle weight; this can be a powerful instrument to encourage the purchase of small, energy-efficient cars. In some African countries, taxes are used to discourage imports of second-hand vehicles, while, in others, vehicles older than five years are banned (Davidson, 1993).

Recently, several governments have considered the possibility of using "feebates": taxes for vehicles with high fuel consumption along with rebates for vehicles with low fuel consumption. Such a scheme is in operation in Ontario, Canada, with a tax ranging from Can$75 to 4,400 (about US$55 to 3,300) on new cars with fuel consumption over 6 L/100 km sold in the province; purchasers of cars with fuel consumption under 6 L/100 km receive a Can$100 (about US$75) rebate (Canada, 1994).

21.4.5.2. Fuel Taxes

Road-transport fuel taxes mostly are used as a means of revenue raising, often to cover the costs of infrastructure and other transport services. Differential taxes are used in many countries to encourage the use of cleaner fuels, such as unleaded gasoline and low-sulfur diesel, or alternative fuels, such as LPG, CNG, and alcohols. Taxes are usually higher on gasoline than on diesel, a cross-subsidy from car users to truck operators that has a side effect of encouraging the use of diesel cars. The implications for CO_2 emissions are not clear: Diesel cars on average have lower CO_2 emissions per km than gasoline cars, but since the fuel is cheap, their owners will tend to drive their cars farther than do gasoline car owners. On the other hand, if gasoline taxes are higher than they otherwise would be, gasoline-car owners will tend to drive less.

In the case of air travel, contracting states of the International Civil Aviation Organization have agreed on a policy that fuel used for international operations should be exempt from all taxes (ICAO, 1994b). The world average price for aviation fuel for international scheduled services in 1991 was US$0.2/L (ICAO, 1994c). A 10% increase in fuel prices would lead to roughly a 1.5% increase in total passenger-travel costs and might be expected to lead to roughly a 1% short-term decrease in travel (based on ICAO, 1992). The longer-term effect of fuel prices on aircraft energy efficiency is expected to be quite large because the aviation industry pays close attention to life-cycle cost-effectiveness in considering aircraft design.

21.4.6. Combining Measures

Success in reducing greenhouse gas emissions will depend on using combinations of different measures. This applies in particular to measures that aim to restrict travel or vehicle use. Constraints on car use can have unintended effects; parking controls implemented alone could lead to increased travel (NOVEM, 1992). People making short trips are more likely to

be discouraged by parking difficulties than those making long trips. Displacing short-trip traffic creates more parking space for long-trip traffic. Other measures such as fuel taxation, energy-efficiency standards, or more general road pricing could be needed to avoid an increase in energy use for long trips. Similarly, if air travel is constrained by airport congestion, the promotion of high-speed rail as an alternative to short-haul air travel may reduce the number of short-haul flights, opening airport takeoff and landing slots for long-haul flights and encouraging additional energy use.

Combinations of measures, including information and education, are needed to be effective in bringing about modal shifts. Drivers tend to underestimate the costs of car travel (partly because they only notice fuel costs) and overestimate the cost and inconvenience of travel by public transport (Brög, 1993).

Many cities have attempted to implement integrated transport policies, using a wide range of measures to reduce traffic and encourage the use of more energy-efficient, low-emission vehicles (ECMT/OECD, 1995). Usually, these attempts are hard to assess because it is difficult to judge what would have occurred if the policies had not been implemented. One analysis of the effect of the transport policy in Singapore is summarized in Box 21-5.

Box 21-5. Singapore: Effects of Integrated Transport Policy

Singapore is a small island state with 2.8 million people in an area of 633 km² (44/ha). Since the early 1970s, it has adopted a variety of measures to control the traffic problems associated with high population density and rapid economic growth.

Computerized traffic-signal systems have been widely implemented in the central business district (CBD).

The *Area Licensing Scheme* (ALS), a road-pricing scheme introduced in 1975, was aimed at reducing morning peak traffic in the CBD. Drivers were required to purchase windscreen stickers, which were checked on entering the ALS zone. The program immediately reduced the number of vehicles entering the zone during the morning peak and shifted many people's morning commute habits. The success of the scheme led to its extension to include evening peak hours in 1989 and then to the whole day in 1994. In 1996, an electronic road-pricing system will replace the ALS.

The *Weekend Car Scheme* was introduced in 1991. Owners of cars registered under the scheme can normally drive only on weekends and receive a rebate on vehicle registration fees and import duty. They can purchase day licenses to operate their cars during the week in peak or off-peak hours.

Fiscal measures, including high import duties, vehicle registration fees, and annual road taxes, have been implemented to discourage car ownership. In 1994, import duties and registration fees amounted to 195% of car import values.

The *Vehicle Quota System* was introduced in 1990, limiting new registrations of cars and other vehicles. New-vehicle buyers have to bid for quota allocations in a monthly public auction.

Road tax increases with engine capacity, encouraging the purchase of small, energy-efficient cars.

Fuel tax is approximately 40 US¢/litre.

Public transport is of high quality, with buses providing a 20 km/h average service. There is a 67-km mass rapid-transit system, with more than half of Singapore's homes and work locations within 1 km of the route.

The *road network* has been upgraded and the capacity expanded constantly to provide more efficient transport links and to maximize the effectiveness of the road system.

Settlement planning is systematic, with colocation of homes, shops, schools, recreational facilities, factories, and offices in each of seventeen new towns or housing estates.

The result of this combination of measures on traffic and energy use has been estimated by Ang (1992).

Table 21-9: *Estimated 1990 fuel consumption in Singapore without car constraint policies (in millions of L).*

	Gasoline	Diesel
Actual Consumption	741	465
Impact of not having policy		
– Passenger traffic increase	+153	
– Modal shift	+218	-84
– Shift to larger cars	+52	
– Traffic congestion	+122	+77
Consumption without Policy	1286	458
Estimated Impact of Policy on Consumption	-42%	+2%

Source: Ang, 1992, 1993.

As the Singapore example illustrates, measures of many different types can be coordinated to achieve one set of policy objectives. Many other examples can be found, including Curitiba, Zurich, Hannover, Oxford, and Portland, Oregon, where coordinated policies have been used to slow or even reverse the growth in car use (Rabinovitch, 1993; Brög, 1993; Ott, 1993; ECMT/OECD, 1995).

Appropriate mixes of policies will vary between cities and countries. Birk and Zegras (1993) provide case studies of four Asian cities to illustrate different approaches to an integrated strategy for managing the environmental effects of transport. They summarize the potential for policy coordination in a matrix, on which Table 21-10 is based.

21.4.7. Implementation

Greenhouse gas emission reduction in the transport sector, more than in any other sector, depends on obtaining cooperation among the various stakeholders or interest groups who are able to take action or who might be affected by policies. Almost all members of society and all organizations have some involvement in the transport system. There are numerous overlaps between transport policy and other areas of government policy. Inevitably, there will be some clashes of interest, but there also will be areas of agreement. Where government departments and other institutions, organizations, and interest groups can agree on economic, environmental, and social aims, there will be more scope for a coordinated approach to transport policy. Coordination among regions is also important.

The following steps are important in any attempt to implement transport policies.

Understanding the current system and its evolution. Ideally this step would include:

- Carrying out surveys of vehicle flow rates and occupancies, analyzing the records of commercial transport operators, and requesting them or requiring them to keep records
- Employing economists and social scientists to evaluate the importance of different aspects of the transport system to its users
- Establishing processes for consultation with transport users and their representatives
- Examining past trends and evaluating a range of possible futures (a multidisciplinary team is more likely to produce a realistic view of the future than economists, planners, or engineers alone.)
- Considering uncertainty by developing several scenarios against which strategies can be assessed; a robust strategy is one that produces an acceptable outcome in all scenarios.

These activities represent a significant and ongoing commitment of resources to data collection and monitoring that may not always be possible. Information-collection efforts can be approached in stages and have to be designed in the context of the resources available.

Considering a wide range of measures. These might include taxes and fees, alternative-fuel promotion, standards for fuels and vehicles, land-use and infrastructure changes, and promotion of communication technologies.

Evaluation of options would ideally involve a cost-benefit analysis, taking account of all of the social benefits and costs of each measure. While social accounting might become a viable and valuable tool at some time in the future, such techniques are not currently available, and some analysts doubt whether they ever will be—or should be—developed. In the absence of a single quantitative evaluation technique, policymakers can make use of multidisciplinary teams to identify costs and benefits of the various measures and to provide a qualitative evaluation.

Consulting stakeholders. In addition to the importance of stakeholder consultation to obtain information about their needs and activities, measures in the transport sector are more likely to be effective if the people who will be influenced by the outcome are involved in the decision-making process. It is important for stakeholders to be given access to information in the development of transport policy and to be allowed to comment on and possibly correct it as the understanding of the system is developed. In many countries, some form of public consultation is a statutory requirement in the planning process. Consultation can be one of the most valuable steps in decisionmaking more generally, as it may generate new ideas, can help to select the most satisfactory outcomes, and can help to give the eventual users of the system a sense of ownership.

Monitoring and adjustment. Even the best-planned measures are likely to have unexpected outcomes. These occurrences are opportunities to learn and can be dealt with, provided sufficient flexibility is allowed for in the plans. A key to success, therefore, is to plan responsiveness into the decisionmaking process by continuing data collection and analysis to monitor the effects of measures and to allow decisionmakers to make follow-up decisions.

Table 21-10: *Matrix of transport system improvement options (derived from Birk and Zegras, 1993).*

Options	Situation		
	High level of existing infrastructure and strong influence on technology	Rapidly developing infrastructure and relatively little influence on technology	Small towns, relatively simple infrastructure, little influence on technology
Reducing Vehicle Emissions	Impose vehicle standards or emission-related taxes/rebates Set up inspection and maintenance programs Driver and police training for efficient driving and traffic control Public-awareness campaigns Research, development, and demonstration (RD&D)	Work with other cities and regions to encourage use of improved vehicles Set up inspection and maintenance programs Driver and police training for efficient driving and traffic control Public-awareness campaigns	Work with other cities and regions to encourage use of improved vehicles Set up inspection and maintenance programs Driver and police training for efficient driving and traffic control Public-awareness campaigns
Shifting to Cleaner or Alternative Fuels	Fuel-quality standards, mandates, and taxes Evaluate options for alternative fuels, especially in large fleets including public transport RD&D	Work with other cities and regions to encourage use of cleaner fuels Evaluate options for alternative fuels, especially in large fleets including public transport	Work with other cities and regions to encourage use of cleaner fuels Evaluate options for alternative fuels, especially in large fleets including public transport
Shifting to Modes with Lower Emissions	Provide facilities for nonmotorized modes Consider nonmotorized streets and zones Exclusive bus lanes and bus/tram priority Consider subsidies/fare controls for public transport Consider investment in public transport	Exclusive bus lanes and bus priority Segregate nonmotorized modes Consider possibility of rail conversion to exclusive bus lanes Consider subsidies/fare controls for public transport Consider investment in public transport	Begin to give priority to mass transit in urban transport policy Ensure access to public transport Exclusive bus lanes and bus priority in new development Segregate nonmotorized modes
Transport Demand Management	Regulate or charge for parking Consider vehicle-free zones or restrictions Consider road-user fees, and vehicle and fuel taxes Investigate telecommuting, etc., as alternatives to transport Carpool and high-occupancy vehicle incentives	Restrict on-street parking Consider vehicle-free zones or restrictions Consider road-user fees, and vehicle and fuel taxes Investigate improved communication as alternative to transport Carpool and high-occupancy vehicle incentives	Formal parking controls or fees Consider vehicle-free zones or restrictions Investigate long-term role of road-user fees to manage traffic Investigate improved communication as alternative to transport Car-pool and high-occupancy vehicle incentives
Transport Infrastructure Development	Computerized traffic control Maintain and provide infrastructure for nonmotorized and public transport Segregated nonmotorized and public transport corridors	Improved traffic control Maintain and provide infrastructure for nonmotorized and public transport Segregated nonmotorized and public transport corridors Consider bypasses	Improved traffic control Give priority to public transport and nonmotorized transport in new infrastructure
Land-Use Planning	Consider deemphasizing central zone as major focus of activity Encourage mixed use, non-motorized/public transport-oriented suburban development Promote mixed use and non-motorized/public transport access in urban redevelopment Discourage parking provision in development and redevelopment	Desegregate land use; allow mixed use in central business district Promote mixed use and non-motorized/public transport access in new development Encourage mixed use, non-motorized/public transport-oriented suburban development	Ensure transport development that enhances rather than hampers economic health of central business district Take transport trends into account and plan transport services in coordination with other development

CONTENTS

EXECUTIVE SUMMARY

This chapter provides a summary of current knowledge of options for reducing the emissions of greenhouse gases (GHGs) in human settlements. The largest portion of GHG emissions in human settlements is in the form of carbon dioxide (CO_2) from energy use in buildings (including emissions from power plants that produce electricity for buildings), amounting to about 1.7 billion tons of carbon. The other three major sources of GHG emissions are methane from urban solid waste (equivalent to 135–275 million tons of carbon in the form of CO_2), methane from domestic and industrial wastewater (200–275 million tons of carbon equivalent), and a variety of GHGs produced through the combustion of biomass in cookstoves throughout the developing world (estimated to be 100 million tons of carbon equivalent). This chapter does not cover CO_2 emissions from the combustion of biomass; this complex topic is treated in Chapters 15 and 24.

Regarding CO_2, we note the following:

- Residential buildings contributed 19% of total global emissions of CO_2 in 1990.
- Commercial buildings contributed an additional 10% of total global emissions of CO_2 in 1990.
- Industrial (primarily OECD) countries produced 63% of global CO_2 emissions in 1990; 19% came from the former Soviet Union and Eastern Europe and 18% from the developing world.
- Overall growth in emissions of CO_2 from buildings was slightly over 1% per year from 1973 to 1990. Almost all of this growth took place in the developing world and in the former Soviet Union and Eastern Europe.

Key Factors Affecting the Growth of Greenhouse Emissions

The potential for the greatest growth in CO_2 emissions—in both percentage and absolute terms—is in the developing world, where per capita energy consumption in human settlements is very low. Even in the industrialized countries, however, if policies to minimize such emissions are not enacted and rigorously carried out, the already high levels of CO_2 emissions can increase. The most significant factors influencing the growth of GHG emissions in human settlements are likely to be efficiency of energy use, carbon intensity of fuels used directly in human settlements or to produce electricity, population growth, the nature of development in the developing world, the nature and rate of global economic growth, and implementation of policies that are directed toward fulfilling national commitments to reducing GHG emissions.

Technical and Economic Potential for Reducing GHG Emissions

Many cost-effective technologies are available to reduce energy consumption and hence CO_2 emissions. Some examples include more efficient space-conditioning systems; improved insulation and reduced air leakage in windows, walls, and roofs—leading to reduced heat losses; and more efficient lighting and appliances (refrigerators, water heaters, cook stoves, etc.). In addition, measures to counter trends toward higher ambient temperatures in urban areas through increased vegetation and greater reflectivity of roofing and siding materials can yield significant reductions in space-cooling energy requirements in warm climates. Finally, technologies for capturing methane gases and converting them to useful purposes exist and are cost-effective in many applications. Other technologies that can reduce or prevent the formation of methane (e.g., in landfills) are also increasingly available.

Policy Options

Policy options for reducing the growth of carbon emissions from human settlements include energy pricing strategies, regulatory programs, utility demand-side management programs, demonstration and commercialization programs, and research and development. Each type of program has been carried out, primarily in industrialized countries, and many have achieved significant energy savings.

Because there has been considerable experience with these policies in many industrialized countries and because the technical and economic potential for energy savings is still high even after many years of improved energy efficiency, improvements in energy efficiency will be possible for many years. The developing world has even greater opportunities to improve energy efficiency. However, resources need to be made available (especially collaborations in training activities and institution building) so that these countries can develop the expertise to bring about higher efficiency.

Energy Scenarios: Potential Impacts of Energy Efficiency

Many "business-as-usual" energy scenarios postulate a 2% annual growth in buildings' energy use—much like that observed during the past several decades. Under the assumption that developing-country economies continue their growth at current rates and that industrialized economies continue their

growth at a slower rate than in the past, this 2% annual growth in energy use in buildings assumes significant continued improvement in energy efficiency.

Aggressive energy-efficiency scenarios for buildings show reductions in overall energy demand growth of 0.5 to 1.0% per year. Over 35 years (1990 to 2025), a 2% annual growth rate leads to a doubling of energy use; 1.5% per year leads to a 68% increase; and 1% per year leads to a 42% increase. Thus, energy efficiency alone could contribute about half of the reductions needed to maintain 1990 levels of CO_2 emissions. Such energy efficiency scenarios, however, will require strong and significant policy measures, well beyond what has been adopted to date. In addition to energy and economic policies, the growth of CO_2 emissions will also depend critically on worldwide population growth.

During the same period (through 2025), technologies for control of methane emissions from landfills and wastewater can achieve relative emissions reductions comparable to those of energy-efficiency measures.

Scenarios for the longer term that are aimed at increasing the efficiency of energy use while providing needed energy services suggest that radical transformations in the ways energy is used are possible. A plausible case can be made for a society that meets human needs and aspirations that is not nearly as energy and resource intensive as today's society.

22.1. Introduction

We define human settlements as cities, towns, villages, and even sparsely settled rural dwellings and collections of dwellings. We are concerned with GHG emissions attributable to CO_2 emissions resulting from the production and distribution of fossil fuel and electricity needed for all energy-using activities that take place within residential buildings, CO_2 emissions from energy use in commercial buildings, and the release of methane gas to the atmosphere by processes currently used for waste disposal. This chapter excludes all transport and industrial sources of GHG emissions because these are treated in other chapters.

First we describe the nature of GHG emissions from human settlements to better understand what actions could stabilize or reduce these emissions. Next we review estimates of GHG emissions from human settlements; describe the key factors that affect the growth of these emissions; assess the technical and economic potential for reducing these emissions; and describe policy measures at the local, national, and international levels that can help reduce emissions. We have grouped countries into three categories: industrialized countries (OECD and several newly industrialized countries), the former Soviet Union and Eastern Europe (FSU/EE), and developing countries.

22.2. Historic Trends in GHG Emissions from Human Settlements

Carbon dioxide from energy use in buildings amounts to about 1.7 billion tons of carbon. The other three major sources of GHG emissions are methane from urban solid waste (equivalent to 135–275 million tons of carbon in the form of CO_2), methane from domestic and industrial wastewater (200–275 million tons of carbon equivalent), and a variety of GHGs produced through the combustion of biomass in cookstoves throughout the developing world (estimated to be 100 million tons of carbon equivalent).

22.2.1. *CO_2 Emissions*

Figure 22-1 shows trends in CO_2 emissions associated with residential and commercial consumption of fossil fuels for the three groups of countries. The data do not include emissions of CO_2 from biomass fuels; although their use in the residential sector of many developing countries is considerable, past and current consumption levels are very uncertain.[1] Further, it is difficult to determine what fraction of biofuels consumption represents net emissions. The IPCC Draft Guidelines for National Greenhouse Gas Inventories require that net CO_2 emissions from burning biomass fuels be treated as zero because these releases are considered within the category Land-Use Change and Forestry.

The majority (63%) of (non-biomass) global CO_2 emissions from the residential/commercial sector in 1990 came from the
Figure 22-1: Global CO_2 emissions from residential/commercial energy consumption (Scheinbaum and Schipper, 1993; Cooper, 1993; Meyers *et al.*, 1993b).

industrialized countries. The developing countries and FSU/EE each accounted for about 19% of the total, with those shares rising since the 1970s. Whereas CO_2 emissions from the industrialized countries in 1990 were at approximately the same level as in 1973, emissions from the developing countries and FSU/EE have grown because of population growth and an increase in per capita levels of energy services. The growth in FSU/EE emissions reflects a change in heating technology from stoves to district heat.

Figure 22-2 shows that residential buildings account for two-thirds of total CO_2 emissions from buildings in nine industrialized countries. Whereas emissions from energy use in residential buildings in 1990 were slightly below their 1973 level, emissions from commercial buildings have risen. This increase reflects both the growth in floor space and the important role played by electricity.

Estimates for 12 major developing countries for 1985 show the residential sector accounting for 70% of total residential/commercial CO_2 emissions (Sathaye and Ketoff, 1991). Because of uncertain definitions of residential and commercial building space in developing countries, these figures are highly uncertain. The residential sector is estimated to have used 75% of final residential/commercial energy consumed in the former Soviet Union in 1988 (Cooper and Schipper, 1991).

Figure 22-2 also shows emissions for residential energy disaggregated by end-use (Scheinbaum and Schipper, 1993). Space heating accounts for more CO_2 emissions than any other end-use, but its share of the total has declined. Energy use for heating per square meter of living area has decreased considerably in North America and Western Europe since 1973, mainly because of improvements in existing homes and the entry of new, more energy-efficient homes and heating equipment into the stock (Schipper and Meyers, 1992). The share of electric appliances in energy consumption has grown considerably

---

[1] Hall (1991) derives national estimates of biomass consumption for nearly all developing countries; the total for 1988 for all sectors amounts to 36 EJ, not far below the 47 EJ of commercial energy consumption. Human settlements account for an estimated 80–90% of total biomass use.
Figure 22-2: CO_2 emissions from residential and commercial energy consumption in the United States, Japan, former West Germany, France, United Kingdom, Italy, Sweden, Norway, and Denmark (Scheinbaum and Schipper, 1993; Cooper, 1993; Meyers *et al*., 1993b; Meyers, 1994).

since the early 1970s, as rising levels of ownership and increases in the size and features of some appliances have had more impact on energy consumption than have gains in appliance efficiency (Schipper and Hawk, 1991).

The evolution of emissions (or energy use) by end-use for the commercial sector of the industrial countries and for both the residential and commercial sectors of the FSU/EE and the developing countries is less well known. Space heating dominates energy use in both the residential and commercial sectors of the FSU/EE, with an estimated share of around 75% (Cooper and Schipper, 1991). In the developing countries, space heating accounts for only about 20% of total CO_2 emissions, with virtually all of that originating in China (Liu, 1993). Emissions associated with energy use by residential appliances and commercial-sector space conditioning have increased in the past decade.

Using the data and estimates described above, we estimate that the residential and commercial sectors accounted for 19% and 10%, respectively, of global CO_2 emissions from the use of fossil fuels in 1990 (Figure 22-3).

22.2.2. Non-CO_2 Emissions

Regardless of the method of harvest, burning of biofuels (and biomass in general) results in net emissions of methane (CH_4), carbon monoxide (CO), nitrous oxide (N_2O), and nitrogen oxides (NO_x) in addition to CO_2. Of these, methane (CH_4) is the most significant because of its larger global warming potential (GWP)—which is 24.5 times that of CO_2—and the large volume of emission compared to the other gases.[2] The data of Hall (1991) on global biofuels combustion indicate that methane emissions from this source in 1988 amounted to approximately 14 million tons. The GWP is about 100 million tons of carbon-equivalent, which compares to global CO_2 emissions from human settlements of approximately 1.7 billion tons carbon (C) (for a 100-year time horizon).

Methane from landfills and from the disposal of domestic and industrial wastewater constitutes the other main source of methane emissions associated with human settlements. Total global methane release from these sources is estimated to be 50 to 80 million tons, as discussed in Section 22.4.4. This amount corresponds to the equivalent of 335 to 535 million tons of carbon-equivalent (using a GWP based on a 100-year time horizon).

22.3. Factors Affecting Future Growth of GHG Emissions from Human Settlements

Future levels of GHG emissions from human settlements will be shaped by four basic factors: population, per capita level of energy-using services, energy intensity of the technologies used to provide those services, and energy sources used by those technologies.[3]

22.3.1. Population

Population growth rates depend on a complex mix of cultural, economic, and technological factors, as well as government policies. Declining birth rates are linked to increased economic security, improved health care, and improved opportunities for women, as

---

[2] We use a GWP of 24.5 for methane based on the IPCC report *Radiative Forcing of Climate Change*, 1995. The GWP corresponds to a GWP of 1 for CO_2 over a 100-year time horizon. In order to convert this into tons of carbon equivalent, the GWP is multiplied by the ratio of the atomic weight of carbon to the molecular weight of CO_2. Thus, to convert tons of methane to tons of atmospheric carbon equivalent, we multiply tons of methane by 24.5 x 12/44 = 6.7.

[3] If the energy source is electricity, the level of CO_2 emissions also depends on the mix of fuels used for electricity generation and the efficiency of generation and delivery.

well as access to birth-control techniques. The pace of urbanization, which depends in part on the extent of economic development in rural areas, also will affect birth rates. The willingness of countries to adopt and implement policies that limit population growth will play a major role in affecting future population levels.

Projections of population growth vary with the assumptions made about fertility rates and other factors. Recent projections from the World Bank (1993) show an average annual growth between 2000 and 2025 of 0.3% and 0.4% in the OECD and FSU/EE, respectively, but 1.4% in the developing countries. Among the developing countries, projected growth is much slower in China (0.8% per year)—which has and is expected to continue strict population-control policies—than in middle- and low-income countries (1.5% and 1.7%, respectively).

22.3.2. Activity Levels in the Residential Sector

The level of energy-using activity in the residential sector depends greatly on income growth and distribution, household size, and the cost of housing and home appliances. The real cost of most appliances has declined over time, which means that households outside the industrialized countries can acquire them at lower income levels than was the case for industrial-country households in the past. Levels of energy-using activity do not expand linearly with income because saturation of major energy-using equipment begins to appear at higher income levels.

22.3.2.1. Industrialized Countries

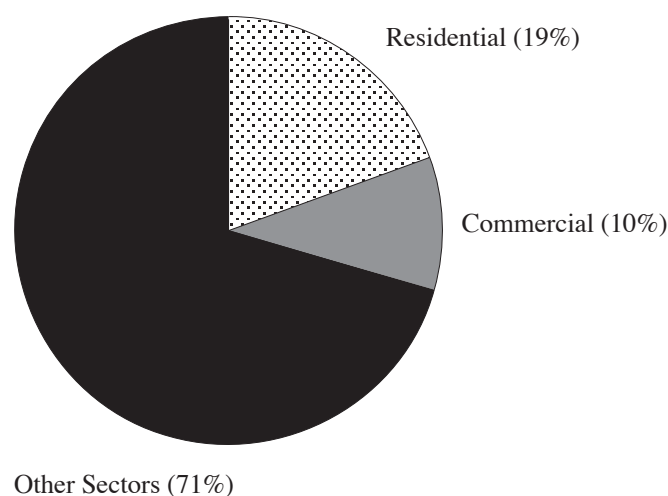
The number of households is increasing faster than population because of a decline in household size. Decline in household


Figure 22-3: Shares of residential and commercial sectors in global CO$_2$ emissions from energy consumption, 1990. Global emissions in 1990 are estimated as 5.75 billion tons of carbon, using the ratio of 1990 to 1985 global commercial energy consumption, and 1985 global CO$_2$ emissions given by the IPCC (1991). See text for sources of residential/commercial CO$_2$ emissions.

size will have the largest impact in Japan, which has much larger households today than the other industrialized countries.

Growth in per capita ownership of major appliances, which pushed household electricity use up considerably in the 1970s, will have a much smaller impact in the future because ownership of refrigerator-freezers, freezers, color televisions, and clothes washers is approaching saturation.

22.3.2.2. Developing Countries

The combination of rising population, urbanization, increases in per capita income, and further spread of electrification in rural areas will lead to tremendous growth in demand for residential energy services in the developing countries. Household size will fall with urbanization and decline in fertility rates, as has already occurred in newly industrialized economies in Asia. As in other parts of the world, this decline in household size will increase per capita energy use.

Changes in equipment and fuels will have a major impact on cooking, currently the most important residential end-use in the developing countries. The transition from biomass fuels to kerosene and liquefied petroleum gas (or electricity in some cases) already has occurred to a large extent in urban Latin American households and is proceeding rapidly in urban Asian households (Sathaye and Tyler, 1991). In much of sub-Saharan Africa, on the other hand, the transition to non-biomass fuels has been slowed because of a decline in incomes and fuel distribution problems. The transition will be much slower among rural households that have greater access to biomass resources as well as lower incomes.

Where electricity is not available, kerosene is generally used for lighting, providing much lower lighting levels and consuming far more energy than does electric lighting (Fitzgerald *et al.*, 1991). Thus, electrification will reduce energy use for lighting; at the same time, it will provide an enormous potential for growth in appliance ownership, especially in Asia and Africa. Market penetration of TV sets already is relatively high among electrified households, but penetration of refrigerators is still low (20 to 25%) even in middle-income countries like Thailand and the Philippines—and is lower still in populous countries such as India, China, and Indonesia (Meyers *et al.*, 1990). Refrigerator ownership will grow rapidly as the economies of these countries expand. The other major appliance whose penetration is likely to grow considerably is the automatic clothes washer.

A key uncertainty is the extent to which air conditioning will grow. Its market penetration currently is very low: 2% of homes in the Philippines, 1% in Thailand, and 4% in Brazil. However, the experience of Taiwan, where the proportion of dwellings with air conditioning rose from 12% to 29% of households in the 1980s, suggests that the use of air conditioning could rise in warm climates as households reach upper middle-income levels.

22.3.2.3. *Former Soviet Union/Eastern Europe*

Overall, increased demand for energy services in the residential sector in the FSU/EE will depend critically on how soon the region can reestablish its various economies. Following fundamental restructuring of the economies and economic recovery, the demand for increased energy services will be largely driven by two factors: increasing housing area per capita (which could rise very rapidly under favorable economic conditions) and increasing demand for appliances. Population is growing slowly, but household size (currently between 3 and 3.5 persons) will fall as more housing is built. House area may grow, particularly if private initiatives lead to increased construction of low-rise and detached (or semi-detached) housing. Central heating penetration will increase, particularly outside of large cities with district heat. Ownership of various electric appliances also will grow somewhat, as will their size and features.

22.3.3. *Activity Levels in Commercial Buildings*

22.3.3.1. *Industrialized Countries*

Between 1973 and 1988, the service sector grew 1.3 times as fast as total gross domestic product (GDP) in the United States, 1.4 times as fast in Japan, and 1.8 times as fast in the former West Germany. The service sector is expected to continue to grow more rapidly than GDP in the industrialized countries for the foreseeable future.

Expansion of service-sector floor space is likely to be especially strong in health-care (because of aging populations) and leisure-related buildings (because of increased leisure time among workers and growth in the numbers of retired persons). Both of these sectors are relatively energy-intensive.

22.3.3.2. *Developing Countries and Former Soviet Union/Eastern Europe*

Large increases in service-sector floor area will occur in the developing countries. Many types of services that have fed the growth of the commercial sector in industrialized countries are just beginning to expand in many developing countries. Hotels and other facilities for tourists also will grow substantially. In the public sector, growth in population will require a substantial increase in education and health-care buildings.

The FSU/EE region currently has less than 5 m² of service-sector area per capita—about half the level of Italy (Cooper and Schipper, 1991). Office and retail space will increase considerably to meet the demands of the emerging private sector. Growth also will occur in lodging and restaurants.

22.4. **Potential for Reducing GHG Emissions**

22.4.1. *Residential Buildings*

The potential for cost-effective improvement in energy efficiency in the residential sector is high in all regions and for all end-uses. Although a large majority of the net global CO_2 emissions from the residential sector is from industrialized countries, their share of the technical potential for improvement is somewhat smaller for two reasons. First, considerable improvement in the energy efficiency of existing homes, new homes, and equipment in the industrial countries has already taken place over the past two decades, prompted both by higher energy prices and by policies and programs. Thus, the potential for further cost-effective gains, while still considerable, is less than it was in the past.

Second, growth in both the number of households and in equipment stocks per household is increasing much faster in the developing countries than in the industrialized countries, and the average efficiency of new equipment is lower because of the need to keep initial costs low. Much of the new equipment uses electricity, and a good share of the growth in ownership is occurring in countries whose power supply is likely to be dominated by coal. Thus, there is much potential to affect future CO_2 emissions by improving the efficiency of residential buildings and appliances in these countries.

22.4.1.1. *Space Conditioning*

Space conditioning (heating and cooling) accounts for about half of residential CO_2 emissions from North America and Europe; the largest portion of this is heating rather than cooling. In contrast, relatively little energy is consumed for space conditioning in developing countries, with the important exception of China. This is due, in part, to the much warmer climate in the majority of developing countries and, in part, to the lower level of economic development. As these countries develop, air conditioning will consume rapidly increasing amounts of energy.

The energy consumed for space conditioning can be reduced through increases in the thermal integrity of buildings (i.e., improvements in walls, roofs, and windows), increases in the efficiency of space-conditioning equipment, and improved controls for such equipment. Other ways to alter buildings to reduce energy use include reductions in leaks in ducts carrying hot or cold air to the conditioned space (of particular importance in North America), design changes (e.g., the use of passive solar design), and environmental changes (e.g., the adoption of increased shading and wind breaks from trees and other vegetation). Finally, behavioral factors, such as the timing and level of indoor-temperature settings, have a great deal of influence on the energy use of residences.

Switching from high-CO_2 to low- or no-CO_2 energy sources also can reduce CO_2 emissions from space heating. In the industrialized countries, a significant shift to natural gas and

nuclear-generated electricity has already occurred during the past 20 years; further movement toward gas is likely in Western Europe. Eastern Europe and China have considerable potential for switching away from inefficient coal stoves to gas or district heating.

22.4.1.1.1. Building thermal integrity

Opportunities to enhance the energy efficiency of a building shell occur throughout a building's lifetime. Prior to construction, designs with proper orientation, adequate insulation levels, overhangs, and high-quality windows will reduce energy use. In construction, proper sealing and adequate and well-distributed insulation will reduce losses through building shells. Lastly, retrofits—such as the addition of insulation, and storm doors and windows, as well as reduction of thermal bypasses and air leakage—often can save considerable energy. Reducing infiltration is particularly important in many climates; techniques now exist to do this while minimizing the impact on indoor-air quality. So-called "low-energy" homes have demonstrated the technical feasibility of reducing heating requirements to very low levels through the use of high levels of insulation, passive solar design techniques, and other measures, but these have achieved only limited market penetration to date.

Low-emissivity (or low-e) coatings (clear coatings added to glass surfaces) allow the transmission of solar radiation into the interior but reduce radiative heat losses (Rosenfeld and Price, 1992). The addition of a low-e coating can reduce the heat losses of a double-pane window by about one-third. Low-e windows cost 10 to 20% more than regular windows and therefore are generally cost-effective. A double-pane window with gas-filled spaces and two suspended reflective films inside can reduce heat loses by 75%. Improvements in window frames—e.g., greater use of thermal breaks to limit conduction losses through the frame—offer another opportunity for energy savings.

A study for the former West Germany that evaluated homes of different vintages in five building types found that, on average, investments that save 40% of baseline heating energy would be cost-effective even when future energy prices are low (Ebel *et al*., 1990). A 50% reduction in energy expenditure, however, costs considerably more and would be cost-effective only when energy prices are high.

In the United States, recent studies estimate that energy savings of 30 to 35% could be attained between 1990 and 2010 through retrofits in dwellings built before 1975, but only about half of these retrofits would be cost-effective (EIA, 1990; Koomey *et al*., 1991). The energy-savings potential for dwellings built between 1975 and 1987 is somewhat less than that for those built before 1975. In the United States, an estimated 25% of residential heating and cooling energy use is associated with losses through windows (Bevington and Rosenfeld, 1990). Analysis for the U.S. housing stock suggests that most cost-effective, currently available energy-saving window systems

could reduce energy losses through windows by two-thirds (Frost *et al*., 1993).

Among industrialized countries, Sweden has gone the furthest in institutionalizing high levels of thermal integrity in new homes (Schipper *et al*., 1985). Adoption of Swedish-type practices, which rely heavily on factory-built components, in the rest of Western Europe and North America would probably bring a reduction of at least 25% in the space-heating requirements of new dwellings relative to those built in the late 1980s (Schipper and Meyers, 1992).

Building practices in Eastern Europe have resulted in energy efficiency that is well below Western levels (Cooper and Schipper, 1991; Meyers *et al*., 1993b). Although there are no reliable estimates for the magnitude of energy savings that could be achieved by improving the thermal characteristics of building shells, the potential is likely to be much greater than for Western Europe. Particularly large improvements are possible through reducing air infiltration, increasing roof insulation, and improving the performance of windows. Adequate metering and occupant control systems are needed.

In developing countries where the use of air conditioning is rising, improvements in building thermal integrity can reduce cooling requirements. A study for Thailand found that installing 7.5 cm of insulation in the attic of a typical single-family house would reduce air-conditioning requirements 30% (Parker, 1991). For new homes, building design, reflective materials, and landscaping strategies that minimize solar gains in the summer and enhance natural ventilation can eliminate the need for mechanical cooling even in warm climates and reduce cooling loads in hot, humid climates.

China has a large number of households in regions requiring heating, a large potential for growth in heating demand as restrictions on heating are eased, and heavy reliance on and inefficient use of coal. Considerable potential exists to improve building thermal integrity (especially in new buildings). Since indoor temperatures in most homes are lower than desired, some or even most of the savings from efficiency will go toward greater indoor comfort rather than reduced energy use. Even so, increases in wall and ceiling insulation and in the thermal characteristics of windows can reduce energy use by 40% relative to mid-1980s practice, while allowing a considerable increase in indoor temperatures (Huang, 1989). The government has introduced a standard that calls for new buildings in cities to be designed to use 30% less heating energy relative to 1980 practice, with implementation in the early stages (Siwei and Huang, 1992).

22.4.1.1.2. Space-heating equipment and
air distribution systems

In 1992, the United States set a minimum efficiency of 78% for new gas-fired, warm-air furnaces. However, units using "condensing" technology, in which the latent heat of water in the

flue gas is recovered, are far more efficient—in the range of 90 to 97%. At present, sales of condensing furnaces are 20 to 25% of total sales, even though their price is considerably higher (typically about $600 more than noncondensing units). The cost-effectiveness of these furnaces depends on the climate and the cost of fuel; measured energy savings from condensing-furnace installations in colder climates in the United States yield simple paybacks of 4 to 7 years (Cohen *et al.*, 1991).

Electric air-source heat pumps are about twice as efficient as electric resistance heaters, and technological improvements could increase the coefficient of performance (COP; the heat delivered divided by the energy consumed by the pump) to as high as 5 in moderate climates (Morgan, 1992). Ground-source heat pumps are even more efficient than air-source heat pumps (U.S. EPA, 1993f). Heat pumps are most effective where both heating in winter and cooling in summer are needed.

Recent research has indicated that, for houses in the United States in which hot or cold air from the furnace or air conditioner is carried by ducts in contact with the outside, leaks and thermal losses from the ducts are typically 30 to 40% of the energy carried by the ducts (Modera, 1993). New techniques are under development to treat ductwork in existing and new houses to reduce or eliminate these leaks (Jump and Modera, 1994; Modera *et al.*, 1992; Treidler and Modera, 1994; and Proctor *et al.*, 1993).

In the FSU/EE, the majority of residential complexes are heated through district heating systems, with or without cogeneration. In addition to significant technical efficiency improvements in these often-antiquated heating systems and better insulation of pipes that carry heat to and among buildings and apartment units, energy savings can be realized through improvement of the operation and control of heating systems. Lack of metering and controls for district heat discourages household conservation efforts. Options include repairing inoperative radiator valves and installing thermostats and individual apartment meters. The latter cannot be easily installed in all buildings, however, because heating systems piped in series (where the output of one radiator is the input to another) require the installation of a bypass pipe. Building heat-distribution systems can be improved through controls that adjust hot-water temperature in response to outdoor temperature, shut off the hot water when no space heating is necessary, or set back temperatures at night (U.S. Congress, OTA, 1993b).

In China, 75% of heated residential space is heated by coal-burning stoves, and 25% is supplied through small boilers or district-heating systems (Liu, 1993). The efficiency of central-heating systems in China often is quite low, and there are many opportunities for cost-effective efficiency improvements (Liu, 1993). Conversion from coal-burning stoves to more modern heating systems appears to increase energy use; however, it does greatly reduce indoor air pollution, provide better control of temperature, and greatly reduce personal effort and inconvenience. Thus, trends to modernize heating in urban areas of China could actually increase carbon emissions as compared

with direct coal-burning stoves, but that increase can be moderated by investments in efficient equipment.

22.4.1.1.3. Air-conditioning equipment

Efficiency improvements for air conditioners include better internal insulation in the equipment, larger heat exchangers, higher evaporator temperatures, dual-speed or variable-speed compressor motors to reduce on-off cycling, more efficient rotors and compressors, advanced refrigerants, and more sophisticated electronic sensors and controls (Morgan, 1992). A typical central air conditioner in the United States purchased in 1990 was 36% more efficient than a 1976 model (Levine *et al.*, 1992). The most efficient models in the market are 40% more efficient than the average new model; 20% efficiency gains over the average new model are cost-effective in many regions of the United States (Levine *et al.*, 1992; and Koomey *et al.*, 1991).

In the developing countries in particular, considerable improvement in the efficiency of air conditioners is possible through more widespread use of design options that are common in the industrialized countries (Meyers *et al.*, 1990). In Thailand, for example, the average home air conditioner draws 1.6 kW, whereas the best units require less than 1 kW to provide the same cooling capacity (Parker, 1991).

22.4.1.2. Water Heating

As with space heating, water heating is a major end-use, mainly in North America and Europe. Increased insulation of water heaters, electronic ignition of gas water heaters, and higher efficiency gas burners all promise significant savings over conventional technology. Air-source heat-pump water heaters can provide very high efficiency in warm climates; exhaust-air heat pumps (in which the heat from the exhaust air in ventilation systems is pumped into the stored hot water) are another promising option. Ground-source heat pumps (for space conditioning and heating water) can further increase efficiency and allow application into colder climates. In Eastern Europe, separate provision of domestic hot water from space heating—to reduce the enormous summertime losses in large-scale heat systems that provide only domestic hot water—can contribute energy savings.

Although water heating is not a major end-use in developing countries, it is becoming more common. Options similar to those common in the industrialized countries are available, but increased insulation for storage water heaters yields smaller benefits in warm climates. Solar water heaters are cost-effective in many areas, provided demand for hot water is sufficient, but their high initial cost is a barrier.

22.4.1.3. Lighting

In most developing countries, lighting is the most important electric end-use. Expanded use of compact fluorescent lamps

(CFLs), which require 20 to 25% of the electricity of standard incandescent lamps to produce the same light output, could have a major impact there. Studies of the potential for CFLs in India and Brazil have shown that their use would be highly cost-effective from national and utility perspectives (Gadgil and Jannuzzi, 1991). The cost of avoided peak installed electric capacity from the use of CFLs rather than incandescent lamps is as low as 10% and 15% of the cost of new installed capacity for Brazil and India, respectively, but subsidized electricity prices and the high initial cost of CFLs limit their attractiveness to households. The extent to which these lamps spread will depend on programs to overcome the first-cost barrier.

Replacing a kerosene wick lamp with a 16-watt compact fluorescent lamp increases light output 22-fold, while reducing the fuel-use rate by a factor of 8, even taking into account energy losses in generating electricity (van der Plas, 1988). The potential for cost-effective energy savings in electric lamps is especially large for households that do not yet have access to electricity. According to one estimate, some 2.1 billion people (about 35% of the world total) do not have electricity (Efforsat and Farcot, 1994); they consume an estimated 0.29 EJ of kerosene (Dutt and Mills, 1994; Dutt, 1994).

22.4.1.4. Cooking

Cooking is a relatively minor end-use in the industrialized countries and Eastern Europe, but it is the largest home energy use in most developing countries. Its predominant role is caused not only by the low saturation of other equipment and the lack of space-heating demand but also by the low conversion efficiency of the biomass stoves upon which most households rely. Traditional stoves are only 12 to 18% efficient.

The impact of the transition from biomass fuels to kerosene and liquid petroleum gas (LPG) on global warming depends on the source of the biofuels (whether harvested sustainably or not), the magnitude of products of incomplete combustion (PIC) from biomass stoves, and the global warming potential (GWP) of PIC, which can be considerable. PIC from biomass stoves include CO, methane, and a range of volatile organics. As a mixture, the total PIC GWP from a typical biofuel stove is usually greater than the GWP of the same amount of carbon as CO_2. Exactly how much greater depends on whether indirect as well as direct warming effects are included in the GWP calculations, the time horizon used, and the particular PIC mixture. A kerosene stove produces far less PIC; in addition, much less carbon is involved because a kerosene stove is more efficient and the fuel has more energy per carbon atom than does biomass. In a measured experiment based on cooking the same meal on a kerosene stove and a wood stove, the combined GWP of CO_2 (assuming nonsustainable harvest) and PIC (assuming a 20-year time horizon and including indirect warming effects) was about five times greater for a wood stove than for a kerosene stove (Smith *et al*., 1993). Using a 100-year time horizon would reduce the effects of combusting biomass in a wood stove to about 2.5 times that of a kerosene

stove. These factors are highly uncertain because the GWP of PICs is not known accurately (IPCC, 1994).

Fuel used for cooking a standard meal can be reduced by 30 to 40% through improved wood-burning stoves (Leach and Gowan, 1987; Smith, pers. comm.). An additional 50% fuel savings could be realized by switching to a kerosene stove (Dutt and Ravindranath, 1993). Although producing a significant savings, the switch from wood to kerosene reduces fuel use less than expected because some of the fuel savings is taken back through improved cooking (Fitzgerald *et al*., 1991). Where fuelwood is gathered and traditional cookstoves are homemade, there are no direct economic benefits to the households of switching to kerosene for cooking. In urban areas, or wherever fuelwood is sold, improved fuelwood stoves as well as kerosene stoves are likely to have far lower life-cycle cost (Dutt and Ravindranath, 1993). The diffusion of improved fuelwood stoves often has failed, however, because they did not fulfill cooking requirements or because of cultural factors, especially in rural areas (Piacquadio Losada, 1994).

Biogas, derived from the anaerobic decomposition of crop wastes and dung, is an alternative cooking fuel, either at the household level or at a community level. The production and use of biogas can result in no net CO_2 emissions and overall reduction in methane emissions compared to spontaneous decay. However, production of biogas as a cooking fuel is not economical compared to improved fuelwood or kerosene stoves (Dutt and Ravindranath, 1993).

Ethanol produced from sugar-cane fermentation is an alternative cooking fuel in areas with surplus sugar-cane production. At the lower end of the range of ethanol production costs, around $7/GJ (Ahmed, 1994), ethanol could be cost-competitive with other cooking alternatives (Dutt and Ravindranath, 1993). There are no net emissions of CO_2 from the use of biogas or ethanol.

Solar ovens are used to replace biomass fuels in many developing countries. Use of these ovens reduces the harvesting of carbon-sequestering trees and eliminates GHG emissions from burning wood or substitute fuels, such as kerosene and LPG. Currently, an estimated 100,000 solar ovens are in use in China, and more than 300,000 in India. Other countries with large numbers of solar ovens include Kenya, Costa Rica, Jamaica, Guatemala, Belize, El Salvador, and Honduras.

In the industrialized countries, there is relatively limited potential (10 to 20%) to improve the energy efficiency of primary cooking devices. In these countries, cooking energy use per household is likely to decline somewhat because of the proliferation of small kitchen appliances and changes in cooking habits (e.g., increased use of microwave in place of infrared heating systems).

22.4.1.5. Electric Appliances

Because most home appliances have lifetimes of 10 to 20 years, changes in new appliances shape the intensity of the

stock rather quickly. Such changes can be significant in developing countries, where stocks are growing rapidly.

A series of analyses conducted to support setting energy-efficiency standards in the United States established considerable potential for cost-effective efficiency improvement for most major electric appliances (U.S. DOE, 1989a, 1989b, 1990, 1993). For new refrigerators in the United States, the average efficiency (measured in terms of refrigerated volume per unit of electricity consumption) has increased by almost 200% between 1972 and 1994 (Association of Home Appliance Manufacturers, 1995). Energy use has not declined in proportion to the increase in efficiency because of new features such as icemakers and larger model sizes. Standards applied in 1993 reduced electricity use by 28% relative to the average model produced in 1989 (Turiel *et al.*, 1991). Advanced compressors, evacuated panel insulation, and other features have the potential to produce commercial and cost-effective refrigerators that consume half as much electricity per unit volume as those that meet the 1993 standard. Such a refrigerator would consume 20% as much electricity as a typical 1972 U.S. model. Recent studies found similar results for European refrigerators and freezers (Lebot *et al.*, 1991; GEA, 1993).

For clothes washers and dishwashers, analysis for the United States found that design options that reduce energy use by 30% (including energy to heat water) are cost-effective (EIA, 1990). For clothes washers, a change from vertical-axis to horizontal-axis technology would reduce energy use by about two-thirds relative to the baseline (mainly because of much lower use of hot water). Increasing the spin speed during the spin-dry cycle of a clothes washer can reduce drying energy use by 30 to 50% (because much less energy is expended in mechanical water removal than in thermal water removal). Many European washers are horizontal axis and use higher spin speeds than are standard in the United States. For clothes dryers, the cost-effective reduction in energy use is only 15%, but much greater savings (about 70% relative to the baseline) are possible through the use of a heat-pump dryer. The latter has a significantly higher cost, but a prototype has been developed and successfully tested.

In Eastern Europe, inefficient components are currently being used in most domestic appliances. Refrigeration appliances produced in Poland consume substantially more energy than similar models made in Western Europe (Meyers *et al.*, 1993a). Production facilities are in need of substantial modernization to produce higher quality and more-efficient appliances.

In the developing countries, the most important appliance to target for efficiency improvement in the near term is the refrigerator, whose saturation is growing rapidly. In the longer term, air conditioners will be of great importance. The majority of refrigerators and air conditioners sold in the developing world are well below the state of the art, although the lack of test data makes detailed knowledge of efficiency and energy use impossible (Meyers *et al.*, 1990). A study that considered a variety of appliances in Indonesia estimated that the use of best-available cost-effective technology would result in a

reduction in energy use of 20 to 30% relative to the 1988 stock average (Schipper and Meyers, 1991).

22.4.1.6. The Overall Potential for Residential Energy Savings

Several studies at the national and regional levels in the industrial countries have developed estimates of future residential energy use if greater use is made of energy-efficient technologies and practices. Estimating cost-effective savings is a difficult task. Technology is just one of many factors affecting energy use, and the effects of technological change may be masked by population increases, demographic shifts, and other factors. Technology is not stagnant; costs, performance, and efficiencies change as technology is improved and refined. The diversity of the building stock, climatic variations, and uncertainty over future energy costs all make estimating the economic potential for energy savings an uncertain exercise. Furthermore, there are several measures of cost-effectiveness, and one can consider different perspectives—such as the consumer, the utility, and society as a whole. Finally, one can vary the values of inputs in economic calculations, notably the discount rate.

Bearing in mind the inevitable uncertainties and effects of the different definitions of "cost-effective," it is nevertheless useful to review estimates of the energy savings that could result from greater use of cost-effective technologies.[4]

One study estimates that, relative to the predicted business-as-usual 2010 consumption, 13% of the energy used in U.S. homes could be saved with cost-effective technologies; 26% could be saved with technically feasible, but not necessarily cost-effective, technologies (EIA, 1990). These estimates are at the low end of the range of cost-effective savings found in other studies, probably partly due to conservative assumptions concerning building shell retrofits.

One assessment of the residential efficiency potential for electrical end-uses in the United States looked in detail at measures for all end-uses and different building types (Koomey *et al.*, 1991). The study estimates 40% cost-effective savings for the year 2010, where savings were calculated from a baseline with energy efficiency fixed at today's levels, current energy prices were used, and no new technology was assumed (see Figure 22-4).[5]

---

[4] This refers to technologies that save energy at a cost lower than the average cost of energy or the cost of new supply, depending on the measure of cost-effectiveness used. The cost may be calculated using a discount rate of 6–10% real, reflecting the customers' cost of capital in an industrialized country, or 3–4% real if a social discount rate is used.

[5] As noted, the baseline assumes that buildings and appliances existing in 1990 remain at 1990 efficiency levels (no retrofits) and that all new homes and appliances that enter the stock remain at the efficiency of new systems in 1990. Thus, stock turnover reduces average energy intensities in the baseline case even though new and existing devices are frozen at their 1990 efficiencies.
Figure 22-4: Conservation supply curve for electricity in the U.S. residential sector (each "step" represents a specific electricity conservation measure).

Studies conducted in Japan have assessed cost-effective energy savings potential in the year 2010 and thereafter (Japanese Environment Agency, 1992; Tsuchiya, 1990). The greatest energy savings for residential buildings would come from reduction of heating demand through greater insulation in the building envelope and double-glazed windows; provision of space heating and cooling, along with hot water, through multifunction heat pumps; and introduction of solar water heaters. Without energy-efficiency improvements, CO_2 emissions from residential energy use in Japan are projected to increase to 150% of 1990 levels by 2010; with a strong

effort to implement cost-effective efficiency measures, CO_2 emissions are projected to be 107 to 123% of 1990 levels. In the longer term (2020 and beyond)—with more time for turnover of building and equipment stock—energy-efficiency measures are projected to be able to bring CO_2 emissions to 97% of 1990 levels.

The energy savings and costs associated with a variety of measures that could be applied for existing and new housing in former West Germany, France, Italy, the United Kingdom, and the Netherlands are evaluated by Krause *et al.* (1994). Cost-effective savings of 40 to 45% in heating requirements are considered possible for gas- or oil-heated residential buildings existing in 1985 that survive to 2020. Cost-effective savings of 28 to 35% are estimated for existing buildings with district heating systems. For residential buildings built between 1985 and 2020, heating energy requirements could be reduced in a cost-effective manner by as much as 70%.

Although the modern sector of developing countries shares many of these opportunities, there is an important difference: The energy consumption in developing countries is much lower but generally has higher rates of growth, because of population increase as well as the increase in energy services per capita. Thus, opportunities are more significant in new buildings and equipment than in retrofits. There also are opportunities unique to developing countries. The overall potential for CO_2 emissions reduction through energy-efficiency improvement and fuel switching is illustrated in Table 22-1 for India. Emissions reductions of 40 Mt (35%) from 1987–88 emission levels are projected. By the year 2010, with a 1.46-fold increase in population and a doubling of the per capita demand for energy services, CO_2 emissions would scale up to 336 Mt with no mitigation but only to 217 Mt with successful mitigation.

Table 22-1: Potential for CO_2 emissions reductions in India.

	CO_2 Emissions (Mt) (1987–1988)	Reduction Potential (%)	CO_2 Emissions (Mt) with Mitigation (1987–1988)
Biomass Combustion	47.6	35	30.9
Kerosene Lamps	8.0	87.5	1.0
Incandescent Lamps	8.4	50	4.2
Fluorescent Lamps	5.3	25	4.0
Fans	7.9	20	6.3
Refrigerators	5.3	50	2.7
Commercial Light	11.8	25	8.9
All Other	20.6	20	16.5
Total	**114.9**	–	**74.5**

Notes: Estimates based on background analysis conducted for Govinda Rao, Dutt, and Philips (1991). Some 16% of all biomass fuels used were logs; this is assumed to be nonrenewable harvesting. Kerosene lamps are assumed to be replaced by fluorescent lamps; the CO_2 emissions of fluorescent lamps are shown in the kerosene-lamp row. Far larger emissions reductions are technically possible with existing technology (e.g., refrigerator energy use can fall by 80% or more, commercial lighting use could be reduced by over 50%, etc.).

22.4.2. Commercial Buildings

The commercial sector is especially diverse, even within a single country, with a wide range of building sizes, growth rates, fuels used, operating hours, functions served within buildings, amenity levels, and climates. Larger commercial buildings differ from residential buildings because they tend to have more complex space-conditioning systems (often with mechanical ventilation systems to maintain indoor air quality) and are usually internal-load dominated—meaning that space-conditioning demands arise largely from activities within the building (e.g., people, lighting, and equipment) rather than from exterior conditions. In industrialized countries, commercial buildings tend to be relatively large (e.g., in the United States, 80% of the commercial floor area is in buildings larger than 1,000 m²) and designed for high amenity levels in terms of thermal and lighting conditions. In developing countries, buildings are smaller, with fewer amenities—though the trend is toward the styles of industrialized countries. Commercial building types include offices, hotels, retail stores, schools, health-care facilities, food-service and sales buildings, warehouses, theaters, museums, and religious buildings. The commercial sector includes buildings in both the public and private sectors.

Electricity is the major form of energy consumed in commercial buildings worldwide, dominating all end-uses except space and water heating and cooking. In the U.S. and OECD commercial sector, electricity meets about 70% of demand in terms of resource energy (EIA, 1994). Within the OECD, the share of electricity (on a resource energy basis) in the commercial-sector fuel-mix ranges from a low of 40% in hospitals in Japan to a high of 80% in hotels and restaurants in Norway.

The major commercial sector end-uses include lighting, space heating, space cooling, ventilation, service water heating, office equipment and other plug loads, refrigeration, and cooking. Data on national average end-use shares of energy in commercial buildings are rare. For the United States, Figure 22-5 shows the end-use breakdown for resource energy (Belzer *et al.*, 1993). In developing countries, the end-use shares for energy differ considerably from those in industrialized countries. For example, lighting is estimated to account for 50% of total electricity in Indian commercial buildings, with space conditioning and refrigeration accounting for 40% and other end-uses the remaining 10% (Nadel *et al.*, 1991).

22.4.2.1. Space Conditioning

22.4.2.1.1. Building thermal integrity

Although larger commercial buildings tend to be internal load-dominated, important savings opportunities nonetheless exist in the design of the building envelope. Windows often represent the largest pathway for heat gain and loss through both conductive and radiative heat transfer. Strategies for reducing energy use associated with windows include: reducing window
Figure 22-5: Shares of U.S. commercial resource energy by end-use, 1989.

area, installing external and internal window shading devices, using multiple-pane windows, injecting rare-earth gases between window panes, and applying low-emittance coatings to window glazing surfaces (Sullivan *et al.*, 1992). Low-emittance windows can reduce thermal heat transfer while still transmitting visible light into the interior space, making this technology particularly effective in daylighting applications.

Heat loss and gain through opaque walls and roofs can be reduced by adding insulation and using high solar-reflectance materials for exterior surfaces, though the effectiveness of these measures diminishes for larger buildings with small surface-to-volume ratios.

Shading low-rise commercial buildings by planting trees for sun and wind protection can reduce cooling and heating loads, respectively (Akbari *et al.*, 1992). Through careful window sizing and placement, interior design, and building siting, natural ventilation can be used in some circumstances to augment or supplant the need for mechanical cooling (e.g., Bauman *et al.*, 1992; Boon-Long *et al.*, 1992).

22.4.2.1.2. Space-heating equipment and air distribution systems

Systems for heating, ventilating, and air conditioning (HVAC) account for 40 to 50% of electricity use in commercial buildings in some industrialized countries, such as the United States and Germany (IEA, 1989). In other industrialized countries, such as Japan, and in many developing countries, HVAC represents less than 25% of electricity use in commercial buildings.

For commercial buildings, there have been moderate improvements in the efficiency of larger air-conditioning systems during the past decade or so. Levine *et al.* (1992) estimate the potential for cost-effective efficiency improvements in chillers in the United States to be 25 to 38% with currently available technology. Advanced technology—more efficient condensers and improved heat exchangers, wider applicability of large

water-cooled chillers, development and application of evaporative cooling techniques, and application of gas-driven chillers—has the potential to increase energy-savings opportunities over the next decades.

For space heating, the typical electric system is either electric-resistance or heat-pump technology, the latter being far more efficient though less common. The typical gas or oil system is either an atmospherically vented furnace or boiler. Improvements in heat exchange to extract the heat of condensation from flue gases, power-venting, and pulsed-combustion technology increase gas-furnace efficiency from a typical 50 to 60% to upward of 90% (Krauss, 1992).

District heating involves the production of heat in a central plant, which is then distributed in the form of steam or hot water to many buildings via underground pipes. Such systems are common in Europe. In Denmark, for instance, district heating is used to meet almost half of the space-heating needs in buildings (U.S. Congress, OTA, 1993b). The efficiency of district heating depends on the system used to produce and distribute the heat. When collected as waste heat from some industrial process or in a cogeneration application, overall efficiency can be very high relative to more traditional on-site space-heating methods.

Energy for air and water transport within buildings can be reduced by employing efficient motors and impeller designs, by good duct and pipe design to reduce static pressure, and by allowing fans and pumps to operate at speeds that closely match thermal loads. With this last approach, a variable-air-volume (VAV) HVAC system with variable-speed drives on the fans is a significant efficiency improvement over constant-volume systems. The savings from VAV range from 30 to 80% (Usibelli *et al.*, 1985). The efficiency advantages of the VAV system have been so well recognized in the United States that more than three-quarters of central systems installed in new buildings are now VAV (Pietsch, 1992). VAV systems are still uncommon in most regions of the developing world.

Greatly increased use of economizers, heat exchangers, and control systems can yield very significant energy savings. Economizers switch the system to the use of outside air when the outdoor temperature is low enough to cool the building. Heat exchangers reclaim heat from exhaust air from space heating, from waste heat in hot-water circulation, or from the ground. Control systems vary from simple zone temperature control with thermostats to comprehensive energy-management control systems that control a variety of systems in the building in addition to HVAC.

22.4.2.2. Water Heating

For many old water-heating systems, combined hot water and space-heating systems are typically highly inefficient. Replacement by stand-alone systems can save 65% (Nadel *et al.*, 1993). The same technologies for improving gas-fired boilers for space heating are applicable for water heating. Electric heat-pump water heaters also are an option for commercial water heating applications, where COPs as high as 5 are available (Abrams, 1992). The heat rejected from food-storage or air-conditioning systems can, under the proper circumstances, be cost-effectively reclaimed for water heating.

22.4.2.3. Lighting

Commercial lighting is provided by three types of systems: incandescent, fluorescent, and high-intensity discharge (HID). As with residential applications, replacing incandescent lamps with CFLs in commercial buildings is a viable savings option and, because of higher usage, can be even more economically attractive in commercial applications.

Fluorescent lighting systems are the most common type of lighting in commercial buildings. Data from OECD countries show fluorescent system market shares for lighting in commercial buildings ranging from 59% in Italy to 90% in Norway (IEA, 1991). In the U.S. commercial sector, fluorescent lamps are in use in 76% of the floor area; incandescent and HID lamps are in use in 19% and 6% of the floor area, respectively (EIA, 1992a). In India, the share of fluorescent lighting is estimated to be around 80% (Nadel *et al.*, 1991).

Five technical options are available to improve fluorescent lamp efficiency: higher surface-area-to-volume ratio, reduced wattage, increased surface area, better phosphors, and reflector lamps (Mills and Piette, 1993).

A lamp ballast is needed to provide a suitable starting voltage, thereafter limiting current flow during operation of fluorescent (and mercury-vapor) lamps. Ordinary magnetic ballasts dissipate about 20% of the total power entering a fixture (Geller and Miller, 1988). In some developing countries, poor-quality ballasts may dissipate as much as 30% (Turiel *et al.*, 1990). More efficient electromagnetic ballasts (also known as core/coil ballasts) make use of better materials to reduce ballast losses to about 10%. Solid-state electronic ballasts cut ballast losses even further and also increase lamp efficacy (lumens of light output per watt of power input) because of high-frequency operation. Such ballasts increase the efficiency of the ballast/lamp system by approximately 20 to 25% relative to that of a system with an ordinary ballast (Verderber, 1988).

Lighting-fixture efficiencies vary from less than 40% to about 92% (Mills and Piette, 1993). Specular reflective surfaces inside a fluorescent lamp fixture can increase the amount of light emitted from a fixture, thereby permitting the removal of lamps (delamping) in retrofit applications or permitting fixtures with fewer lamps to be used in new applications.

HID lamps are used primarily for industrial and outdoor lighting, where very high lighting intensity is required. There are five main types of HID lamps (with efficacy provided in lumens per watt): self-ballasted mercury vapor (20), externally ballasted

mercury vapor (38.5), metal halide (54.2), high-pressure sodium (82.5), and low-pressure sodium (136.4) (Levine *et al.*, 1992). Generally, the most common upgrade is to replace mercury-vapor lamps with high-pressure sodium lamps, for which the lighting quality is little changed.

A number of energy-saving lighting controls are now on the market, including multilevel switches, timers, photocell controls, occupancy sensors, and daylight dimming systems. In addition, "task lights" (small lights that illuminate only the work surface) can reduce general lighting needs. These measures typically result in savings of 10 to 15% for photocell controls, 15 to 30% for occupancy sensors, and up to 50% in perimeter zones for daylighting systems (Mills and Piette, 1993; Eley Associates, 1990; and Rubenstein and Verderber, 1990).

Studies of cost-effective energy savings for lighting in commercial buildings in different countries have produced a range of savings estimates: 35% for the United States (Atkinson *et al.*, 1992); between 36 and 86% for five countries in Western Europe (Nilsson and Aronsson, 1993); 70% in Thailand (Busch *et al.*, 1993); 22% in Brazil (Jannuzzi *et al.*, 1991); and 35% in India (Nadel *et al.*, 1991). All of these studies show substantial savings opportunities; results differ in many cases because of differing assumptions.

22.4.2.4. Office Equipment

Office equipment accounts for one of the fastest-growing end-uses for energy in commercial buildings. This equipment includes computers, monitors, printers, photocopiers, facsimile machines, typewriters, telecommunications equipment, automatic teller machines, cash registers, medical electronics, and other miscellaneous plug loads. Much of this equipment is left on when not in use during the day, overnight, and on weekends, often consuming energy at close to full load. Laptop computers, which rely on battery power, use special low-power microprocessors and have technology built into the microprocessor that automatically switches it to a low-power mode when not in use, returning quickly to full capability when needed. Recognizing this, the U.S. Environmental Protection Agency (EPA) instituted the "Energy Star" program to promote efficiency improvements first in computers but eventually to include other office electronics. For instance, personal computers with the capability of switching to a low-power mode of 30 watts or less (about 75% less than current models) qualify for the EPA logo that identifies high-efficiency equipment (U.S. Congress, OTA, 1993a). A recent analysis of the impact of changes in the energy efficiency of office equipment in New York state found that today's Energy Star equipment could reduce office equipment energy use by 30% by the year 2000 and by 43% by 2010 (Piette *et al.*, 1995).

22.4.2.5. The Overall Potential for Commercial Energy Savings

A number of efforts have been undertaken to combine detailed information about individual technologies for energy saving, as described above, with economic data and information about the existing building stock and planned additions to estimate overall energy-savings potential in commercial buildings in various countries. The analyses have many complexities and uncertainties, including:

- The wide variety of building types among commercial buildings and the difficulty of generalizing to the whole sector
- Differences in opportunities for energy efficiency between new and existing buildings
- Interactions among multiple energy-conservation measures
- Comprehensiveness of the study and criteria used to select measures
- Economic criteria for cost-effectiveness.

As Figure 22-6 shows, a commercial-sector electricity conservation study conducted for the state of New York found economic electricity-savings potential in the commercial sector to be 47% of present consumption from the societal perspective (Miller *et al.*, 1989). At the national level, the Electric Power Research Institute (EPRI) projected from 22 to 49% maximum technical potential for commercial electricity savings (Faruqui *et al.*, 1990). Also at the national level, Rosenfeld *et al.* (1993) found an economic potential of 55% of present electricity consumption in the commercial sector. These savings are for a future year (typically 2020), and they represent savings from current levels of energy efficiency. They are, however, based on current technology and costs, so additional potential savings will be possible over time if energy prices rise in real terms and new energy-efficiency technologies become available.

Such energy-conservation supply-curve studies are much more rare for natural-gas use in commercial buildings; a compilation of assessments by U.S. gas utilities found between 8 and 24% economic potential in their service territories (Goldman *et al.*, 1993).
Figure 22-6: Conservation supply curve for electricity in New York state's commercial sector.

In Canada, the economic savings potential for all energy used in offices and retail outlets was estimated at 40 and 28%, respectively (Peat, Marwick, Stevenson, & Kellogg, 1991).

An assessment of energy savings potential for commercial buildings in Japan concluded that energy-efficiency measures, primarily for space conditioning and lighting, could reduce emissions of CO_2 in 2010 from 125% of 1990 levels (without efficiency gains) to 112% of these levels (Japanese Environment Agency, 1992; Tsuchiya, 1990). The longer term potential was about 70% of 1990 levels.

A recent analysis of the Swedish commercial sector found that total electricity use could remain constant through 2010, despite 45% growth in energy services, through implementation of cost-effective retrofit and new construction measures combined with various government and utility incentive programs (Swisher *et al.*, 1994). A Danish project found a large number of electricity-saving measures in commercial buildings (Gjelstrup *et al.*, 1989). One study, which considered lighting, ventilation, pumping, cooling, refrigeration, and other technologies, found that 24% of public-sector (schools, hospitals, etc.) electricity could be saved by behavior and management changes, and an additional 18% reduction was possible with available technologies (Johansson and Pedersen, 1988). Most or all of these savings were thought to be cost-effective. A study of the private service sector found a somewhat lower conservation potential: 10 to 18% through behavior and management changes and an additional 15% reduction through retrofit (Nielsen, 1987).

Among developing countries, a study of economic electricity-savings potential in Brazil estimated 25% cost-effective savings potential in the commercial sector over the next 20 to 30 years (Geller, 1991). In Thailand's large building sector, a comprehensive analysis of efficiency measures in offices, hotels, and retail buildings calculated savings from 45 to 56% (Busch, 1990). Across Southeast Asia, more than 200 audits of existing commercial buildings have indicated average savings from proposed energy-conservation measures between 10 and 20% (Loewen, 1992).

22.4.3. Community-Level Measures: Reducing Urban Heat Islands

The urbanization of the natural landscape—roads, parking lots, bridges, dams, houses, and high-rises—has dramatically altered waters, soils, and vegetation. Replacing vegetation and soil with concrete and asphalt reduces the landscape's ability to lower daytime temperatures through evapotranspiration and eliminates the benefits of shade. The use of dark-colored materials on roads, buildings, and other surfaces creates entire cities that absorb, rather than reflect, incoming solar energy. The combination of reduced reflectivity (called "albedo") and reduced vegetation has resulted in a temperature difference between urban and rural areas that is greatest in late afternoon and early evening, when roads, sidewalks, and walls begin to release the heat they have stored throughout the day.

Throughout the past century, increasing rates of urbanization and industrialization have exacerbated the heat-island effect. Summer temperatures in urban areas are now typically 1 to 3°C higher than in their rural surroundings. Peak temperatures in Los Angeles, for instance, have risen by 3°C in the past 50 years, and mean summertime temperatures in Washington, D.C., have climbed 2°C during the past 80 years. Today, tropical cities are often markedly warmer than their surroundings. Winter nighttime heat islands of 9°C in Mexico City and 6°C in Bombay and Poona, India have been measured (Jauregui, 1984). A comprehensive summary of the heat-island effect in U.S., European, and East Asian cities is provided in Yoshimo (1975, 1991) and Oke (1978).

Heat islands can have either beneficial or detrimental impacts on energy use, depending on geography, climate, and other factors. In warm to hot climates, however, heat islands exacerbate cooling energy use in the summer. For U.S. cities with populations larger than 100,000, electricity use for cooling will increase 10 to 15% for every 1°C increase in temperature (Akbari *et al.*, 1992).[6]

Because urban temperatures during summer afternoons have increased by 1 to 2°C in the past 4 decades, 10 to 20% of the current urban electricity for the cooling of buildings is used to compensate for the heat-island effect alone. Expanded urbanization throughout the world will lead to increasing effects of urban heat islands in the coming decades.

In addition to increasing cooling energy use, heat islands and long-term urban warming affect the concentration and distribution of urban pollution because heat accelerates the chemical reactions that lead to high ozone concentrations [see Akbari *et al.* (1990) for an assessment of effects on ozone levels in Los Angeles].

22.4.3.1. Heat-Island Mitigation

Two factors contributing to urban heat islands can be altered: the amount of vegetation and the solar reflectance of surfaces.

22.4.3.1.1. Vegetation

Trees affect urban climates and building energy use through shading, lowering of windspeeds, and evapotranspiration.

The cooling energy use of two similar sites in Sacramento, California—one with and one without shade trees—was monitored; the shaded site consumed 30% less energy (Akbari *et al.*, 1993). Actual savings at any particular site will depend on

---

[6] In a typical city in the United States, cooling accounts for 40% of urban electricity use. Thus, total use is increased (reduced) by 4.5 to 6% for every 1°C increase (reduction) in temperature. Peak demand is typically increased (reduced) by about 60% of this amount.

the nature of the shade trees and the climate. In addition, a tree can transpire up to 380 liters of water a day. In a hot, dry location, this produces a cooling effect similar to that of five average air conditioners running for 20 hours (Akbari *et al*., 1986). In a hot, humid location, however, evapotranspiration is not an effective cooling process.

Considerably greater effects on cooling can be achieved through large-scale tree-planting programs that exert an indirect effect on the community through increased evapotranspiration. Evapotranspiration and shading effects together can reduce air temperatures by as much as 8°C. In Nanjing, China, for instance, after 34 million trees were planted in the late 1940s, average summer temperatures dropped almost 3°C (Garbesi *et al*., 1989).

22.4.3.1.2. Solar reflectance of surfaces

The practice of using high solar-reflectance surfaces to keep buildings and outdoor urban areas cool is not new. In many tropical and Mediterranean countries, particularly those with large amounts of sunshine, the traditional architecture has numerous examples of light-colored walls, roofs, and streets. However, in the many industrialized countries—and increasingly throughout the world—architects and urban planners have overlooked this energy-conscious design principle, relying instead on mechanical air conditioning to maintain comfort during the summer months.

Changing the albedo of a building can reduce direct cooling requirements for houses, single-story industrial buildings, and small commercial buildings significantly. For example, 20% reductions in cooling energy requirements have been estimated for a single-story house (Taha *et al*., 1988). Measurements made on a sunny day in November in Berkeley, California, showed that the noontime temperature of a dull black surface was 63°C, whereas that of a white acrylic paint surface was only 25°C (Rosenfeld *et al*., 1994). Similar results would be expected in any location on a hot, sunny day.

Indirect effects (those resulting from the generally lowered temperatures produced by wide-scale increases in albedo) appear to have a larger effect than direct ones. A major program for modifying albedo could reduce urban temperatures by 2 to 3°C, resulting in an estimated reduction of total urban electricity requirements of 8 to 17% and total urban cooling requirements of 21 to 42% (Taha *et al*., 1988).

22.4.3.2. Costs and Benefits of Urban Heat-Island Mitigation

Through direct shading and evapotranspiration, trees reduce summer cooling energy use in buildings at only about 1% of the capital cost of avoided power plants plus air-conditioning equipment (Akbari *et al*., 1988). Water consumption and tree-maintenance costs are typically a very small fraction of the costs of avoided electricity, except in hot and very dry climates

where water is scarce (Akbari *et al*., 1992). In the latter climates, most of the savings can be achieved through increased albedo combined with drought-resistant vegetation. Increasing the albedo of a city may be very inexpensive if the change is made at the time of routine maintenance. Buildings are typically repainted every 10 years, and high solar-reflectance paint may be used for no additional cost. Similarly, many roof types, including single-ply membrane and built-up roofing, are available in high solar-reflectance materials for no additional cost.

It has been estimated that a nationwide program of planting urban shade trees and lightening surfaces in the United States could, by the year 2015, reduce cooling energy use by 20%. This annual savings of 108 TWh, worth $7 billion (in 1990 dollars), would prevent the emission of 27 Mt of carbon.[7] (For comparison, the recent Climate Change Action Plan for the United States calls for a carbon reduction of 108 Mt by the year 2000.) Applying similar measures to urban areas in wealthy countries in the rest of the world could approximately double these savings to 50 Mt of carbon by 2015 or 2020. As in the United States, such savings would require very aggressive programs for 20 years or longer.

22.4.4. Methane Emissions from Waste Disposal and Wastewater

22.4.4.1. Magnitude of Emissions

The anaerobic decomposition of wastes disposed of in landfills or open dumps is a major global source of methane. Recent estimates suggest that 20 to 40 million tons of methane, or about 10% of global methane emissions from human-related activities, are emitted from this source annually (U.S. EPA, 1993a).[8] The large uncertainties in these estimates derive from a lack of information about the amount of organic material actually disposed of in landfills or open dumps by different countries, waste-management practices employed, the portion of organic wastes that decompose anaerobically, and the extent to which these wastes will ultimately decompose (Bingemer and Crutzen, 1987; Orlich, 1990; RIVM, 1993; OECD, 1991; U.S. EPA, 1993a).

Methane emissions result largely from urban areas throughout the world. The industrialized countries of the world contribute about two-thirds of these methane emissions, EE/FSU about 15%, and developing countries about 20% (U.S. EPA, 1993a). Ten countries represent about 60 to 70% of global methane emissions from solid-waste disposal—with the United States

---

[7] The analysis assumes that 40% of buildings are eligible for increased vegetation and reflectivity. The potential savings from direct effects is about 11%. The indirect effect is based on a 2.2°C citywide cooling and is estimated to be about 12%. The combined direct and indirect effects are then about 20% (Rosenfeld, 1994).

[8] Methane emissions of 20 to 40 million tons per year are equivalent to about 135 to 275 million tons of carbon per year using a GWP of 24.5 for methane, as discussed in Section 22.2.2.

representing about 33%, or around 10 million tons (U.S. EPA, 1993b). With continuing trends in population growth and urbanization, developing countries could account for 30 to 40% of methane emissions from this source by 2000 (U.S. EPA, 1993c).

Methane emissions also result from domestic and industrial wastewater disposal. Recent estimates suggest that 30 to 40 million tons of methane (200 to 275 million tons of carbon in CO_2) are emitted annually from wastewater disposal, primarily from the disposal of industrial wastes (RIVM, 1993; U.S. EPA, 1993a). Regional contributions have not been estimated because of the lack of data.

22.4.4.2. Reducing Methane Emissions

With available technologies and practices, methane emissions may be reduced either by recovering and using the gas or by reducing the source of methane (U.S. EPA, 1993d). The former approach is most suitable for existing solid-waste disposal sites, which often emit methane (often called landfill gas) for 10 to 30 years or more (RIVM, 1993). Frequently, more than 50% of the generated methane can be recovered (Bhide *et al*., 1990). In many cases, the recovered methane can be used for heating or electricity generation, which is already common in many countries. Although more expensive, landfill gas also can be purified and injected into a natural-gas pipeline or distribution system; there are several such projects in the United States. In Brazil, purified landfill gas has been used as a fuel to power a fleet of garbage trucks and taxicabs. High-rate anaerobic processes for the treatment of liquid effluents with high organic content (sewage, food-processing wastes, etc.) can help reduce uncontrolled methane emissions and are particularly suited to the warmer climates of most developing countries (Lettinga and van Haandel, 1993).

Options for reducing the source of methane emissions include recycling paper products, composting, and incineration (U.S. EPA, 1993d). Paper products make up a significant part of solid waste in industrialized countries (e.g., 40% in the United States) and a growing proportion in some urban centers of developing countries (typically 5 to 20%) (U.S. AID, 1988; Volger, 1984). A variety of recycling processes, differing in technical complexity, can turn this waste into material indistinguishable from virgin products. Composting—an aerobic process for treating moist organic wastes that generates little or no methane—is most applicable in developing countries, where this type of waste makes up a larger fraction of the total; the residue has fertilizer value. As land-disposal costs rise, incineration (often combined with combustion-energy recovery) has become more cost-effective, especially in lower moisture landfills found in industrialized countries.

Existing methane-recovery and source-reduction projects represent a small portion of the potential. Recent studies suggest that global methane emissions from solid-waste disposal can be reduced by about 30% through the widespread use of existing technologies and practices, making both economic and environmental sense (Richards, 1989; U.S. EPA, 1993c, 1993e). A large part of these reductions could take place in the United States, where a pending landfill rule is expected to reduce emissions nationwide by about 6 million tons, or 60%, by the year 2000.[9] Methane recovery is more economical at large waste-disposal sites located close to large urban areas. Fortunately, such sites represent the majority of methane emissions in many countries.

22.5. Policy Options

22.5.1. Buildings

Greater use of available, cost-effective technologies to increase energy efficiency in buildings could lead to sharp reductions in emissions of CO_2 and other gases contributing to climate change. However, policies to promote these technologies often are needed.[10] Consumers and other decision-makers often do not invest in efficiency, even though it appears to offer life-cycle cost savings, for several reasons, including:

- Many buildings are rented, causing a separation between those purchasing energy-using equipment and those paying to operate the equipment.
- Individuals pursue several goals when making energy-related decisions (such as minimizing capital outlays), but very few pursue the goal of minimizing life-cycle or societal costs (see Komor and Wiggins, 1988).
- In new construction, where the greatest and most cost-effective savings are available, the builder does not have to face paying energy bills and often works to minimize initial cost.
- Energy costs are relatively low (e.g., about 1% of salary costs in a typical office in industrialized countries), so those concerned with cost reduction often focus their attention elsewhere.

Analysis of U.S. energy-efficiency choices in the residential sector suggests that markets often behave as if consumers had a discount rate of 50% or more (Ruderman *et al*., 1987; U.S. Congress, OTA, 1992b). Discount rates implicit in purchasing decisions involving tradeoffs between capital and operating expenses can be 150% or higher among the poorest Indian households.

---

[9] The landfill rule is designed to reduce emissions of nonmethane organic compounds and air toxics to reduce their adverse air-quality and human-health impacts. It will reduce methane as a side benefit. Greater reductions in methane are expected from this rule than would result if only projects for which reductions in methane releases to the environment were economically viable were undertaken.

[10] For a recent extensive discussion of market failures and energy-efficiency policy issues for the United States, see Levine *et al*. (1994). For a discussion of similar issues related to energy markets in developing countries, see Reddy (1991).

The existence of numerous untapped opportunities for energy savings throughout the world suggests that current market conditions alone will not ensure full implementation of these opportunities. Moreover, energy production and use has significant environmental impacts and other externalities—effects not captured in price.

Yet enthusiasm for policy change must be tempered with a recognition that attempts to increase energy efficiency through regulation or other governmental action may have unanticipated administrative or other costs. Also, current levels of energy efficiency reflect consumer preferences given existing economic incentives, levels of information, and conditions in the market. Finally, there is little consensus on the best policies to promote energy efficiency.

In recent years, many countries have experimented with policies to promote energy efficiency, and evaluation of these efforts has yielded a rich history that can guide future policy efforts. This section describes and summarizes experiences with a range of policy options, including financial incentives, such as energy taxes and rebates; regulations, such as codes and standards; changes in utility regulation; research and development; and improved consumer information.

22.5.1.1. Financial Incentives

A basic policy strategy to motivate greater energy efficiency is to decrease the expense and/or increase the financial benefits of saving energy. Specific options include energy price reform and energy taxes, grants and low-interest loans for building retrofits, rebates for the purchase of energy-efficient appliances, tax credits for energy-efficiency investments, and inclusion of energy efficiency in innovative loans and mortgages.

Energy, especially electricity, is often underpriced; its true costs to society are higher than the price paid by consumers. For example, a World Bank review of energy-pricing policies in the developing world found the average market price of electricity was 4.3¢/kWh, whereas the average cost of new supply was 8.0¢/kWh (Mashayeki, 1990).

Reasons for this often glaring discrepancy between market (consumer) prices and true costs include the following:

- Government agencies set prices in response to multiple goals (provision of basic energy services regardless of ability to pay, promotion of specific policies like industrial development, etc.).
- The marginal cost of electricity varies with system load, and marginal cost pricing is technically difficult.
- There is little agreement on the environmental costs of energy production, distribution, and consumption (EPRI, 1991).

Despite these factors, some countries are attempting to move energy prices to include social costs. In the United States, for example, some utilities are incorporating environmental damage costs, including those caused by CO_2, into planning decisions (CECA, 1993). Many Central and Eastern European countries, in transition from centrally planned to market-driven economies, are instituting large energy price increases in an attempt to close the gap between societal and market prices. Several European countries are considering or implementing carbon taxes on fossil fuels (CECA, 1993).

There also are circumstances in which electricity prices are far above private marginal cost. For example, advanced turbines using natural gas can produce electricity at costs considerably lower than current costs in most utilities in the United States. This has led to a push for major restructuring of the industry in the United States.

Several key points about energy taxes are worthy of note:

- Energy taxes can raise a tremendous amount of revenue, often at relatively low administrative costs. For example, a 0.1 cent (1 mill) per kWh tax on electricity used in buildings in the United States would raise about $1.7 billion annually (EIA, 1993).
- There is only moderate agreement on the effects of price changes on energy consumption or behavior. Estimates of the price elasticity of energy demand (defined as the percent change in energy consumption resulting from a 1% change in price) range from -0.3 to -1.0 for the buildings sector (Energy Modeling Forum, 1981).
- Taxes may have undesired distributional effects. For example, in the United States, low-income households spend a larger fraction of their income on energy services than do higher income households. Therefore, an energy tax would be regressive (USDOC, 1993). Energy taxes also can be an instrument of income redistribution. Many countries tax gasoline and use a part of the revenues for social expenditures, such as universal health care and education. For example, a small tax on urban electricity consumption in Argentina is used to finance the expansion of rural electrification.

Financial incentives to increase energy efficiency—including grants and low-interest loans for building retrofits, rebates for the purchase of energy-efficient equipment, and tax credits for efficiency investments—account for the majority of public-sector expenditures on energy efficiency in many countries. For example, 84% of the U.S. Department of Energy (DOE) budget devoted exclusively to buildings energy conservation (including research and development) is in the form of grants for retrofits to existing buildings; these grants totaled $230 million in 1991 (U.S. Congress, OTA, 1992a). Similarly, electric and gas utilities are spending an increasing fraction of their demand-side budgets on rebates and direct-payment programs.

Several countries have used innovative technology-procurement programs to promote the development and adoption of

energy-efficient technologies. This approach is known as market transformation because its intent is to transform the market from one using standard-efficiency technologies to one using highly efficient ones. For example, the Swedish government offered a prize for the development of a window with energy losses half that of a conventional triple-glazed window. To ensure marketability, the contest also required maximum visible light transmission, low weight, and low noise transmission. The window that was developed has a typical payback of about 3 to 4 years compared to a double-pane window and 6 to 8 years compared to a triple-glazed window. The winning company received a cash prize, and additional financial incentives of guaranteed first orders for the new model were offered to promote market penetration of the winning design. The United States used a similar approach to promote the development and commercialization of a highly energy-efficient refrigerator.

Financial incentive programs have achieved mixed results. Some programs, such as direct payments to manufacturers for the production of highly efficient products, appear to be quite successful (Lee and Bennett, 1992). Others, such as tax credits, appear to have limited success (U.S. Congress, OTA, 1992a). Program success appears to be tied to the visibility and timeliness of the incentive. For example, a direct cash payment for the desired behavior (e.g., purchase of a highly efficient appliance) often is more effective than a credit for future energy or tax liability, which can be seen as uncertain and less tangible.

22.5.1.2. Building Codes

An increasing number of countries are requiring minimum levels of energy efficiency in new construction. As of 1992, at least 30 countries had some type of building energy code (Janda and Busch, 1992). These codes range from voluntary goals for certain types of buildings to comprehensive requirements covering all aspects of building energy use.

A recent field study found that about half of the new commercial buildings in the United States have significant energy-code violations, such as incorrectly sized HVAC systems (Baylon, 1992). This results largely from code complexity and the resulting poor understanding of code requirements by designers, contractors, and regulators. New code requirements must be accompanied by training and education, or compliance will suffer. There is some evidence that simpler building codes do receive greater compliance [e.g., the New Zealand code (Isaacs and Trethowen, 1985)].

The actual savings achieved as a result of energy codes depends on the reliability and effectiveness of technologies employed, the level of code compliance, and the manner in which a building is operated after it is occupied. Building commissioning (inspecting energy-using systems and measuring energy use after construction) is one way to help ensure that actual building energy use meets design goals.

22.5.1.3. Appliance Standards

A small but growing number of countries require minimum energy-efficiency levels for energy-using appliances. For example, the United States in 1987 set requirements for residential appliances and in 1992 extended standards to many commercial building appliances (U.S. Congress, OTA, 1992a). The European Community (EC) is considering standards for residential appliances (Lebot *et al.*, 1992; GEA, 1993).

Appliance standards eliminate the least-efficient new appliances by setting minimum energy-efficiency levels for new units. In the United States, appliance efficiency standards already enacted are projected to reduce electricity needs by 22 GW from 1990 to 2015 (Levine *et al.*, 1994).

22.5.1.4. Utility Regulation

Energy production, conversion (such as coal into electricity), and transportation for use in human settlements is dominated by government-operated or government-regulated entities because of the large capital requirements of energy supply systems, the importance of these systems to national security, and the natural monopoly status of many energy-distribution systems. For energy used in buildings (predominantly electricity and natural gas), service typically is provided by government-owned or regulated utilities.

In the past, these utilities viewed their role as providing dependable electric and gas supplies at a reasonable cost; they were not involved in how the energy was used. In recent years, however, uncertainty over future demand, plant siting constraints, environmental regulations, and other concerns have put increasing pressure on utilities to better plan their future capacity needs. One result of these forces is the emergence of a concept of utility planning called integrated resource planning (IRP). IRP has been an especially important aspect of utility planning in the United States during the past decade.

A basic tenet of IRP is that consumers do not require energy *per se* but rather energy services (e.g., lighting, heating, and cooling) and are therefore best served if these services are provided at the lowest overall cost. For example, it may be less expensive for a utility to install energy-efficient lights in offices than to build a new power plant to meet the demand of less-efficient lights. The service provided is the same, but the overall cost to provide it may be lower. IRP is the process of evaluating demand and supply options together to determine how to meet energy-service needs at the lowest cost.

Beginning in the late 1980s, changes in utility regulation in the United States to promote or require utilities to perform IRP led many utilities to invest in energy efficiency rather than in new energy supplies (Krause and Eto, 1988). These regulatory changes included limiting disincentives for efficiency—for example, by decoupling revenues from sales—and providing positive incentives for efficiency. In response to these changes,

in 1992 U.S. utilities invested $2.36 billion in demand-side management (DSM) programs—which include energy efficiency as well as peak shifting, peak reduction, and other activities intended to affect the timing or amount of customer energy use (Hirst, 1994). This investment was directed at a wide range of programs, including rebates to utility customers for the purchase of energy-efficiency measures, information programs providing audits and technical assistance, research and development, and funds for energy-service companies that bid against one another to provide energy-efficiency measures to customers (who typically pay a portion of the costs of the demand-side measures).

By one estimate, utility-run DSM programs in the United States led to national reductions in electricity peak demand of 3.7 to 4.2% from 1988 to 1990—about 20 GW of summer on-peak demand (EPRI, 1990). The cost-effectiveness of these investments is somewhat uncertain. A recent analysis of the costs and measured energy savings of 20 utility DSM programs for lighting, representing a total investment of $250 million, estimates the cost of the avoided electricity at 4.7 ± 1.9¢/kWh, compared with 6.9¢/kWh for average current U.S. electricity prices (Eto *et al.*, 1994). In many cases, DSM is less expensive than traditional supply-side options, even in markets such as the United States in which considerable effort has been undertaken by means other than utility programs to increase energy efficiency.

More recently, forces that are leading to deregulation of the utility industry in the United States have reduced U.S. utilities' interest in promoting DSM. The future of large-scale utility DSM programs in the United States is much less certain as a result of possible regulatory changes, although various approaches have been proposed to continue such activities even in a much more deregulated environment. Because the United States has been a leader in this area, many other countries are closely watching these developments, and their own efforts are likely to be influenced by the evolution of utility DSM in the United States.

22.5.1.5. Research and Development

Research and development (R&D) is the process that generates and refines new energy-efficient technologies. In general, only large industries and governments have the resources and interest to conduct R&D. The building industry, in contrast, is highly fragmented. For example, single-family residential construction firms in the United States alone number more than 90,000 (U.S. Congress, OTA, 1992a). This fragmentation makes it difficult for the industry to pool its resources to conduct R&D.

Government-supported R&D has played a key role in developing and commercializing energy-efficient technologies. Low-e windows, electronic ballasts, and high-efficiency refrigerator compressors are examples of widely used technologies whose origins can be traced to public-sector funding of research. Maintaining public support for energy-efficiency R&D (with effective mechanisms to weed out unsuccessful

projects and avoid duplication of private investment) will help ensure the availability of the next generation of energy-efficient technologies.

Much of the R&D in industrialized countries is directly applicable to developing countries. Yet there are problems specific to developing countries that do not exist or are not central to industrialized countries. Examples include house design and construction in hot, humid climates for poor people; energy embodied in house construction, which often is greater than the energy used during house operation; and improved fuelwood and kerosene stoves. While researchers in industrialized countries can contribute to these tasks, also needed is an R&D infrastructure based in developing countries, as well as collaboration among different developing countries that share similar problems. Examples of such collaborative efforts include the Foundation for Woodstove Dissemination (based in Nairobi, with regional focal points in various countries) and the International Energy Initiative (with principal offices in Bangalore and São Paulo).

22.5.1.6. Information Programs

Energy information can be imparted in many forms—including labels and rating systems, demonstration programs, energy audits, and workshops. For example, in the United States and Australia, all major energy-using appliances carry energy labels showing estimated annual energy consumption (IEA, 1993).

Evidence is growing that information programs by themselves have only limited effects on behavior or on energy use. One review concludes that "informational programs are not sufficient to induce individuals to engage in resource conserving behaviors" (Katzev and Johnson, 1987). Information programs are built on the premise that people will generally do what is cost-effective if they know what specific opportunities exist. However, consumers and other decisionmakers often define "cost-effective" differently than do analysts, and consumers often lack the incentive or motivation to use energy-efficient technologies. In such cases, information alone will have little effect. Information programs generally are more effective if they are targeted at specific people and specific behaviors; combined with other programs, such as incentives; and evaluated regularly, with the results of these evaluations used to improve the program.

Programs that establish the performance of energy-using equipment often are prerequisites for other policy approaches. Other programs, such as appliance standards, rebates, and building codes, depend on a credible energy rating.

A new type of information program combines site-specific technical information, public commitment, and positive feedback to encourage cost-effective lighting retrofits. The Green Lights program, run by the U.S. EPA, has had considerable success in encouraging large corporations to undertake comprehensive lighting retrofits. This voluntary program offers

participating companies positive publicity and free technical support. In exchange, the participants must agree to implement all cost-effective lighting retrofits. By one estimate, this program had reduced electricity demand by 70 MW as of December 1993 (U.S. EPA, 1994). A similar program exists for personal computers: Those meeting the EPA's energy efficiency standard are allowed to be labeled as "Energy Stars" (see Section 22.4.2.4). This is seen as a marketing advantage, and many manufacturers have increased the efficiency of their computers to meet the voluntary standard.

22.5.1.7. Special Policy Options for Developing Countries

Besides policy options shared with industrialized countries, developing countries require training, institution-building, capital, and promotion of rural development to increase energy efficiency in buildings (Munasinghe, 1991).

Training efforts need to address all major elements of energy efficiency and related technologies for reducing GHG emissions, including in-depth studies in engineering, economics, public policy, and management. The training needs to be both theoretical and practical. Much of the training will probably best be done within the developing countries, but substantial assistance from industrialized countries in creating and carrying out training courses will be necessary.

In some cases, new institutions (such as the energy-efficiency centers that have been created in Russia, Eastern Europe, and China) will be needed to coordinate a broad range of activities. Such institutions are needed to make certain that energy efficiency and alternative energy investments are treated equally with traditional supply investments and make it possible to "bundle" a large number of demand-side investments into a large investment so that they can attract capital (Gadgil and Sastry, 1992).

Capital needs to be made available for energy-efficiency projects. This availability of capital depends in large measure on the success of training and institution-building—which will enable developing countries to identify viable projects for investment—as well as on the financial climate of the developing nation. The multinational development banks and the Global Environment Facility—a joint program of the United Nations Development Programme, The World Bank, and the United Nations Environment Programme—can assist greatly in providing large-scale "demonstrations" of energy-efficiency projects in developing countries.

Effective rural development will reduce both migration to urban areas and population growth. Examples of important thrusts for rural development include provision of electricity to all households; improved fuelwood stoves, as well as stoves and fuel supply for kerosene and alcohol; adequate water supply and sewage; adequately matched end-use devices and energy sources (e.g., kerosene stoves but not lamps; biogas for electricity generation but not gas lamps; fluorescent, not incandescent, lamps) (Dutt, 1992); identification of leapfrogging opportunities in appliances (e.g., refrigerators) and other energy-using equipment; and use of high-rate anaerobic processes for wastewater treatment.

There are efforts underway through international organizations, overseas development programs, and developing countries using their own resources (China, Thailand, and Brazil are notable examples) that represent an important start in creating the infrastructure for much more efficient use of energy in developing nations.

22.5.1.8. Summary/Conclusions

Table 22-2 summarizes key characteristics of the options discussed in Section 22.5.1. In addition, several lessons have

Table 22-2: *Key characteristics of selected policy options.*

Policy	New Building Construction	Can Affect Existing Building Retrofit	Appliance Selection	Energy Savings Potential[1]	Direct Cost to Government
Energy Taxes	Yes	Yes	Yes	High	Negative
$ Incentives	Yes	Yes	Yes	High	High[2]
Building Codes	Yes	(3)	(4)	Medium	Low
Appliance Standards	No	No	Yes	High	Low
IRP	Yes	Yes	Yes	High	Low
R&D	(5)	(5)	No	Variable	Medium
Information Programs	Yes	Yes	Yes	Low	Low

[1]Energy savings will, of course, vary; this table shows *potential*, and assumes aggressive implementation (e.g., high energy taxes).
[2]If an incentive is offered by a utility, the direct cost is borne by the utility (which is, in many cases, run by the government).
[3]Some cities, such as San Francisco, require existing buildings to meet energy codes as a condition of change in ownership.
[4]Most code requirements apply to the building shell only; however, some codes apply to appliances as well.
[5]R&D effects are long-term.

been learned from past experience that apply to all options, as follows:

- All policies should be evaluated frequently to determine their effectiveness.
- Many policies work in combination with others. Mutually reinforcing regulatory, information, incentive, and other programs offer the best hope for achieving significant portions of the cost-effective energy-efficiency potential.
- Finally, policy experimentation should be encouraged on a small scale. The process of experimenting, evaluating, improving, and expanding can result in policies that will successfully implement the wealth of technologies now available for reducing the emissions of gases contributing to climate change.

22.5.2. Heat Islands

Afforestation efforts or purchases of forested lands to protect them from deforestation have been undertaken to sequester carbon. However, no systematic and comprehensive effort has been made to plant trees or increase the reflectivity of urban areas to mitigate the impact of heat islands. For such an effort to be undertaken, the following steps need to be carried out:

- Create test procedures, ratings, and labels for cool materials.
- Assemble a database on all measures to reduce urban heat islands.
- Incorporate cool roofs and shade trees into building codes in climates where their impact is beneficial.
- Offer utility rebates or other incentives to beat the standards.
- Establish demonstration centers in which the concept of community-wide planting of trees and increased reflectivity is demonstrated to reduce cooling requirements.

22.5.3. Methane Reduction

An awareness of the economics of alternatives for methane recovery and use is often lacking among government officials and potential developers in various countries. Experience with techniques for methane recovery and use for power generation also is lacking. Appropriate demonstration projects can help overcome this problem.

Often, many groups are responsible for different aspects of waste management. Any one weakness in the chain of responsibility can cause failures in the overall waste-management system. Furthermore, different groups generally are responsible for energy generation, fertilizer supply, and waste management. In many places, laws and regulations about waste disposal are either unclear, not enforced, or not supportive of measures to collect methane and use it productively.

These problems have been overcome in some communities by organizing joint management groups for waste management, fertilizer supply, and energy generation (U.S. EPA, 1993b). This single entity, which can be private or public, needs to have the capability and authority to deal with these matters simultaneously.

In many developing countries, projects with higher initial costs that are otherwise profitable are not undertaken because of lack of capital for investment (often resulting from uncertain financial institutions that make capital difficult to attract). Also, as noted, many developing countries have highly subsidized energy prices that make methane recovery not cost-effective. Financing of methane recovery (such as that carried out in China under the auspices of the Global Environment Facility) can help solve these problems, as can the deregulation of energy prices.

22.6. Scenarios

The scenarios discussed below focus on GHG emissions from energy consumption in buildings because buildings represent 75% of the emissions treated in this chapter. It is likely, however, that two of the other three sources of GHG emissions from human settlements—methane from landfills and wastewater—could be controlled as much as CO_2 emissions resulting from energy use in buildings. The third source, PICs from burning of biomass in cookstoves, is likely to be largely eliminated over the long term as biomass is converted into or replaced by modern fuel forms.

We focus on two time periods: the intermediate term (2025) and the long term (2075 to 2100). There has been sufficient work on the development of scenarios to make observations regarding the intermediate time period. Comments about the long term are necessarily more speculative.

22.6.1. Historical Perspective

Table 22-3 shows total energy use and CO_2 emissions attributed to residential and commercial buildings. This information is presented for the years 1973, 1983, and 1990 for three major regions of the world (OECD, FSU/EE, and developing countries) and for the world as a whole. Table 22-4 is derived from the data in Table 22-3 and shows the annual growth rates of energy consumption and CO_2 emissions for three time periods: 1973 to 1983, 1983 to 1990, and 1973 to 1990. The key points follow:

- Average energy growth in buildings between 1973 and 1990 worldwide was 2.5% per year, compared with an average increase in energy use in all sectors of 2.7% per year during the same period.
- Average annual increase in CO_2 emissions was 1.2% per year. Thus, the carbon emissions increased an average of 1.3% less per year than buildings energy use between 1973 and 1990, indicating an improvement in carbon intensity (carbon emissions per unit of buildings energy use).

Table 22-3: *Primary energy use and CO_2 emissions from energy use in residential and commercial buildings (1973–1990).[1]*

	Residential		Commercial		Total	
	Energy (EJ)	Emissions (Mt C)	Energy (EJ)	Emissions (Mt C)	Energy (EJ)	Emissions (Mt C)
OECD						
1973	31	694	17	347	48	1041
1983	33	626	20	355	53	981
1990	36	666	25	407	61	1073
FSU/EE						
1973	9	133	3	44	12	177
1983	14	197	6	66	20	263
1990	15	225	8	75	23	300
Developing Countries						
1973	6	109	2	47	7	156
1983	11	154	3	66	13	220
1990	15	225	4	97	19	322

1973	45	936	22	438	67	1374
1983	57	977	29	487	86	1464
1990	66	1116	37	579	103	1695

[1]Primary energy data are from WEC (1995) and supporting documentation for that report. Residential emissions data for industrialized countries are based on extrapolation of data for nine countries (Schienbaum and Schipper, 1993); commercial emissions data for industrialized countries are based on unpublished energy use data for the same nine countries collated from national sources by Lawrence Berkeley Laboratory. Emissions for developing countries are based on extrapolation of energy use data for 16 developing countries based on unpublished energy use data collated from national sources by Lawrence Berkeley Laboratory. Emissions for FSU/EE are based on data for the former Soviet Union (Cooper, 1993) and Poland (Meyers *et al.*, 1993b).

- In the OECD, there was almost no increase in carbon emissions from buildings energy use between 1973 and 1990 (0.2 % per year); however, the annual growth of carbon emissions from energy consumption went from -0.6% (1973 to 1983) to +1.3% (1983 to 1990).
- In the FSU/EE, energy use in buildings increased relatively steadily from 1973 to 1990; however, the rate of growth in carbon emissions from energy used in buildings declined from 4.0% per year (1973 to 1983) to 1.9% per year (1983 to 1990). After 1990, energy use in the region declined because of the economic disintegration experienced as an aftermath of the breakup of the Soviet Union.
- The average increase in energy use in buildings in developing countries from 1973 to 1990 was 5.8%; the annual increase in carbon emissions was 4.4%.
- Overall, residential buildings use about twice as much energy and are responsible for about twice the carbon emissions as commercial buildings. However, annual energy use in commercial buildings has grown over 35% faster between 1973 and 1990, and their annual carbon emissions have grown 60% faster.

22.6.2. The Intermediate Term (2020–2025)

None of the well-known global energy scenarios has been devoted only to residential and commercial buildings for the period

2020 to 2025.[11] However, many scenarios have treated all sectors in terms of both energy and CO_2 emissions (IPCC, 1995). We review the following cases: (1) IPCC's 1992 ISb scenario (Pepper *et al.*, 1992); (2) the most recent World Energy Council (WEC) cases (WEC, 1993); and (3) a study for the Global Energy Efficiency Initiative (GEEI) (Levine *et al.*, 1991). We present total energy because these cases do not provide sufficient information to obtain energy used by buildings. We also present an estimate of energy use in buildings and associated CO_2 emissions that are roughly consistent with the three sets of scenarios.[12]

22.6.2.1. Reference Cases

A comparison of the reference cases developed by these three groups reveals surprising similarities among them. The energy

---

[11] A recent World Energy Council report, not yet widely distributed, provides detailed scenarios for residential and commercial buildings to 2020 (WEC, 1995).

[12] In all of the cases considered, energy in buildings approximately tracks total energy use, as best as can be determined from the information provided. Energy demand growth in residential and commercial buildings is somewhat above that of all end-use sectors for the developing countries and somewhat below that for the industrialized countries. Therefore, we multiply the results for all end-use sectors by 0.30 to obtain estimates of energy use and emissions associated with residential and commercial buildings.

Table 22-4: *Annual average growth rates (%) of primary energy use and CO$_2$ emissions from energy use in residential and commercial buildings (1973–1990).*

	Energy	**Emissions**
OECD		
1973–1983	1.0	-0.6
1983–1990	2.0	1.3
1973–1990	*1.4*	*0.2*
FSU/EE		
1973–1983	5.3	4.0
1983–1990	2.2	1.9
1973–1990	*4.0*	*3.2*
LDC		
1973–1983	6.1	3.5
1983–1990	5.4	5.6
1973–1990	*5.8*	*4.4*
World		
1973–1983	2.5	0.6
1983–1990	2.6	2.1
1973–1990	*2.5*	*1.2*

demand in 2025 is between 1.65 and 2.05 times that in 1990, and the average annual growth rate is between 1.5 and 2.0% per year. All three groups produce a 2025 reference case with energy use very nearly double 1990 levels, corresponding to an annual growth rate of 1.9 to 2.0%.

On the one hand, this close agreement among the different groups on an expected reference case for energy in the year 2025 is surprising because of the tremendous number of unknowns about future energy demand. As noted in Section 24.3, a large number of factors influence energy demand growth. The average annual growth in energy demand since 1973 has been about 2.4% per year (with energy in buildings growing at 2.1% per year during the period). Thus, the similarity among the scenarios reveals that the best guess about the future is that it will be much like the past. In this case, it appears that analysts implicitly assume that the next three decades will be much like the two decades since the oil embargo.

The WEC case shows almost the entire energy growth during the period occurring in the developing world. The IPCC and GEEI cases have about 70% of energy growth happening in the developing world. In spite of this concentration of growth, energy per capita in the developing world in all of the reference cases remains a small fraction of that in the industrialized countries. For example, in IPCC reference cases IS92a and IS92b, energy per capita in developing countries grows from 10% of that of industrialized countries in 1990 to 17.5% in 2025.

22.6.2.2. *Efficiency Cases*

WEC provides two energy-efficiency policy cases. One assumes that very significant efforts are made throughout the world to achieve energy efficiency. This case results in a reduction in energy growth by 0.6% per year from the reference case. The other is an extremely high-efficiency case with a "rate of reduction in energy intensity far in excess of anything achieved historically" and a "very low increase in energy demand in the developing countries." In this second case, energy growth diminishes an additional 0.6% per year, resulting in an increase in energy demand of 0.9% per year. In this case, the energy consumption in the OECD declines 25%, that in the former Soviet Union and Eastern Europe remains about the same as in 1990, and that in the developing world doubles.

The GEEI energy-efficiency case reduces annual energy demand growth by 0.73%, yielding an annual increase of 1.1% per year. This case assumes a very significant push for energy efficiency in both the industrialized and the developing countries. In the GEEI efficiency case, energy demand in the OECD is essentially unchanged between the present and 2025, whereas energy demand in the developing world almost doubles.

IPCC does not provide any policy cases. However, the U.S. Environmental Protection Agency produced policy scenarios that are useful in a general way in indicating global energy-efficiency opportunities for 2025 and beyond (U.S. EPA, 1990). The Rapidly Changing World scenarios most nearly approximate the WEC and GEEI cases considered above. Policies promoting energy efficiency reduce the annual growth rate of energy by 0.5% per year, from 1.95 to 1.43% annually, from the present to 2025. In the other major pair of reference and policy cases analyzed by EPA, the Slowly Changing World scenarios, energy demand was reduced by 0.41% per year, but from a much lower growth rate of 1.07% per year.

Although there is tremendous uncertainty about the future demand for energy (IPCC, 1995), the reference case of key analyses hovers around 2% per year energy growth for this time period. Under these assumptions (business much as it has been during the past 2 decades), with considerable emphasis on energy efficiency in these reference cases and most of the energy growth in the developing world, aggressive policies to increase energy efficiency could reduce annual demand growth by 0.5 to 1.0%.

What would be required to maintain carbon emissions from energy at current levels between 1990 and 2025? These studies suggest that, in a reference case with energy demand growing at an average of 2% per year during the period, strong policies to promote energy efficiency could be responsible for about 30% to 60% of the effort needed to achieve zero growth in carbon emissions from energy.[13] The remaining 40 to 70% reductions in carbon emissions would need to come from fuel switching—from fuels of higher to those of lower or zero carbon intensity (i.e., greater use of natural gas, renewable energy sources, or nuclear energy)—to achieve 1990 carbon emissions

---

[13] A 2% annual energy growth for 35 years will double energy demand; a 1.5% annual growth over this period results in a 68% increase in energy demand; a 1% annual growth increases energy demand by 41%.

in 2020 under the reference-case assumptions. Another way of saying this is that aggressive policy to promote energy efficiency over the next three to four decades could, under typical reference-case assumptions, contribute about half of the effort needed to maintain carbon emissions from energy use at current levels.

22.6.3. The Long Term (2025–2100)

Scenarios for energy demand to the year 2100 vary dramatically (IPCC, 1995). Carbon emissions vary much more than energy consumption because energy of widely varying carbon contents can be used. In reviewing a large number of global scenarios for the year 2100, the IPCC (1995) notes that energy intensity varies by less than a factor of 3. More specifically, the different scenarios calculate (or assume) an energy intensity index varying from about 0.2 to 0.55 for 2100, whereas the index is 1.0 today (the index is a measure of energy use per unit gross world product).

Thus, in this very aggregate view, if gross world product grows to about 4.5 times 2025 levels by 2100 (as assumed in IPCC IS92a and b), then global energy use by 2100 might be expected to grow by a factor of about two to three times that of 2025. Higher and lower growth rates of gross world product per capita and of population would increase or decrease energy growth in this period accordingly. The most extreme of the six IPCC cases has gross world product per capita growing somewhat more than twice and less than half the size of the base case in 2100; population projections also show significant variations by 2100.

This review of long-term scenarios suggests that one might expect energy use in 2100 to be about two to three times that of 2025 if the world economy grows at a modest rate (e.g., 2%) during the period and population growth declines to about 0.4% per year. Lower economic and population growth could significantly lower the energy projection, and higher growth rates would increase it. We believe that this review of energy scenarios applies well to energy in buildings as well. Most long-term scenarios for energy show buildings using 30 to 35% of total energy, both at present and in the long term.

Goldemberg *et al*. (1987a, 1987b, 1988) describe end-use oriented strategies for industrialized countries that suggest ways in which per capita energy use can decline by substantial amounts. They also provide energy strategies for developing countries that increase per capita energy use to meet needed energy services and avoid inefficient energy uses. While the authors carry their analysis only to 2020, their ideas apply well to a longer term view in which major transformations in all energy-using stock will take place.

A low-energy future for buildings in 2100 could include the following:

- Virtual elimination of space heating in all climates by means of building shells with very high resistance to heat loss or gain, involving high-insulation walls, ceilings, and floors and triple-pane windows with transparent, heat-reflecting films; wide use of passive solar designs; and mass-produced components (walls, ceilings, etc.) with very low infiltration rates
- Reduced need for space cooling and dehumidification because of improved building design and use of passive cooling; provision of cooling and dehumidification by very high-efficiency systems; and use of low-resistance ducts and high-efficiency variable-speed motors for pumps
- Water heating that uses active solar systems combined with the use of waste heat from refrigerators
- Advanced lamp technology combined with lighting controls, task lighting, and greater use of natural light, reducing lighting energy requirements to 10 to 15% of today's levels
- A dramatic decline in refrigerator/freezers' energy use through the use of high insulating walls and doors, efficient compressors, advanced motors, and so forth. Energy use declines to 250 kWh/year by 2025. After 2025, entirely new ways of storing and cooling food could further reduce energy requirements.
- Residential and low-rise commercial buildings that become net producers of energy as roofs incorporate photovoltaic panels and small biofuel power plants provide backup electricity.

Such a future could result in long-term declines in residential energy use in the industrialized world and relatively modest added requirements in the developing world after 2025. Energy use in commercial buildings, on the other hand, will likely continue to increase much longer than in residential buildings.

One scenario for low energy use in residential and commercial buildings in 2100 has been developed by Lazarus *et al*. (1993). In this scenario, delivered energy use for residences in 2100 is very close to today's level.[14] Delivered energy for commercial buildings is triple today's level. All of this increase occurs in the developing world; delivered energy use in commercial buildings in the OECD declines from today's levels.

CONTENTS

EXECUTIVE SUMMARY

Agriculture accounts for one-fifth of the annual increase in anthropogenic greenhouse warming. Most of this is due to methane (CH_4) and nitrous oxide (N_2O); agriculture produces about 50 and 70%, respectively, of their anthropogenic emissions. This chapter on mitigation options confirms earlier IPCC estimates and quantifies potential contributions by agriculture to reduce greenhouse gas emissions.

Between 400 and 800 Mt C/yr could be sequestered worldwide in agricultural soils by implementation of appropriate management practices to increase productivity—including increased input of crop residues, reduced tillage, and restoration of wasteland soils. However, soil carbon (C) sequestration has a finite capacity over a period of 50–100 years, as new equilibrium levels of soil organic matter are established.

Biofuel production on 10–15% of the land area currently in agricultural use or in agricultural set-asides could substitute for 300–1,300 Mt of fossil fuel C per year. Recovery and conversion of crop residues could substitute for an additional 100–200 Mt fossil fuel C per year. However, the possible offsets by increased N_2O emissions need to be considered.

Energy use by agriculture relative to farm production has decreased greatly since the 1970s. Fossil fuel use by agriculture in industrialized countries, although constituting only 3–4% of overall consumption, can be further reduced by, for example, minimum tillage, irrigation scheduling, solar drying of crops, and improved fertilizer management.

Significant decreases in CH_4 emissions from agriculture can be achieved through improved nutrition of ruminant animals and better management of paddy rice fields. Additional CH_4 decreases are possible by altered treatment and management of animal wastes and by reduction of biomass burning. These combined practices could reduce CH_4 emissions from agriculture by 15–56%.

The primary sources of N_2O are mineral fertilizers, legume cropping, and animal waste. Some N_2O also is emitted from biomass burning. N_2O emissions from agriculture could be reduced by 9–26% by improving agricultural management with available techniques.

Ranges in estimates of potential mitigation reflect uncertainty in the effectiveness of recommended management options and in the degree of future implementation globally. Comprehensive model-based analyses and improved global databases on soils, land use, and trace gas fluxes are needed to reduce the uncertainty in these estimates.

Farmers will not voluntarily adopt greenhouse gas (GHG) mitigation techniques unless they improve profitability. Some techniques, such as no-till agriculture or strategic fertilizer placement and timing, already are being adopted for reasons other than concern for climate change. Proposed options for reducing GHG emissions are consistent with maintaining or increasing agricultural productivity.

23.1. Introduction

Agriculture contributes significantly to anthropogenic emissions of carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O). Based on IPCC data (IPCC, 1994) and additional estimates described below, agriculture accounts for about one-fifth of the annual increase in radiative forcing (Figure 23-1). Land-use changes related to agriculture especially in the tropics, including biomass burning and soil degradation, are also major contributors.

The large influence of agriculture needs to be traced back to its individual sources so that effective mitigations can be sought. Options such as those proposed by the International Workshop on Greenhouse Gas Emissions from Agricultural Systems (U.S. EPA, 1990a), and others that have been proposed more recently, are shown in Table 23-1.

The IPCC First Assessment Report (IPCC, 1990a, 1990b) concluded that land-use changes are the most important source of anthropogenic CO_2 after fossil fuel combustion. Improving the productivity of existing farmland was proposed to mitigate these emissions. Regarding the other two trace gases, it was suggested that CH_4 from rice fields could be reduced by 20–40% and CH_4 from ruminant animals by 25–75%. Improving Nitrogen (N) fertilizer efficiency and minimizing N surpluses were cited as important approaches for reducing agricultural N_2O emissions, but no quantitative assessment was made at that time.

Subsequent IPCC assessments (IPCC, 1991, 1992) corroborated most of the earlier suggestions, but estimates of CH_4 emissions from rice were considerably reduced, and animal manure was identified as an additional CH_4 source. The importance of N_2O emissions from heavily fertilized soils was further emphasized, but the quantities involved still remained highly uncertain.

Since then, the availability of new regional and global databases (FAO, 1990a, 1990b, 1990c; Eswaran *et al.*, 1993; Sombroek *et al.*, 1993), additional site-specific measurements, and the utilization of more thoroughly tested simulation models (Raich *et al.*, 1991; Ojima *et al.*, 1993c; Parton *et al.*, 1993; Potter *et al.*, 1993) have improved the possibilities for quantification. However, information concerning greenhouse gas (GHG) fluxes from agricultural systems is still limited.

Global food production needs and farmer/society acceptability considerations suggest that mitigation technologies should meet the following general guidelines: (1) agricultural production levels will be maintained or enhanced in parts of the world where food production and population demand are in delicate balance; (2) additional benefits will accrue to the farmer (e.g., reduced labor, reduced or more efficient use of inputs); (3) agricultural products will be accepted by local consumers.

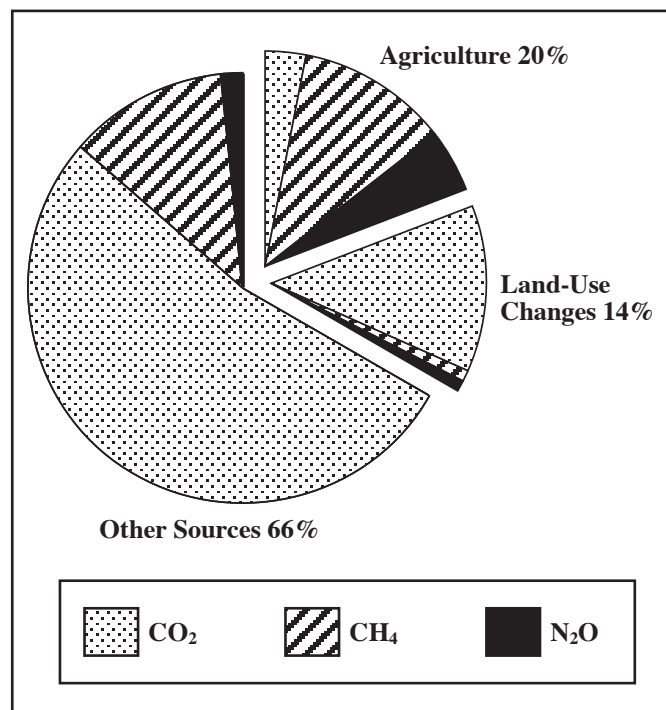
Table 23-1 summarizes greenhouse gas mitigation options related to agriculture. These options are grouped into different


Figure 23-1: Proportions of the annual increase in global radiative forcing attributable to agriculture and agriculture-related land-use changes.

activities, and the list includes a qualitative assessment of their relevance for the three trace gases CO_2, CH_4, and N_2O. Emphasis in this chapter will be given to quantifying these mitigation potentials.

23.2. Carbon Dioxide

Options to mitigate CO_2 emissions from agriculture and land-use changes include the reduction of emissions from present sources and the creation and strengthening of carbon sinks. Increasing the role of agricultural land as a sink for CO_2 includes C storage in managed soils and C sequestration after reversion of surplus farm lands to natural ecosystems (Follett, 1993). Biofuel production on agricultural lands has a considerable potential for mitigation of CO_2 emissions by providing C offsets to use of fossil fuel.

23.2.1. Land-Use Changes

23.2.1.1. Land-Use Changes in the Tropics

Biomass burning and loss of soil C associated with the conversion of native ecosystems to agricultural use in the tropics is believed to be the largest non-fossil fuel source of CO_2 input to the atmosphere. The net release of CO_2 from land-use conversion is thought to be in the range of 1.6 ± 1.0 Gt C/yr (IPCC, 1994). Of the C losses attributed to land use, soil C loss has been estimated to account for 20–40% (Detwiler, 1986;

Houghton and Skole, 1990). Recent data, however, suggest that soil C losses following deforestation may have been overestimated, particularly for forest conversions to pasture, where soil C can recover to levels equal to or higher than native forest within a few years (Lugo and Brown, 1993; Cerri *et al*., 1994). However, a reduction in land conversion rates remains an important CO_2 mitigation option (see Chapter 19).

Population increase, unresolved land tenure issues, desire for higher living standards, and other sociopolitical factors drive the demand for new cropland in the tropics. However, the suitability and management of this new cropland is often poor, resulting in soil degradation that exerts additional pressure to convert new lands to agriculture. Currently only half of the conversion of tropical forests to agriculture contributes to an

increase in productive agricultural area; the other half is used to replace previously cultivated land that has been degraded and abandoned from production (Houghton, 1994). The only way to break out of this cycle is through more sustainable use and improved productivity of existing farmland (Sanchez *et al*., 1990) and better protection of native ecosystems.

The mitigation options associated with land-use changes are strongly related to major climatic zones. The most significant opportunities appear to be in the humid tropics and in tropical wetlands. In sub-humid zones, much of the land area has already been converted to permanent agriculture. However, improved management and productivity on these lands could help to reduce agricultural expansion (and hence deforestation) in humid zones, especially in Latin America and Africa. In the

semi-arid zone, soil and biomass C stocks are smaller and differ less as a function of land use; therefore, the scope for CO_2 mitigation through changing land-use patterns is more limited.

23.2.1.2. Reversion of Agricultural Land in Temperate Zones

In temperate regions there is little development of new agricultural lands, and in regions with food surpluses (e.g., United States, Canada, Western Europe) the agricultural land base is being reduced. A similar situation may occur in the longer term for countries in Eastern Europe and the former Soviet Union (FSU) as per area productivity increases. Thus, the reversion of marginal agricultural land to forest (including shelterbelts and plantations), grassland, and wetlands represents a potential for C sequestration.

Rates of C accumulation in reverted agricultural soils vary greatly depending on climate and soil conditions, the vegetation type established, and the degree of management (Table 23-2).

Upon release from agricultural production, C sequestration would continue only until soils reached a new equilibrium value, most of which would be realized over a 50–100 year period. An exception is the case of reversion to wetlands, where the buildup of organic soils provides a more sustained C sink. About 8 Mha of organic soil-wetlands are currently under cultivation in the temperate zone. As of 1980, these soils were estimated to provide a net C source of ~5 Mt/yr, but represent a potential sink of ~55 Mt C/yr in their native state, with sustained rates of C accumulation of 20–225 g C/m²/yr (Amentano and Menges, 1986).

Currently about 25 Mha in the United States, Canada, and the European Union (EU) (~15% of total cropland) has been taken out of production by government set-aside programs. The U.S. Conservation Reserve Program, started in 1985, is scheduled to begin expiring in 1996, and 75% of the land is expected to return to agriculture by 2005 unless the program is extended. The EU agricultural set-aside programs are for 1–5 years and can include annual cropping for non-food production (e.g., oilseed for fuel), although separate programs exist for tree planting. Because C stocks are likely to be depleted again when lands are returned to cultivation, short duration set-asides have little or no effect on C sequestration. If soils are left uncultivated and allowed to revert to native vegetation, C contents in upper soil horizons could eventually reach levels comparable to their precultivation condition. Considering the ~640 Mha of cropland with real or potential surpluses (United States, Canada, FSU, Europe, Australia, and Argentina) and assuming recovery of the soil C originally lost due to cultivation (25–30% per Davidson and Ackerman, 1993), a permanent set-aside of 15% of the land area might sequester 1.5–3 Gt C.

A large-scale reversion or afforestation of agricultural land is possible only if adequate supplies of food, fiber, and energy can be obtained from the remaining area. This is currently possible in the EU and United States through intensive farming systems. However, if farming intensity changes because of environmental concerns or changes in policy (Enquete Commission, 1995; Sauerbeck, 1994a), this mitigation option may no longer be available.

23.2.2. Carbon Sequestration in Agroecosystems

Losses of soil C as a consequence of cultivation are ubiquitous and well-documented (Haas *et al.*, 1957; Greenland and Nye, 1959; Davidson and Ackerman, 1993). Historical losses of C observed in many soils were due, in part, to low production levels, erosion, inadequate fertilization, removal of crop residues, and intensive tillage. Improved management is capable of

Volcanic Soils	31	7	5	2
Other Soils	308	18	13	5
Total	**1727**	**222**	**167**	**55**

[a] Soil groups are aggregated according to the global distribution of cultivated soils in major FAO soil groups by Bouwman (1990). Aggregations included the following soil types: Forest (Acrisols, Podzoluvisols, Ferralsols, Luvisol, Cambisol, Nitosol, Podzol, Chromic Luvisol, Planosol), grassland (Chernozem, Phaeozem, Greyzem, Kastanozem, Vertisol), wetland (Gleysol, Histosol), volcanic (Andosol), and other (Lithosol, Arenosol, Regosol, Solonchak, Solonetz, Xerosol). Some soil types (e.g., Acrisols) that contain subgroups occurring in different vegetation types (e.g., forest vs. grassland) were aggregated under a single soil group (e.g., forest) designation.

[b] C contents, to 1m depth, were calculated separately for each FAO soil type (excluding Histosols) using data from Sombroek *et al*. (1993), then aggregated. C contents for Histosols (112 kg/m²) were from Amentano and Menges (1986).

[c] Carbon loss due to cultivation of mineral soils was assumed to be 26% of C in the top 30 cm, based on the average reported by Davidson and Ackerman (1993). Losses were calculated separately for the surface layer of soil groups given by Sombroek *et al*. (1993), then aggregated. Estimates of C lost from cultivation of Histosols to 1990 (8 Gt C) were from Amentano and Menges (1986). C mass in cultivated soils was calculated as the difference between uncultivated C contents and C loss estimates.

increasing C levels on present agricultural soils and reducing losses from newly cultivated soils. In general, high residue production, perennial forage crops, elimination of bare fallow, and reduced tillage will promote C sequestration.

An estimate based on the distribution of cultivated soils across major soil groups, their associated C contents, and average loss rates due to cultivation yields a current global stock in cultivated lands of 167 Gt C and a historical loss from these soils of 55 Gt C (Table 23-3). Comparable estimates have been obtained by Houghton and coworkers (Houghton *et al*., 1983; Houghton and Skole, 1990) from a more detailed analysis of historical land-use data. They estimated global losses of soil C since 1860 to be 30 Gt C (15% of the total 170 Gt C lost from vegetation and soils), or 41 Gt C since the beginning of settled agriculture (Houghton and Skole, 1990). These land use-based estimates do not include C loss from drainage of wetland soils, which could account for the higher value calculated in Table 23-3.

These global estimates of C loss from cultivated soils provide a reference level for the C sequestration that might be achieved through improved management. Increasing C levels in artificially drained wetland soils (e.g., Histosols) is unlikely except in cases where they are reverted to wetlands. Therefore, the potential to increase C levels in cultivated systems is largely restricted to upland soils. Assuming a recovery of one-half to two-thirds of historic C losses as a reasonable upper limit, the global potential for C sequestration in cultivated soils over the next 50–100 years would be on the order of 20–30 Gt. This would require increased production and major improvements in management on much of the world's cultivated areas, particularly in less-developed regions. Under current conditions, it

is estimated that there is little or no net C sequestration in temperate soils as a whole, and cultivated soils in the tropics are probably a net source of C (Cole *et al*., 1993; Sauerbeck, 1993). To identify the most important management factors and constraints on C sequestration, more detailed regional information is provided in Sections 23.2.2.1 through 23.2.2.3.

23.2.2.1. Tropical Agroecosystems

The decrease in soil C with permanent cultivation is of the same order as that for temperate regions, often 20–50% or more, although C losses typically are more rapid in the tropics. It is estimated that arable land and pasture use in the tropics currently contributes a net C flux of 90–230 Mt C annually (Lal and Logan, in press). Decreases in soil C are a result of lower organic matter inputs relative to native systems, enhanced decomposition rates, and/or erosion. Management to increase soil C levels is a high priority for improving the productivity and sustainability of tropical agricultural systems (Swift and Sanchez, 1984). Opportunities to increase soil C levels include improved management of presently cultivated land and the restoration of degraded lands. The latter will include conversion to nonagricultural uses such as forest or biofuel production, but some areas may be suitable for agricultural production as well.

Management practices to increase soil C stocks include reduced tillage, increased production and crop residue return, perennial crops (including agroforestry), and reduced bare fallow frequency. Introduction of deep-rooting cultivars of tropical grasses also shows promise (Fisher *et al*., 1994). However, there are

economic, educational, and sociological constraints to improved soil management in much of the tropics. Many tropical farmers cannot afford or have limited access to purchased inputs such as fertilizer and herbicides. Crop residues often are needed for livestock feed, fuel, or other household uses, which reduces C inputs to soil (Elwell, 1993). On the other hand, development efforts that seek to increase the sustainability and productivity of tropical agriculture will be largely compatible with CO_2 mitigation needs. To the extent that improved management is based on significantly increased fossil fuel consumption, however, benefits for CO_2 mitigation will be decreased.

Increasing soil C levels depends on increasing crop productivity and input of organic matter to the soil (through irrigation, soil fertility improvement, multiple-cropping, controlled grazing) and/or decreasing decomposition rates (through reducing tillage, residue quality, pH, temperature, moisture). The relative importance of these factors will vary according to climate and soil type.

In much of the semi-arid tropics, the predominant land use is pastoral, and grazing control is an important option for maintenance of soil C. Data from northeastern Brazil suggest that improved pastures can maintain C levels comparable to those of native systems (1–1.5% C), which are roughly twice those in shifting cultivation systems (Tiessen, pers. comm.). Water availability is the main determinant of productivity, and the use of reduced tillage and mulching to increase available water and to reduce surface erosion can promote increased soil C (Lal, 1986). In areas where cropping and livestock are closely integrated, such as parts of the west African Sahel and the Miombo zone in southern Africa, better efficiency of manure utilization and supplemental commercial fertilizer can increase productivity and soil C (Feller and Garin, pers. comm.). Overall, however, C stocks are low even under native ecosystems, and therefore CO_2 mitigation options are limited.

In sub-humid and humid zones, CO_2 mitigation potentials are higher. With greater water availability, the physical condition and fertility of soils become more important as production constraints. The inherent physical conditions of these soils are generally good but can be degraded with intensive tillage. Reduced tillage, mulch farming, alley cropping, and other agroforestry practices can contribute to maintenance of soil structure and reduction of erosion and can provide increased organic matter inputs and reduced decomposition rates (by reducing soil temperatures and soil disturbance). In wetland soils, especially paddy fields, low aeration slows decomposition and leads to high C contents, especially in continuously wet soils. When soils dry up during part of the cropping cycle, C contents will decrease unless green manures or large amounts of crop residues (e.g., wheat) are produced in the dry season. The widespread burning of rice straw reduces organic C inputs to the soil. Higher C stocks in wetland soils generally increase CH_4 emissions, although better water management can help control CH_4 emissions.

Restoration of degraded lands is a significant mitigation option. Worldwide there are about 1,200 Mha of moderately to severely degraded lands, which constitute a large potential C sink (Oldeman *et al.*, 1990). In the tropical and subtropical regions of China, about 48 Mha is classified as "wasteland," of which 80% is considered suitable for forestry and 8% and 6% could be restored as cropland and pasture, respectively (Zhao, pers. comm.). Based on field experiments, net C increases in soils reclaimed for agriculture are on the order of 2.4 kg C/m^2 over a 10-year period, which represents a net C sink of 92 Mt C. Higher increases could be obtained for the larger area suitable for reforestation. In India, more than 100 Mha are classified as degraded and greatly depleted in soil C. Experiments have shown that salt- and alkali-affected soils have a relatively high potential for C sequestration if suitable tree and grass species and water management measures are used (Gupta and Rao, 1994). These authors estimated that a restoration of 35 Mha of wasteland area in India could sequester up to 2 Gt C.

23.2.2.2. Temperate Agroecosystems

Most temperate agricultural soils have been cultivated for decades to centuries, and most probably have attained a C content close to equilibrium value. Very little land in the temperate zone is currently being converted to agriculture. For industrialized agriculture (i.e., United States, EU), soil C probably is increasing slightly due to increased productivity and hence greater crop residue inputs, improved residue management, and reduced tillage. In less industrialized agriculture (e.g., FSU) and in areas that have been brought into cultivation more recently, soil C probably is decreasing slightly. As a first approximation, it is reasonable to assume that temperate agricultural soils are not a large source or sink of C under current practices (Cole *et al.*, 1993; Sauerbeck, 1993). However, soil organic C in permanently cropped fields can be increased through a number of management practices, including greater returns of organic materials to soil, decreased periods of fallow, use of perennial and winter cover crops, recycling of organic wastes, reduced tillage, erosion control, and agroforestry.

Soil C levels are closely tied to the rate of C return from crop residues and other sources. Numerous long-term field experiments demonstrate that for many soils, organic C levels are directly proportional to the annual rate of C input (Rasmussen and Collins, 1991; Paustian *et al.*, 1995). Increasing crop production through better nutrient management, reduced fallow periods, and improved cultivars can increase C inputs to soil if crop residues are retained.

Summer fallow is used extensively in semi-arid areas of Canada, the United States, Australia, and the FSU to offset rainfall variability and increase soil water storage. Eliminating or reducing summer fallow through better water management could significantly increase C in semi-arid croplands and decrease soil erosion (Janzen, 1987; Campbell *et al.*, 1990). During fallow periods, mineralization of soil organic C generally is faster than under a crop, and there is no input of crop

residues (e.g., in a spring wheat-fallow rotation, there may be only 4 months of crop cover per 24 months).

Greater use of perennial forage crops can significantly increase soil C levels, due to high root C production, lack of tillage disturbance, and protection from erosion. Increases of up to 100 g C/m²/yr have been documented for cultivated land planted to grassland (see Table 23-2). Where climate permits, winter cover crops decrease erosion and provide additional inputs of C, thereby increasing soil organic carbon (SOC). Simulation of the U.S. cornbelt with the EPIC model suggested an additional C sequestration of 400 g C/m² in 100 years from the use of winter cover crops (Lee *et al.*, 1993).

Large applications of manure can increase soil C as much as can reversion to natural vegetation. For example, in the Broadbalk Wheat Experiment at Rothamsted, UK, the application of farmyard manure (FYM) at the very high rate of 35 t/ha annually since 1843 has increased %C in topsoil (0–23 cm) from 0.92% (measured in 1881) to 2.8%. However, such an application rate is not possible on a large scale, and the off-site impacts of large manure application need to be considered.

Reduced- or no-till systems often (but not always) increase soil C. Reduced tillage generally causes organic matter to be concentrated near the surface, but this does not necessarily represent an increase within the total profile (Powlson *et al.*, 1987). However, several studies have shown genuine increases in SOC as a result of reduced tillage (e.g., Dick *et al.*, 1986; Saffigna *et al.*, 1989; Balesdent *et al.*, 1990; Ismail *et al.*, 1994). For the United States, Kern and Johnson (1993) estimate that an increase in the use of reduced tillage from current levels of 27% to 76% of cultivated area by the year 2020 would result in a net C sequestration of 0.2–0.3 Gt C versus a net loss of 0.2 Gt C with current practices. Gaston *et al.* (1993) estimate that no-till management of 181 Mha of climatically suitable land in the FSU could sequester as much as 3.3 Gt C.

In the FSU, significant effort has been made to prevent losses of soil organic matter by using straw mulch and shelterbelts, and terracing steep slopes. Planting of 18 Mha of shelterbelts and afforestation of 53 Mha of degraded landscapes and heavily polluted lands would allow 16 Gt C to be sequestered and conserved over 100 years (160 Mt C/yr)(Kolchugina and Vinson, pers. comm.).

23.2.2.3. Regional Analyses

A rigorous assessment of soil C changes and the potential impacts of various mitigation strategies requires the integration of information on land-use and management practices, soils, and climate at regional scales. The growing availability of national and, to a lesser extent, global databases, together with the use of simulation modeling, provide the framework for such analyses. While no such global-scale analyses of C in agricultural systems have yet been done, three regional analyses for

areas in North America illustrate the utility of such an approach, as well as problems and information constraints.

Impacts of different management on soil C content for the U.S. cornbelt region over a 100-year period were assessed by Lee *et al.* (1993) using the EPIC model (Sharpley and Williams, 1990). This study suggested continued losses of C under the current mix of tillage practices. However, widespread use of no-till plus winter cover crops resulted in a net accumulation of 0.10 Mt C/yr. Lee *et al.* (1993) projected that the net effect of a shift to widespread use of no-till plus winter cover crops could conserve 3.3 Mt C/yr over the next 100 years.

The potential C sequestration in Canadian agricultural soils over the next 50 years was assessed by Dumanski *et al.* (pers. comm.) using long-term field data and the Century model (Parton *et al.*, 1987). They assumed that cropland area would remain within 5% of the current area; that there would be a major reduction in summer/fallow in the Chernozemic soil zone; and that cropping practices would be intensified, with increased fertilizer use, improved residue management with reduced tillage, and better erosion control. Over a 50-year period they projected an increased storage of 22 Mt C due to reduction of summer fallow and 69 Mt C from increased hay crops in rotations. Proper fertilization and erosion control through zero-tillage and other measures were projected to further increase C. Summing these management treatments, C equivalent to 3.4% of Canada's present CO_2 emissions could be sequestered annually in improved croplands.

Potential impacts of alternative management practices on soil C in the major agricultural regions of the central United States were analyzed by Donigian *et al.* (1994). They conducted a detailed analysis combining geographic databases on climate, soils, and land use with Century model (Parton *et al.*, 1987) simulations. Management scenarios included increased use of cover crops, increased adoption of reduced tillage, and impacts of land set-aside, as well as potential increases in crop production. This analysis projected an increase in net soil C, primarily due to increases in productivity and crop residue inputs. Thus, a continuation of current trends in agricultural practices would increase C storage by 25 to 50 Mt C per year in a region comprising 70% of U.S. cropland (87 Mha).

A global-level analysis using approaches similar to those outlined above is needed in order to better evaluate potential C changes, including an analysis of management effects and interactions with potential climate change. However, databases on land use and management, soils, and climate for many developing countries are not adequate to provide a reliable framework for analysis. Uncertainties about the distribution of land-use types and management regimes in relation to soils and climate and the behavior of soil organic matter below the surface horizon are important topics that need to be addressed. The current efforts of Food and Agriculture Organization (FAO) to improve such databases at both national and global levels should be expanded.

23.2.3. Fossil Energy Use by Agriculture

Fossil energy use by agriculture is about 3–4.5% of the total consumption in the developed countries of the world (CAST, 1992; Haas *et al*., 1995a, 1995b; Enquete Commission, 1995). Thus, for the primary farm production sector, the mitigation potentials through reduced fuel consumption are relatively small. The ratio of energy use to farm production has decreased markedly since the "oil crisis" of 1973 sharply increased the costs of energy to all sectors including agriculture (Darmstadter, 1993) and continues to decrease at this time (U.S. Government Executive Office, 1995). Further reductions may be expected by expanded use of minimum tillage, irrigation scheduling, solar drying of crops, and improved fertilizer management.

Tillage and harvest operations account for the greatest proportion of fuel consumption in intensive cropping systems. Considerable energy savings are possible because the fuel requirements using no-till or reduced tillage are 55% and 78%, respectively, of that for conventional moldboard plow tillage (Frye, 1984).

The fixation of atmospheric N into synthetic fertilizer requires about 1.2 kg of fossil C equivalents for each kg of fixed N. Therefore, the present global consumption of about 80 Mt fertilizer N corresponds to the consumption of 100 Mt fossil C per year. Although the N fertilizer use in developed countries may not increase much further, it is predicted to double in developing countries by the year 2025 (IPCC, 1992; Sauerbeck, 1994a). Accordingly, the energy required for manufacturing N fertilizers will increase to about 150 Mt fossil C annually. In Southeast Asia, for example, a 30% increase in the use of fossil fuel is considered necessary by the year 2000, if food production is to follow population and economic growth. Thus, optimizing N use efficiency and minimizing N surpluses provide mitigation of CO_2 emissions in addition to reducing N_2O emissions.

High-intensity animal production has become the biggest consumer of fossil energy in modern agriculture (van Heerwarden *et al*., 1992; Enquete Commission, 1995). This needs to be considered more critically, as do recent emissions comparisons between conventional and alternative agricultural systems (Enquete Commission, 1995). As an example, Haas *et al*. (1995a, 1995b) calculated that organic farm systems in Germany emit only 39% of the overall fossil C required by conventional farms. This is due mainly to the replacement of mineral N fertilizers by legume cropping, balanced animal stocking rates, and a much lower consumption of feed concentrates (Koepf *et al*., 1988; Enquete Commission, 1995). Even energy inputs per ton of harvested crop were lower by 20–60% (Haas *et al*., 1995a, 1995b), although this depends on yield levels and cannot be generalized (Nguyen and Haynes, 1995).

Fuel requirements by the food sector as a whole (including processing, preservation, storage, and distribution) account for 10–20% of total fossil energy consumption (Pimentel *et al*., 1990; CAST, 1992; Haas *et al*., 1995a, 1995b). Thus, it may be worthwhile to reconsider the extent of food transport and the overall nutritional habits of the societies in the developed world. For instance, reducing animal protein consumption in Europe and the United States by only one-half of its present excess would decrease N fertilizer requirements by about one-half (Sauerbeck, 1994b; Isermann and Isermann, 1995).

23.2.4. Biofuel Production

Both non-food crops and many conventional agricultural crops produce biomass that is valuable as a feedstock for either energy supply or industrial products. Most of these crops require soil and management conditions similar to food crops and compete for limited resources. The extent to which their production will be expanded in the future depends on the development of new technologies, their economic competitiveness with traditional food and fiber crops as well as with conventional petrochemical feedstocks, and social and political pressures for more renewable and biodegradable materials.

The greatest agricultural potential for mitigating CO_2 lies in increasing the amount and variety of plant biomass used directly for energy production (herein defined as biofuels; see also Chapter 19) as a substitute for fossil energy. This increase could be realized by substituting biofuel crops for other agricultural crops (particularly those in surplus supply), by growing them on lands held in agricultural set-aside programs, or by intermixing biofuel plants with food or forage plants in an agroforestry system.

There are also significant opportunities to utilize crop residues and byproducts for the production of energy to replace fossil fuels. These vary widely, however, in terms of the feasibility of collecting and transporting residues, as well as the extent to which crop residues can be removed from fields without adversely affecting soil C levels and site productivity. In general, it is estimated that only 50% of the residues can be removed without affecting future soil productivity, and only 25% should be considered as recoverable for energy purposes (Sampson *et al*., 1993). Hall *et al*. (1993) estimate that for the world's major crops (wheat, rice, corn, barley, and sugarcane), a 25% residue recovery rate would amount to an annual C amount of 357 Mt. Much of this would be used for heating and cooking, without substituting for coal or petroleum use. Based on assumptions for energy conversion and degree of substitution for fossil C, crop residues could offset 100–200 Mt fossil C.

Other opportunities include converting marginal or surplus crop and pasture land to forest, increasing the use of forest biomass, noncommercial thinning of industrial timber and paper production wastes, and using recycled wood and paper products for biofuels. Many of the agricultural biofuels considered could be advantageously combined with forest biofuels to stagger harvest dates, reduce storage facility needs, create a more uniform year-round feedstock supply, and reduce the collection radius needed for a feasible utilization facility such as a utility-scale electrical power station.

The CO_2 mitigation potential of a large-scale global agricultural biofuel program can be significant (Johansson *et al.*, 1993). Assuming that 10–15% of the world's cropland area could be made available, fossil fuel substitutions in the range of 0.3 to 1.3 Gt C/yr have been estimated. This estimate does not include the indirect CO_2 offsets of biofuel production through increasing C storage in standing woody biomass, and possibly by increased soil C sequestration.

23.2.4.1. Dedicated Biofuel Crops

Dedicated energy plants, including short-rotation woody crops (SRWC), perennial herbaceous energy crops (HEC), and annuals such as whole-plant cereal crops, could be sustainably grown on 8–11% of the marginal to good cropland in the temperate zone (Table 23-4; Sampson *et al.*, 1993). For example, in the EU it has been estimated that 15–20 Mha of good agricultural land will be surplus to food production needs by the year 2010 (Scurlock *et al.*, 1993; Flaig and Mohr, 1994). This would be equivalent to 20–30% of the current cropland area.

Due to increasing agricultural demand in the tropics, a lower percentage of land is likely to be dedicated to energy crops, so a reasonable estimate may be 5–7% (Sampson *et al.*, 1993). In total, however, there could be a significant amount of land available for biofuel production (FAO, 1994), especially from marginal land and land in need of rehabilitation.

In the United States and Europe, dedicated energy crop yields of about 5 t C/ha/yr currently are achievable from good

cropland, and yields of around 9 t C/ha/yr are believed possible by the year 2030 (Wright and Hughes, 1993). In Brazil, SRWC yields in the range of 20 to 30 t C/ha/yr have been reported from trial plots (Betters *et al.*, 1992), representing a doubling of average yields from 30 years ago. Generally, however, average tropical crop yields are lower, ranging from 6 t C/ha/yr currently to perhaps 12 t C/ha/yr in the future (Table 23-4; Sampson *et al.*, 1993).

Given the assumptions in Table 23-4, the range of estimated C emission reductions from energy crops in the tropics is 160 to 513 Mt C/yr. In the temperate regions, C emission reduction could potentially range from 85 to 493 Mt C/yr (Sampson *et al.*, 1993). In addition, agroforestry systems, where trees are grown in intensively managed combinations with food or feed crops, have potential emission reductions of 10 to 55 Mt C/yr in temperate and 46 to 205 Mt C/yr in tropical regions.

23.2.4.2. Biodiesel and Bioethanol

Recently, the use of vegetable oil crops for the production of biodiesel has attracted considerable attention in the United States and the EU (Scurlock *et al.*, 1993). Biodiesel can be burned directly in modified diesel engines or can be used in conventional diesel engines after conversion into methyl or ethyl esters (Vellguth, 1983; Schwab *et al.*, 1987; Sims, 1990). However, it currently costs considerably more to produce than petroleum diesel, so it is not likely to see expanded usage unless technological breakthroughs, ecological considerations, or government subsidies alter the economic situation

Table 23-4: *Potential reduction of C emissions when replacing fossil energy carriers by biofuels of agricultural origin under 2 x CO_2 conditions. Ranges indicate low and high estimates (modified from Sampson et al., 1993).*

Agric. Biofuel Option	Land Area (Mha)[a]	Net C Yield (t C/ha/yr)[b]	Net C Amount (Mt/yr)	Energy Use (%)[c]	Energy Substitution Factor[d]	C Emissions Reduction (Mt/yr)
Dedicated Energy Crops						
Temperate[e]	26–73	5–9	130–657	100	0.65–0.75	85–493
Tropical[f]	41–57	6–12	246–684	100	0.65–0.75	160–513
Temperate Shelterbelts[g]	13–26	2–4	26–104	75	0.50–0.70	10–55
Tropical Agroforestry[h]	41–65	3–6	123–390	75	0.50–0.70	46–205
Total			**525–1835**			**301–1266**

[a]Assuming about 10–15% of world cropland to be available for biofuels. The 10% estimate agrees with Hall *et al.* (1993).

   [h]5–8% tropical.

(Kleinhanss, 1993; Sampson *et al.*, 1993; Scurlock *et al.*, 1993; Flaig and Mohr, 1994).

Generally, crops from which only the oil, starch, or sugar are used are of limited value in reducing CO_2 emissions, due to the low net energy produced and the relatively high fossil fuel inputs required (Marland and Turhollow, 1991; Flaig and Mohr, 1994). Providing one energy equivalent as rapeseed oil requires about 0.5–0.6 equivalents as fossil fuel, and if bioethanol is produced from grains or root crops, the net energy gain may be as low as 13–20% (Leible and Wintzer, 1993; Graef *et al.*, 1994). However, when using sugarcane, the cane waste provides most of the production energy, resulting in a ratio of ethanol energy to the input of fossil fuel of about 5.2 (Goldemberg *et al.*, 1993). Similarly, palm oil obtained in mills driven by residue fuel at yields of 4–5 t/ha can compete with diesel costs at an energy output versus fossil energy input ratio of 9:5 (Wood and Conley, 1991). The burning of whole-plant biomass as an alternative to fossil fuel results in the most significant CO_2 mitigation (Leible and Wintzer, 1993; Reinhardt, 1993; Kaltschmitt and Becher, 1994), although the actual net effect depends on the plant yield and composition and on the intensity of the cropping system.

23.2.4.3. Overall Fossil Fuel Offsets

Estimating biomass energy production potentials requires assumptions not only about available land, productivity, plant species, and percent of the crop to be used but also about collection and transport, conversion efficiencies, and fuel substitution factors. Table 23-4 was developed as an estimate of the primary energy that could be substituted over the next few decades as a result of agricultural biomass production. Assumptions were made about the relative conversion efficiency of individual fuels and regarding which fossil fuel was to be substituted for by the biomass (Sampson *et al.*, 1993). Overall, agricultural biofuels (energy crops, agroforestry, and crop residues) have the potential to substitute for 0.40 to 1.50 Gt fossil fuel C per year.

23.2.5. Summary of CO$_2$ Mitigation in Agriculture

Potential C mitigation options in agriculture are significant in relation to anthropogenic emission rates (Table 23-5). The agricultural sector can reduce CO_2 increases in the atmosphere by reducing agriculturally related emissions, sequestering C in

Table 23-5: *Summary of CO$_2$ mitigation potential for agriculture, expressed as decreases in net C emission rates or as net C storage rates, calculated on an annual basis or accumulated for a 50-year period.*

Category	Annual (Gt C)	Cumulative (Gt C)
Reducing C Emissions		
– Reduction in fossil energy use by agriculture in industrialized countries[a] (assuming 10–50% reduction in current use)	0.01–0.05	0.5–2.5
Increasing C Sinks		
– Increasing soil C through better management of existing agricultural soils (globally)[b]	0.4–0.6	22–29
– Increasing soil C through permanent set-aside of surplus agricultural land in temperate regions		
1) Upland soils[c]	0.015–0.03	0.75–1.5
2) Wetland restoration[d]	0.006–0.012	0.3–0.6
– Restoration of soil C on degraded lands[e] (assuming restoration of 10–50% of global total)	0.024–0.24	1.2–12
Fossil C Offsets		
– Biofuel production from dedicated crops[f]	0.3–1.3	15–65
– Biofuel production from crop residues[g]		
Total Potential CO$_2$ Mitigation	**0.86–2.44**	**45–122**

[a] Based on current use of 3–4.5% of the total fossil C emission (2.8 Gt C/yr; OECD, 1991) by industrialized countries and an arbitrary reduction range of 10–50%.

[b] Assuming a recovery of one-half to two-thirds of the estimated historic loss (44 Gt) of C from currently cultivated soils (excluding wetland soils) over a 50-year period.

[c] Based on an estimated C sequestration of 1.5–3 Gt over a 100-year period, from a 15% set-aside of cultivated soils (~640 Mha), in industrialized countries with current or potential production surpluses; annual and cumulative rates given as 1 and 50% of that total, respectively.

[d] Based on restoration of 10–20% of former wetland area (8 Mha) now under cultivation in temperate regions.

[e] Assuming potential C sequestration of 1–2 kg C/m² over a 50-year period, on an arbitrary 10–50% of moderately to highly degraded land (1.2 x 10⁹ ha globally; Oldeman *et al.*, 1990).

[f] Values from Table 23-4.

[g] Based on 25% recovery of crop residues and assumptions on energy conversion and substitution.

soils, and producing biofuel to replace fossil fuels. However, most of the options dealing with land use and soil C sequestration are limited in duration, in that vegetation and soils (under a given set of environmental and management conditions) have a finite capacity to sequester C. Calculations of C sink increases are based on estimates of the difference between current C stocks and those possible under improved management, considering that most of the increase in C would occur within a 50- to 100-year time frame. An exception is C accumulation in wetlands, where C increases can be sustained for much longer periods. Reductions in fossil C consumption by agriculture and the production of biofuels are mitigation options that can, in principle, be maintained indefinitely.

There is a high degree of uncertainty in our estimates concerning both flux rates and C storage capacity, as well as in the level at which various mitigation options could be implemented. Since the latter is largely a function of policy, several of the mitigation potentials have been expressed in terms of arbitrary ranges (10–50%) in implementation, representing possible lower and upper limits for developing policy scenarios.

Large amounts of C could be sequestered in soils (23–44 Gt over a 50-year period) through improved management of agricultural land, permanent set-asides, and restoration of degraded lands. Increasing soil C levels has additional benefits in terms of improving the productivity and sustainability of agricultural production systems. There are potential costs associated with promoting C storage, including fossil fuel requirements (e.g., fertilizers), lost production (e.g., set-aside programs), and additional labor and financial requirements (e.g., land restoration), which may constrain the potential for increasing C storage. Direct fossil fuel use by agriculture is a relatively minor portion of society's total consumption; therefore, even high reductions in use within agriculture have a modest mitigation potential.

The effects of potential climate change and CO_2 enrichment on mitigation have not been explicitly dealt with in the estimates of mitigation potentials. We recognize the importance of these factors, but the present level of knowledge is insufficient to provide quantitative estimates that would incorporate the complex interactions among CO_2, climate change, and land use and management. Analysis of the effects of these factors on C balance and trace-gas emissions requires an integrated model and data analysis at the global scale.

23.3. Methane and Nitrous Oxide

Successful development and implementation of mitigation strategies for agricultural sources of CH_4 and N_2O require an understanding of the effects of land-use change and agricultural practices on fluxes of these gases and on controlling mechanisms. Current knowledge (Batjes and Bridges, 1992; Beese, 1994; Granli and Bockman, 1994; Kroeze, 1994; Mosier *et al.*, in press; Smith *et al.*, 1994) falls short of these criteria but is sufficient to identify key systems/practices and geographic

areas to target, as well as likely mitigation technologies. Proposed mitigation options need to be evaluated within the context of farm production systems in order to ensure that interactions and/or feedbacks are accounted for. There is a potential for tradeoffs between CH_4 and N_2O that are only partly assessed in this document.

Sections 23.3.1.1 and 23.3.1.2 provide a new assessment of agricultural sources and sinks of CH_4 and sources of N_2O. Appraisal of mitigation potential in agricultural systems is based on these estimates and the management technology available. The sources of CH_4 considered important include ruminant animals, rice production, animal waste, and biomass burning, while agricultural land use impacts the aerobic soil sink for atmospheric CH_4. The direct and indirect production of N_2O in fertilized systems are considered to be the major agricultural source of N_2O. Other sources—such as biomass burning, enhanced production of N_2O after burning, and increased N_2O production after forest clearing for agriculture—are smaller and are given less rigorous attention. Animal feeding operations are considered minor N_2O sources that are not yet adequately characterized.

23.3.1. Agricultural Sources and Sinks of CH_4 and N_2O

23.3.1.1. Methane

Biological generation of CH_4 in anaerobic environments, including enteric fermentation in ruminants (Johnson *et al.*, 1993), flooded rice fields, and anaerobic animal waste processing, is the principal source of CH_4 from agriculture. Biomass burning associated with agriculture also contributes to the global CH_4 budget (Delmas, 1993). The primary sink for CH_4 is oxidation with hydroxyl radicals in the troposphere (Crutzen, 1981); in addition, an aerobic soil sink of 10–20% of CH_4 emissions is now evident (Reeburgh *et al.*, 1993).

23.3.1.1.1. Ruminant animals

Methane emissions from domestic ruminants are estimated to be about 80 Mt/yr, with a range of 65–100 Mt/yr (IPCC, 1992; Hogan, 1993). Cattle and buffalo account for about 80% of the global annual CH_4 emissions from domestic livestock (Hogan, 1993). Non-ruminant livestock make a relatively small contribution (Crutzen *et al.*, 1986; Gibbs and Leng, 1993; Johnson *et al.*, 1993).

Methane emissions associated with enteric fermentation in ruminants range from 3–8% of gross feed energy intake (Gaedeken *et al.*, 1990; Leng, 1991; U.S. EPA, 1992; Gibbs and Leng, 1993; Johnson *et al.*, 1993), producing 25–37 l of CH_4 per kg dry matter intake (Shibata, 1994). However, for the vast majority of the world's domestic ruminants consuming a wide range of diets under common production circumstances, CH_4 emissions fall near 6% of diet gross energy (range of 5.5 to 6.5%) (Johnson *et al.*, 1993). Restricting the amount of

high-quality diet to one-half or less of voluntary consumption, as is frequently done experimentally, can double these percentage losses; however, this seldom occurs in practice. The only production group found markedly different from 6% is the approximately 25 million head of cattle fed very high concentrate diets for about 120 d prior to slaughter (primarily U.S. feedlots), where the emissions average about 3.5% of diet gross energy.

The relatively constant CH_4 emissions as percent of diet for most of the world's livestock has important implications for mitigation strategy. Strategies targeting increased available energy per unit of feedstuff will decrease intake required per unit of product (meat, milk, etc.). Improved feeding and animal management is the only strategy, to date, that has consistently reduced methane emissions. Almost all improved livestock management practices reduce methane per unit of product, and while increased diet energy availability is usually central to the improved practice, a whole array of interrelated inputs are required (protein, minerals, vitamins, improved genetics, reproductive efficiency, animal health, predator control, etc.). The trend worldwide is toward these improved technologies, limited mostly by the market price of animal products.

Examples of methane mitigations that have been analyzed include:

- A variety of feed additives (e.g., antibiotics, ionophore antibiotics and steroids) increase growth rate and increase the feed efficiency of beef cattle, resulting in 5–15% less methane per unit of product (U.S. EPA, 1992).
- Somatotropin (bST) to increase milk production, recently approved in the United States and in several other countries, is projected to reduce methane by 9% if adopted for all dairy cows in the United States (Johnson *et al*., 1991).
- Treatment of cereal straws with ammonia is a much-researched method and increases digestibility and intake, but increases in methane per kg of straw have been found (Birkelo *et al*., 1986).

Estimated potentials for adoption of these practices and associated CH_4 reductions are shown in Table 23-6. The greatest opportunity for reducing CH_4 emissions from ruminants is through feed supplementation of cattle and buffalo in Africa, Asia, and Latin America (Leng, 1991; Lin *et al*., 1994). Supplementation of the diets of native cattle/buffalo in India has been shown to decrease CH_4 emissions per liter of milk produced by a factor of three and per ton of live weight gain by a factor of six (Leng, 1991).

Opportunities for reducing CH_4 emissions from intensively managed cattle are somewhat limited because the CH_4 production per unit of cattle feed is small with a high-quality diet. For dairy cattle, estimated reductions are 10% by genetic improvement, 10% through use of bovine growth hormone (if permitted), and 4% through improved feed formulation (CAST, 1992;

U.S. EPA, 1992). For beef cattle, pharmaceuticals being developed that promote protein gain at the expense of fat could reduce CH_4 emissions by as much as 20% (CAST, 1992). Longer-term opportunities include the production of twins to reduce the need for breeding animals and biotechnological approaches to modify rumen fermentation (CAST, 1992; U.S. EPA, 1992). Overall, the combination of these mitigation options could decrease CH_4 emissions from ruminant animals by approximately 30% (Table 23-6). However, increasing food quality may result in increased N_2O emissions and increased energy use, thereby decreasing the effect of the estimated decreases in CH_4 emissions (Ward *et al*., 1993).

23.3.1.1.2. Animal waste

Significant emissions of CH_4 also occur from animal waste, varying with waste type and management practice (Safley *et al*., 1992; U.S. EPA, 1993). In general, manures from animals having a high-quality diet have higher potential to generate CH_4 than manures from animals having a low-quality diet. Actual CH_4 emission values depend on the amount of manure produced, its potential to generate CH_4, manure handling practices, and climate.

Global CH_4 emissions from livestock manure were an estimated 20–30 Mt/yr (Safley *et al*., 1992). More recently, the U.S. Environmental Protection Agency estimated this source to contribute 10–18 Mt/yr (Gibbs and Woodbury, 1993); a value of 14 Mt CH_4/yr is used here. Manure management systems that store manure under anaerobic conditions contribute about 60% of CH_4 of this source because CH_4 is produced during anaerobic decomposition of organic materials in manure (U.S. EPA, 1994). Methane lost from anaerobic digestion constitutes a wasted energy source that can be recovered by using manure management and treatment practices adapted for CH_4 collection (Hogan, 1993). With current technology, CH_4 emissions can be reduced by 25 to 80%. Hogan (1993) identified CH_4 control options that include (Table 23-6):

- **Covered Lagoons**—This option is associated with large-scale, intensive farm operations that are common in North America, Europe, and regions of Asia and Australia. Covered animal-waste lagoons have the potential to recover completely the CH_4 produced from anaerobic waste fermentation. A reasonable estimate is that 40% of the CH_4 from these regions could be mitigated using this approach.
- **Small-Scale Digesters**—These digesters are designed to utilize anaerobic decomposition of organic materials for CH_4 recovery, typically in small-scale operations. Wang *et al*. (1994) noted that about 10 million such biogas digesters are in use in China. These digesters also seem applicable to parts of Africa and South America. Here we assume an efficiency of 70%.
- **Large-Scale Digesters**—Larger, more technically advanced digesters can be integrated with management practices at large livestock operations.

Table 23-6: *Estimated effect of management practices on CH_4 emissions from ruminant livestock, livestock manures, and flooded rice.*

Mitigation Practice		Estimated Decrease due to Practice (Mt CH_4/yr)
Ruminant Livestock		
– Improving diet quality and nutrient balance		25 (10–35)[a]
– Increasing feed digestibility		2 (1–3)
– Production-enhancing agents		2 (1–6)
– Improved animal genetics		–
– Improved reproduction efficiency		–
	Total	**29 (12–44)**
Livestock Manures		
– Covered lagoons		3.4 (2–6.8)
– Small digesters		1.7 (0.6–1.9)
– Large digesters		–
	Total	**5.1 (2.6–8.7)**
Flooded Rice		
– Irrigation management[e]		5[b] (3.3–9.9)

– New cultivars and other cultural practices		5[d] (2.5–10)
	Total	**20 (8–35)**

[a] Range of estimates.

[b] About 50% of total rice area and 60% of total rice grain produced is under irrigation (Neue, 1992). Methane production is higher in continually flooded systems and with greater biomass production (Sass *et al*., 1991). Sass *et al*. (1992) showed that draining the field at specific times decreased CH_4 production by 88% without decreasing rice yield. The effect will probably not be better than 50% when used in the field. The ability to control flooding and drainage will be available to no more than 30% of the total production.

[c] Lindau *et al*. (1993) showed that CH_4 emissions can be decreased by adding sodium sulfate (by 28–35%) or coated calcium carbide (by 36%) with urea compared to urea alone, and by using ammonium sulfate (20%) in place of urea. With all these approaches, CH_4 production could be decreased by about 20%. We assume that this potential can be utilized for all rice production.

[d] Further mitigation potentials are likely to exist in optimizing rice cultivars and other management practices (Neue, 1992; Sass *et al*., 1992; Lin *et al*., 1994; Sass, 1994). In controlled experiments, a decrease of about 20% was demonstrated for some of these approaches. An estimated 10% reduction can be achieved from global rice production. Composting rice straw before field application also decreases CH_4 from rice fields (Yagi and Minami, 1990).

[e] Drying the soil surface during the cropping season may increase N_2O emissions. The net effect of both gases needs to be evaluated before the practice can be recommended.

23.3.1.1.3. Rice production

The major pathways of CH_4 production in flooded soil are the reduction of CO_2 with H_2, fatty acids, or alcohols as hydrogen donor and the transmethylation of acetic acid or methyl alcohol by methane-producing bacteria (Conrad, 1989). In flooded rice fields, the kinetics of microbial reduction processes are strongly affected by the composition and texture of soil and its content of inorganic electron acceptors (Neue, 1992). The period between flooding and the onset of methanogenesis can be different for various soils (Sass *et al*., 1992). As methane production occurs only under highly reduced conditions, on the order of -200 mv redox potential, intermittent flooding or mid-season drainage decreases CH_4 emissions (Sass *et al*., 1992; Yagi and Minami, 1993). The amount of CH_4 produced in a

system is highly dependent upon the quantity of organic carbon available, either from added rice straw (Schutz *et al*., 1989; Yagi and Minami, 1990; Sass *et al*., 1991; Neue *et al*., 1994; Nouchi *et al*., 1994b) or green manures (Lauren and Duxbury, 1993; Lauren *et al*., 1994). Rice plants influence CH_4 emissions by providing substrate for root exudation and decay (Schutz *et al*., 1989; Sass *et al*., 1991).

There are three processes of CH_4 release into the atmosphere from rice paddies. Methane loss as bubbles is generally a mechanism during the early stages of plant growth and during weeding operations. Diffusion loss of CH_4 across the water surface is another but is a relatively slow process. The third process, transport through rice plant aerenchyma and release to the atmosphere through the shoot nodes, which are not subject

to stomatal control, is generally the most important emission mechanism (Cicerone *et al.*, 1983; Seiler *et al.*, 1984; Nouchi *et al.*, 1990, 1994a, 1994b). During the course of the rice-growing season, a large portion of the CH_4 that is produced in the flooded soil is oxidized before it escapes to the atmosphere (Schutz *et al.*, 1989; Sass *et al.*, 1992).

Revised emission estimates: Minami (1993) proposed the methodology for estimating global CH_4 emission from rice fields and presented a CH_4 emission range of 10 to 113 Mt CH_4/yr from world rice paddy fields. A review of CH_4 studies in China, India, Japan, Thailand, the Philippines, and the United States (Sass, 1994) tightened the range of projected CH_4 emissions from rice fields. In his calculations, Sass combined the data for total area of rice paddies with the flux estimates published in various chapters of Minami *et al.* (1994) to produce Table 23-7. For China and India, the annual CH_4 flux estimates were specified by Wang *et al.* (1994) and Parashar *et al.* (1994), respectively. In the other cases, the figures are based on the minimum and maximum reported emission averages. The rice areas in the countries shown in Sass' estimate represent 63% of the total world rice paddy area and result in a total annual CH_4 emission of 16 to 34 Mt. Extrapolating these data to the world, Sass estimates total CH_4 emissions from rice fields to range between 25.4 and 54 Mt/yr, with 50 Mt/yr as a best-guess global emission value. This value is near the IPCC (1992) best estimate of 60 Mt CH_4/yr, but the range indicates that the actual rate may be lower. Wang *et al.* (1994) estimated the annual CH_4 emissions from rice in China to range between 13 and 17 Mt/yr. Lin *et al.* (1994) estimated a slightly lower value from rice in China of <12 Mt CH_4/yr.

Estimates of CH_4 emission reduction: Applying the following major management options to global rice production could decrease CH_4 production in rice: (1) water management, (2) nutrient management, (3) cultural practices, and (4) new rice cultivars (Table 23-6).

23.3.1.1.4. Biomass burning

The burning of biomass results in the emission of CH_4 because of incomplete combustion. Emission factors for CH_4 (i.e., the fraction relative to emitted CO_2) vary greatly (0.1% to 2.5%) depending on whether the fire is hot, flaming, or smoldering combustion (Levine *et al.*, 1993). In response to declining agricultural yields and increasing population pressures, farmers in many regions convert forests to cropping land, and many of their techniques involve burning. For example, shifting cultivation requires that forests be cut, and logging debris and unwanted vegetation burned; the land is then farmed for several years, then left fallow to rejuvenate. Savanna and rangeland biomass is often burned to improve livestock forage. Agricultural residues are also burned in the field to return nutrients to the soil or reduce shrubs on rotational fallow lands. Such agriculture-related burning may account for 50% of the biomass burned annually. In addition, about 50% of the worldwide crop residues are burned in small-scale cooking and heating stoves (Hao *et al.*, 1988).

Estimates indicate that 8,700 Mt dry matter/yr (Andreae, 1991) of biomass and 1 to 5% of the world's land (U.S. EPA, 1990b) is burned. Of these estimated CH_4 emissions, those from tropical forest clearing for agriculture, savanna burning, and agricultural crop residue burning are portions of total biomass burning that can be attributed to agricultural practices. Those sources total about 22 Mt CH_4/yr. Burning of crop lands, grasslands, and forests may be reduced through sustained land management programs and the promotion of different land-use practices, including the following:

- Increasing the productivity of existing agricultural lands
- Lengthening the rotation times and improving the productivity of shifting agriculture
- Increasing grassland management
- Incorporating crop residues into soil
- Increasing the use of crop residues as household fuel (remembering that a balance between fuel use and maintenance of soil fertility must be maintained)
- Replacing annual or seasonal crops with trees.

Using various combinations of these practices, an estimated 50% of the CH_4 emitted annually from burning of agricultural wastes (~2.7 Mt/yr) and 20% of other agricultural burning (~3.3 Mt/yr) could be eliminated, providing a total potential mitigation of ~6 Mt CH_4/yr.

23.3.1.1.5. Methane oxidation in soil

Land-use changes and other human-induced alterations of C and N cycles during the past centuries appear to have decreased

CH$_4$ oxidation in aerobic soils (Ojima *et al*., 1993), increased N deposition on temperate forest soils (Steudler *et al*., 1989), and decreased CH$_4$ uptake by 30 to 60%. Methane oxidation was decreased by about 50% by tilling a semi-arid grassland even when no N fertilizer was ever applied (Mosier *et al*., 1991). The decrease in CH$_4$ oxidation in soils when forests or grasslands are converted to agricultural use has been observed in tropical (Keller *et al*., 1990, 1993) and temperate (Steudler *et al*., 1989; Mosier *et al*., 1991; Dorr *et al*., 1993; Dobbie and Smith, 1994) environments. The decrease seems to be greater as the intensity of the agricultural practices increases. Ojima *et al*. (1993) estimated that land-use changes during the past 200 years have decreased the global temperate soil sink for CH$_4$ by 20–30%.

A portion of this effect can be attributed to inhibition of CH$_4$ uptake by inorganic N (Steudler *et al*., 1989; Keller *et al*., 1990; Mosier *et al*., 1991; Nesbit and Breitenbeck, 1992; Hütsch *et al*., 1993). Additions of inorganic N have been shown to reduce CH$_4$ uptake in many, but not all, cases (Steudler *et al*., 1989; Mosier *et al*., 1991; Adamsen and King, 1993; Cochran *et al*., 1995).

Reeburgh *et al*. (1993) estimated the global aerobic soil sink to be about 40 Mt CH$_4$/yr. From a review of available CH$_4$ uptake data, Minami *et al*. (1993) constrain total terrestrial CH$_4$ consumption between 7 and 78 Mt/yr. Insufficient information is currently available to recommend agricultural practices to increase the oxidation of CH$_4$ in cultivated soils.

23.3.1.2. Nitrous Oxide

Nitrous oxide is produced primarily by microbial processes in the soil (Bouwman, 1990). Anthropogenic emission of N$_2$O occurs as a result of land conversion to agriculture and is likely to be most intensive in agricultural systems that have high N input. Because soil production is the major agricultural source of N$_2$O, this topic is emphasized (Granli and Bockman, 1994). Agricultural N$_2$O emissions are thought to arise from fertilization of soils with mineral N and animal manures (this N is partly recycled mineral N and relocated soil mineral N), N derived from biological N fixation (legume crops and free-living N-fixing microbes), and from enhanced soil N mineralization (Duxbury and Mosier, 1993). Information is available only to assess the first three sources (Mosier and Bouwman, 1993; Isermann, 1994a). Nitrous oxide also is directly evolved during biomass burning, and produced in soil after burning, and enhanced emissions arise during conversion of tropical forest to agriculture (Batjes and Bridges, 1992).

A variety of factors control rates of the two microbial processes (nitrification and denitrification) that produce N$_2$O and N$_2$O yield. Important variables are soil water content, temperature, nitrate or ammonium concentrations, available organic carbon for denitrification, and pH. Because interactions among the physical, chemical, and biological variables are complex, N$_2$O fluxes from agricultural systems are highly variable in both time and space (Duxbury and McConnaughey, 1986; Smith, 1990; Beese, 1994; Clayton *et al*., 1994; Kroeze, 1994; McTaggart *et al*., 1994). Consequently, prediction of N$_2$O emissions associated with a unit of N applied to a specific field or fixed by legumes (Mosier, 1993) is not yet reliable. Such predictive capabilities are needed because N$_2$O emissions derived from agriculture are >75% of the anthropogenic sources (Isermann, 1994a).

23.3.1.2.1. Revised N$_2$O emission estimates from agricultural soils

Estimates of N inputs to agricultural soils and associated N$_2$O production are presented in Tables 23-8 and 23-9, respectively. The data are grouped into seven regions of the world. These estimates consider both N$_2$O directly emitted from agricultural fields and the indirect emissions that occur during parts of the year other than the cropping season, after the N leaves the field. The N fixation contribution does not include N$_2$O produced in legume pastures. Australia and New Zealand, for

example, contain large areas of pasture land that include legumes as part of the pastoral system. Little data are available for other parts of the globe.

The estimate of synthetic fertilizer N inputs to agricultural soils and the land area of harvested pulses and soybeans are based on country data published by FAO (1990a, 1990b). These values are subject to uncertainty, as are the highly uncertain animal manure N values adapted from Safley (1992) and Bouwman *et al*. (in press). The quantities used as fertilizer for each region are shown in Table 23-8. These numbers are based on estimates of animal distribution and management systems for each region and are not very reliable because of the lack of information.

In addition to including multiple N input sources and N_2O derived from N-fixation, a revised method for calculating the contribution of N_2O from agriculture is used for the estimates in Table 23-9. Earlier estimates generally were based upon assessments derived from reviews of published N_2O emissions data (Bouwman, 1990; Eichner, 1990). More recently, Bouwman *et al*. (in press) reviewed the literature again and presented another assessment of N_2O emissions. They noted that loss of N_2O from agricultural soils may be presented in three ways: (1) the total loss during the period covered by the measurements; (2) the difference between fertilized and control plot, which is referred to as "fertilizer-induced N_2O loss"; and (3) the total loss calculated as a percentage of fertilizer N applied.

Bouwman *et al*. (in press) estimated the total emissions of N_2O from a regression equation: total annual direct field N_2O-N loss = 1 + 0.0125 * N-application (kg N/ha). The value of 1 kg N_2O-N/ha represents the background N_2O-N evolved; the 0.0125 factor accounts for the contribution from fertilization. This estimate includes N sources from a variety of mineral and organic N fertilizers and was based on long-term data sets. The total flux represents N_2O from all sources: native soil N, N from recent atmospheric deposition, past years' fertilization, N from crop residues, N_2O from subsurface aquifers, and current N fertilization.

As explained in Mosier (1993), soil management and cropping systems and unpredictable rainfall inputs affect N_2O emissions more than mineral N sources. As a result, for the purpose of estimating N_2O production from fertilization, we do not use different multiplication factors for different fertilizer types. Limited data also indicate that organic N sources such as animal manures and sewage sludge induce larger N_2O emissions per unit of N added to the soil than does mineral N (Bouwman, 1990, 1994a; Benckiser and Simarmata, 1994). Because of the lack of adequate parallel experiments that cover the range of possibilities of mineral and organic N applications, a single conversion coefficient is used for all sources.

Although these emission estimates are variable, the range is lower than suggested in the OECD/OCDE (1991) calculation methodology. Experience in conducting field flux experiments suggests that much narrower constraints can be placed on the N_2O flux predictions. Bouwman (1994a) estimated that 1.25 ± 1.0% of the applied N was directly emitted, as N_2O encompasses approximately 90% of the direct contributions of fertilization to N_2O emissions.

The indirect contribution of fertilizer N to N_2O emissions, apart from the fields where fertilizer is applied, also must be considered. Based upon the discussions of Duxbury *et al*. (1993), Mosier (1993), and Isermann (1994a), and the large amounts of N_2O frequently found in subsurface aquifers (Bowden and Bormann, 1986; Minami and Ohsawa, 1990), an estimated additional 0.75% of N applications will eventually be evolved to the atmosphere as N_2O resulting from N leaching, runoff, and nitrogen oxides (NO_x) and ammonia (NH_3) volatilization.

The direct and indirect N_2O-N emissions from application of mineral or organic N total approximately 2 ± 1% annually (Mosier *et al*., in press). This estimate is expected to encompass more than 90% of field situations. Nitrous oxide from biological N-fixation is calculated by multiplying the area of land used for growing pulses plus soybeans in each region by 4 kg N/ha (Duxbury *et al*., 1982; Galbally *et al*., 1991).

23.3.1.2.2. Mitigation of N_2O from agricultural soils

A significant fraction of the N_2O evolved from agricultural systems could be avoided if some combination of agricultural management practices listed in Table 23-10 were adopted worldwide. These practices are recommended mainly to improve synthetic fertilizer and manure N use efficiency. The underlying concept in limiting N_2O emissions is that if fertilizer N (all N applied to improve crop growth) is utilized better by the crop, the amount of N needed to meet the growing demand for food will be less; therefore, less N_2O will be produced and less N will leak from the system (Isermann, 1994b; Sauerbeck, 1994a, 1994b). Some of these practices, such as use of nitrification inhibitors, have been shown to have a direct effect on decreasing N_2O emissions in field studies (Aulakh *et al*., 1984; Minami *et al*., 1990; Bronson *et al*., 1992). Ryden (1981) and McTaggart *et al*. (1994) have shown that timing of application of different types of synthetic fertilizer with seasonal water distribution can limit N_2O production.

From Table 23-10 the amount of N_2O-N that is amenable to management is estimated. In these calculations, it is assumed that two-thirds of the N_2O from N applied as manure or synthetic fertilizer is directly emitted from agricultural systems. The remaining one-third is emitted indirectly as a result of runoff, nitrate leaching, and transfer of N to other sections of the ecosystem through NH_3 and NO_x emissions. Only the direct emissions are readily amenable to control by on-farm management, but management options that decrease the amount of external N needed to produce a crop also will decrease indirect N_2O production. It was also assumed that N_2O produced directly from biological N fixation cannot be managed. These estimates were based upon estimated fertilizer use and animal N production in FAO (1990b); thus, they represent estimates for that year and are not future projections.

By better matching N supply to crop demand and more closely integrating animal waste and crop-residue management with crop production, N_2O emissions could be decreased by about 0.38 Mt N_2O-N. Further improvements in farm technology, such as use of controlled-release fertilizers, nitrification inhibitors, timing, and water management, should lead to improvements in N use efficiency and further limit N_2O production by an estimated 0.30 Mt N_2O-N. A total potential reduction of global N_2O emissions from agricultural soils is thus 0.7 (0.34 to 1.0) Mt N_2O-N/yr.

23.3.1.2.3. Release due to biomass burning

Bouwman (1993, 1994b) reviews the status of N_2O formation during biomass burning and estimates a global emission of 0.1 to 0.3 Mt N/yr. This calculation is based on $0.7 \pm 0.3\%$ of the N content of the material burned being lost as N_2O (Lobert *et al*., 1990; Hurst *et al*., 1994). The estimate includes only those emissions related to savanna burning and deforestation (Crutzen and Andreae, 1990; Hao *et al*., 1990). A mean value of 0.2 Mt N/yr

to represent the N_2O emitted directly from biomass burning related to agriculture is used here. The mitigation potential is difficult to assess because if crop residue is returned to the soil, part of the N mineralized will be converted to N_2O. A significant

Table 23-10: *List of practices to improve efficiency of use of synthetic fertilizer and manure N in agriculture and expected reduction of N_2O emissions assuming global application of mitigation practices (Mt N/yr).*

Practice Followed	Estimated Decrease in N_2O Emissions
Match N Supply with Crop Demand	0.24[a]
– Use soil/plant testing to determine fertilizer N needs	
– Minimize fallow periods to limit mineral N accumulation	
– Optimize split application schemes

– Place fertilizers below the soil surface	
– Foliar application of fertilizers	
– Use nitrification inhibitors	
– Match fertilizer type to seasonal precipitation	
Optimize Tillage, Irrigation, and Drainage	0.15[d]
Total	**0.68**

[a] Assumed that fertilizer N use efficiency can be increased to save 20% of N applied in North America, Europe, and FSU (Doerge *et al*., 1991; CAST, 1992; Isermann, 1994a; Peoples *et al*., 1995).

[b] Tightening N cycles may decrease the need for 20% of the N that is used currently in North America, Europe, and FSU, thus saving 20% of fertilizer and reducing N_2O from manure by the same amount where applicable (Buresh *et al*., 1993; Isermann, 1994a).

[c] Controlled-release fertilizers (Minami, 1994), nitrification inhibitors (Bronson *et al*., 1992; Keerthisinghe *et al*., 1993; McTaggart *et al*., 1994; Minami, 1994), and matching fertilizer type with seasonal precipitation can decrease N_2O emissions 40–90%. We assume that 10% of all fertilizer-derived N_2O production can be decreased by 50%.

[d] There is little published data to confirm this assumption (Granli and Bockman, 1994). A conservative assumption of a 5% decrease that can be achieved globally is used.

decrease in the amount of agricultural biomass that is burned could be achieved by composting the material before it is returned to the field. It is not known, however, how much N_2O is released during composting. Burning also may make N and other nutrients more available to soil microorganisms and result in enhanced emissions of N_2O from soil (Anderson *et al*., 1988; Anderson and Poth, 1989). Bouwman (1993) and Bouwman *et al*. (in press) calculate that from about 12 Mt N/yr remaining on the ground after burning (Crutzen and Andreae, 1990), 20% is volatilized as NH_3 and that 1%, 0.1 Mt/yr, of the remaining N is emitted to the atmosphere as N_2O. Because of this uncertainty, we expect a mitigation potential of about 10% of the N_2O-N associated with burning of biomass from agriculture.

23.3.1.2.4. Conversion of tropical forest

Conversion of tropical forests to pastures and arable land may contribute an important amount of N_2O to the atmosphere (Keller *et al*., 1993; Bouwman *et al*., in press). While fluxes may increase by a factor of 5–8 in the first few years after forest clearing (Luizao *et al*., 1989; Keller *et al*., 1993), fluxes gradually decrease during the following 10–20 years (Garcia-Mendez *et al*., 1991; Keller *et al*., 1993). Bouwman (1994b) estimates that about 0.4 Mt of additional N_2O-N is emitted annually. We estimate that a 20% reduction from existing levels can be achieved.

23.3.2. Summary of Methane and Nitrous Oxide Emissions and Potential Decreases

Mitigation options are available that could result in significant decreases in CH_4 and N_2O emissions from agricultural systems.

If implemented, they are likely to increase rather than decrease crop and animal productivity. Implementation has the potential to decrease CH_4 emissions from rice, ruminants, and animal waste by 30–40% (Table 23-11). The key to decreasing N_2O emissions is improving the efficiency of plant utilization of fertilizer N. This could decrease N_2O emissions from agriculture by almost 20%. Using animal waste to produce CH_4 for energy and digested manure for fertilizer may at some time be cost effective. Economic analyses of options proposed should show positive economic as well as environmental benefits.

23.4. Economic Feasibility of Mitigation Options

As shown in the preceding sections of this chapter, there are policies and tools that, if put into effect, can reduce net carbon emissions from agriculture and increase sequestration. Carbon emissions and capture in agriculture can be brought into balance, but agriculture always will be a net source of N_2O and CH_4. Practices are described in this chapter that would reduce these emissions but not eliminate them. In the case of N_2O, these practices include changes in the timing and placement of fertilizer and use of nitrification inhibitors and fertilizer forms that slow the release of N. In the case of CH_4, these practices include shortening the time during which rice paddies are inundated, altering feeding and husbandry practices to diminish emissions per unit of animal product produced, and utilizing animal wastes for biogas production.

Implementation of these practices will require decisions at many different levels. For example, development of a biofuel

[a]Range of estimates.

industry will require changes in infrastructure, institutions, and regional and national policies. At a different scale and level of decisionmaking, the rancher can help reduce CH_4 emissions by providing his/her animals with feed additives. Even the nomadic herder can do this by providing urea-containing blocks for grazing animals to lick. What are the incentives and disincentives for them to do so? Here we examine the feasibility for agricultural producers and the likelihood that they will adopt GHG reduction methods described in this chapter.

It seems reasonable that the world's farmers, ranchers, and pastoralists will not volunteer to implement practices proposed to mitigate greenhouse-forced climate change. This will happen only if the producer is convinced that profitability will improve if these practices are implemented. Incentives such as subsidies can be created to encourage their adoption, and penalties for nonadoption can be imposed.

Examples of mitigation efforts include the following:

- No-till agriculture that increases C storage in the soil is one example of a GHG-mitigating practice that meets the criteria for successful, unforced adaption. No-till practices are used increasingly in the United States in the production of corn, soybeans, and wheat. No-till accounted for about 10–14% of the total acreage of these crops in 1992, double what it had been 5 years earlier.
- Nutrient management practices that result in lower N application rates should reduce emission of N_2O. Soil testing, fertilizer placement, timing, class of fertilizer, and inhibitors are practices that supply nutrients in better accordance with plant physiologic demands. These practices are more likely to be economically feasible on crops that have high N demands (e.g., corn, cotton, and wheat). Because these practices already are being adopted to some extent, only minimal institutional programs may be needed to significantly increase their level of use.
- Reducing the number of days that rice fields are flooded will require large land and water resource investments to provide supplemental storage to change time of flooding. Economic feasibility will be dependent on many unique characteristics of the project site. Such cost estimates will need to address financing and repayment of any structural developments and how such developments change hydrology of water systems and impact other users, in addition to adoption costs incurred by individual producers. As there are no obvious on-farm benefits, and there are adoption costs for this practice, institutional intervention to provide economic incentives or a mandate requiring the practices will likely be needed.
- Increasing quality in livestock feeds is recommended as a means of reducing CH_4 emission per unit of animal product. In developed economies, where there is a high consumption of red meats and dairy

products, most livestock animals already are fed higher quality roughage and concentrates. Producers have the knowledge and technical expertise to improve the quality of feed if it can be shown to increase their profits. In developing or underdeveloped countries, land needed for higher-quality roughage production often competes with the food needs of humans. Livestock rely on crop residue and other coarse roughage produced on land not suited for more intensive uses. To add concentrates to feed and to supplement pasture and range with improved crop species adds to production costs. Also, land resources may not be able to support improved species. Whether the benefits generated exceed these costs can best be determined through cost/benefit case studies involving local conditions. Local production relationships, input prices, and local markets will affect long-term economic feasibility.

In general, practices that recover investment cost and generate a profit in the short term are preferred over practices that require a long term to recover investment costs (Rahm and Huffman, 1984). Practices that have a high probability associated with expected profits are desired over practices that have less certainty about their returns. When human resource constraints or knowledge of the practice prevent adoption, public education programs can improve the knowledge and skills of the work force and managers to help advance adoption. Crop insurance or other programs to share the risk of failure due to natural disaster can aid the adoption of practices that increase productivity or expected returns.

23.5. Uncertainties and Future Research Needs

Uncertainties in our present assessment stem from two main sources. Both of these sources point to future research needed for improving our assessment of mitigation options. One source is the inherent unpredictability of future conditions that are controlled primarily by social, economic, and political forces. These conditions include such things as future trends in fossil fuel usage and the degree to which various mitigation strategies will be implemented—decisions that hinge on factors such as economic conditions, environmental awareness, and political will. The most effective way of dealing with these uncertainties is by developing analytical tools that can incorporate socioeconomic factors as potential scenarios in model gaming exercises. Currently, such tools for agricultural systems on a global basis do not exist.

The second source of uncertainty involves deficiencies in our scientific understanding of GHG processes, as well as inadequacies in the information base needed to apply the knowledge that we do have. Gaps in basic understanding can only be addressed through basic research; however, our current ability to assess GHG mitigation in agricultural systems is probably more constrained by a lack of baseline data, in an organized and usable format, than it is by insufficient scientific

understanding. Thus, the research needs outlined below focus on the need for compiling and analyzing baseline information:

- **Carbon Sequestration in Agricultural Systems**— The assessment of potentials to increase C stocks in agricultural systems could be improved by using a structured, model-based analysis with global coverage. Suitable models for such a task currently exist and have been used for regional-level analyses (see Section 23.2.2.3). The elements that are lacking are: (1) spatial databases linking climate, soils, and land use and management, which are needed as model inputs; and (2) reliable experimental data to calibrate and/or verify model predictions. A compilation of agricultural land-use information to develop a classification and mapping of agroecological/management zones for the world is sorely needed. Existing long-term agricultural experiments can provide information to evaluate model predictions for different management systems, and soil and climate conditions. Efforts are underway to establish networks of long-term experiment sites and data (Paul *et al.*, 1995; Powlson *et al.*, 1995), but they are still at an early stage.

- **Bioenergy Production from Agricultural Lands**— Research needed to improve assessments of CO_2 mitigation potential through increased use of biofuels includes better technical knowledge of biofuel production and energy conversion efficiencies, as well as information on socioeconomic factors affecting the utilization of biofuels. These needs include: (1) improved information on the actual C feedstock value of forest, agroforestry, and agricultural management systems; (2) better data on energy inputs for the production of wooden goods and tree-derived chemicals and their substitutes; (3) better data on land availability, including cultural, social, and political factors that may preclude some lands from use for C offset projects; and (4) better data, including economic analyses, for the use and efficiency of biofuels, particularly where that usage is conducted outside markets.

- **CH_4 and N_2O Emissions from Agricultural Systems**—Research needed to improve assessments of CH_4 and N_2O mitigation options includes improved synthesis and coordination of existing information and additional field measurements:
  - Available field emission/consumption data need to be carefully assimilated so that comparisons of data sets can be made on a uniform basis. Those data sets that were collected over an insufficient period of time, used inadequate methodology, or are from nonrepresentative systems should be omitted.
  - Existing data need to be applied to validate and calibrate process-based models. Model estimates of gas fluxes should incorporate soil, cropping system, climate, and fertilizer management influences.
  - Field data on gas fluxes are still woefully inadequate. Research needs include year-round field flux measurements in a variety of soils, climates,

and cropping systems to compare the impact of management on gas fluxes and to determine the tradeoffs between CH_4 and N_2O flux when management options are exercised. Assessment of entire cropping sequences (e.g., rice-wheat-rice) are needed. The combined use of different flux measurement techniques is needed to evaluate systems over time and space.

Efforts to improve national, regional, and global estimates of gas fluxes are best accomplished through combined efforts. Unfortunately, other than for organizational exercises, little national or international funding has become available to conduct the needed research.

CONTENTS

EXECUTIVE SUMMARY

Three categories of promising forestry practices that promote sustainable management of forests and at the same time conserve and sequester carbon (C) are considered in this chapter: (1) management for conservation of existing C pools in forests by slowing deforestation, changing harvesting regimes, and protecting forests from other anthropogenic disturbances; (2) management for expanding C storage by increasing the area and/or C density in native forests, plantations, and agroforestry and/or in wood products; and (3) management for substitution by increasing the transfer of forest biomass C into products such as biofuels and long-lived wood products that can be used instead of fossil-fuel based products. Since the 1992 assessment, significant new information has been developed that improves estimates of the quantities of C that can be conserved or sequestered—and the associated implementation costs of forest sector mitigation strategies—and better identifies limits to the amount of lands available for such mitigation strategies.

- The most effective long-term (>50 years) ways in which to use forests to mitigate the increase in atmospheric CO_2 are to substitute fuelwood for fossil fuels and for energy-expensive materials. However, over the next 50 years or so, substantial opportunities exist to conserve and increase the C store in living trees and wood products (High Confidence).
- Under baseline conditions (today's climate and no change in the estimated available lands over the period of interest), the cumulative amount of C that could potentially be conserved and sequestered over the period 1995–2050 by slowing deforestation (138 Mha) and promoting natural forest regeneration (217 Mha) in the tropics, combined with the implementation of a global forestation program (345 Mha of plantations and agroforestry), would be about 60 to 87 Gt—equivalent to 12–15% of the projected (IPCC 1992a scenario) cumulative fossil fuel C emissions over the same period (Medium Confidence).
- The annual C gain from the above program would reach about 2.2 Gt/yr by 2050, or about four times the value of 0.5 Gt C/yr estimated in the 1992 assessment. The gradual increase over time occurs because of the time it takes for programs to be implemented and the relatively slow rate at which C accumulates in forest systems (Medium Confidence).
- Uncertainty associated with the C conservation and sequestration estimates is caused mainly by high uncertainty in estimating land availability for forestation and regeneration programs and the rate at which tropical deforestation can actually be reduced; estimates of the net amount of C per unit area conserved

or sequestered under a particular management scheme are more certain (High Confidence).

- The tropics have the potential to conserve and sequester the largest quantity of C—45–72 Gt—more than half of which would be due to promoting natural forest regeneration and slowing deforestation. Tropical America has the largest potential for C conservation and sequestration (46% of the tropical total), followed by tropical Asia (34%) and tropical Africa (20%). The temperate and boreal zones could sequester about 13 Gt and 2.4 Gt, respectively—mainly in the United States, temperate Asia, the former Soviet Union (FSU), China, and New Zealand (Medium Confidence).
- The cumulative cost—excluding land costs and other transaction costs—to conserve and sequester the above amounts of C range from US$247 billion to $302 billion at a unit cost of about $2–8/t C. These unit costs are considerably lower than those in the 1992 assessment, which ranged from $8/t C in tropical latitudes to $28 in non-U.S. Organisation for Economic Cooperation and Development (OECD) countries. Transaction costs may significantly increase these estimated costs (Low Confidence).
- Costs per unit of C sequestered or conserved generally increase from low- to high-latitude nations (High Confidence) and from slowing deforestation and promoting regeneration to establishing plantations (Low Confidence). The latter trend may not hold if transaction costs of slowing deforestation are excessive.
- These cost estimates, although benefitting from improved data and methodology since the first assessment, generally represent only the cost of direct forest practices. These costs could be several times higher if land and opportunity costs and/or the costs of establishing infrastructure, protective fencing, training programs, and tree nurseries were included; on the other hand, costs could be offset by revenues from timber and non-timber products. No complete cost estimates are available (Medium Confidence).
- Under conditions of climate and land-use change as projected by the IMAGE 2.0 model ("conventional wisdom" scenario, akin to the IPCC 1992a scenario), the carbon conservation and sequestration potential may be somewhat less than estimated under baseline conditions because less land may be available in the tropics, unless land was secured for mitigation measures or sustainable agriculture/agroforestry systems were widely adopted, and sequestration by new forests in temperate and boreal regions may be offset by transient decline and the loss of carbon from existing forests in response to climate change (Medium Confidence).

24.1. Introduction

Forest ecosystems merit consideration in biogenic mitigation strategies because they can be both sources and sinks of CO_2, the most abundant greenhouse gas (GHG). Currently the world's forests are estimated to be a net C source, primarily because of deforestation and forest degradation in the tropics. Temperate and boreal forests are a C sink because many are recovering from past natural and human disturbances, and they are actively managed (Dixon *et al*., 1994a). However, there is the potential to lessen projected C emissions by protecting and conserving the C pools in existing forests; to create C sinks by expanding C storage capacities, by increasing the area and/or C density of native forests, plantations, and agroforests, and by increasing the total pool of wood products; and to substitute fossil fuels with fuelwood from sustainably managed forests, short-lived wood products with long-lived wood products, and energy-expensive materials with wood (Grainger, 1988; Dixon *et al*., 1991; IPCC, 1992; Winjum *et al*., 1992a, 1992b; Nilsson and Schopfhauser, 1995; Trexler and Haugen, 1995). This chapter reviews the potential magnitude of forest-based CO_2 stabilization options based on various assessments in recent years; the costs to implement such programs; and the effects of a changed climate, atmospheric composition, and human demographics on the potential amount of C conserved and sequestered. The chapter also suggests how to devise improved assessments to formulate practical strategies.

The first supplemental report to IPCC (Houghton *et al*., 1992) suggested that aggressive forest-sector mitigation strategies involving planting trees on 1 Gha (Gha = 10^9 ha) of land, combined with phasing out net deforestation by 2025, could create a net C sink of about 0.5 Gt/yr (10^{15} g = 1 Pg) by 2050—a value that could then be maintained through the rest of the 21st century. Since 1992, new research results and information have improved the accuracy of estimates of the quantities of C that potentially can be conserved (maintain C on the land) and sequestered (increase C on the land) through the implementation of forest-sector mitigation strategies, provided new estimates of the costs associated with the mitigation options, and made more-accurate estimates of the land available for such strategies. A review and analysis of new research results and information are the main purposes of this chapter.

Scope of the Chapter

This chapter reviews the potential to manage present and potential forest lands capable of supporting tree cover to conserve and sequester C. Urban forests are not included because they contain and accumulate a very small amount of C compared to other forest lands, although they can contribute to reduced energy consumption (Rowntree and Nowak, 1991). Forest management here includes an array of practices in native forests and on nonforested lands—such as protection, forestation (afforestation and reforestation), intermediate silvicultural treatments (e.g., thinning, fertilization), harvesting, and agroforestry—that promote sustained production of goods and services. These promising forestry practices are considered in arriving at national, regional, and global estimates of forest-sector potential for mitigating the accumulation of primarily CO_2, and to some degree other GHGs, in the atmosphere.

Forest lands are divided into three latitudinal belts: high or boreal (approximately 50–75° N and S latitude), mid or temperate (approximately 25–50° N and S latitude), and low or tropical (approximately 0–25°N and S latitude). Nations or regions are grouped into these belts on the basis of the approximate geographic location of their forests.

The key parameters in any assessment of mitigation strategies are the amount of C per unit area of land that can be conserved or sequestered in vegetation and soil under given site conditions and a given management option; the time period over which this C can be conserved or sequestered; the amount of suitable and available land; the mitigation costs; and the different lifetimes of the end wood products. Literature data and discussions on these factors are presented in this chapter, although large uncertainties exist in some data (Houghton *et al*., 1993; Iverson *et al*., 1993; Trexler and Haugen, 1995). Estimates of the mitigation potential and costs of the various options are generated from literature sources. Because no studies to date have addressed the mitigation potential of forests under a changed climate and atmosphere, the mitigation potential could be assessed only under a baseline condition, with no effects of climate change or increased atmospheric CO_2. More briefly, the effects of a changed climate, atmospheric composition, demographics, and land use on the mitigation potential are considered based on interpretation of trends from a global integrated assessment model (Alcamo, 1994). A discussion of new research directions to improve assessments concludes the chapter.

24.2. Role of Forests in the Global Carbon Cycle

24.2.1. Status and Change in Forest Area

Forests cover about 4.1 Gha of the Earth (Dixon *et al*., 1994a, with revisions based on Kolchugina and Vinson, 1995). Most of the forests are in the low latitudes (43%), followed by the high latitudes (32%) and mid-latitudes (25%). Forest plantations are currently estimated to occupy about 0.1 Gha of land. Although the technology for managing forests is well developed, today only about 11% of the world's forests are managed for goods and services (World Resources Institute, 1990; Winjum *et al*., 1992a). The extent of management, however, varies by region: About 20% of the mid-latitude forests, 17% of the high-latitude forests, and less than 4% of the low-latitude forests are managed. In addition, large areas of land technically suitable for forests are degraded or are otherwise underproducing because of human misuse (Winjum *et al*., 1992a). Even though some degraded lands are unsuitable for forestry, there is considerable potential to mitigate CO_2 by better management of forest lands for C conservation, storage, and substitution. However, a balance between objectives for

mitigation and other uses of forests must be achieved (see Section 24.3).

The status and areas of forests change, even in the absence of human interference. However, humans influence the pace and extent of change as forests are subjected to controlled and uncontrolled uses (overharvesting and degradation); large-scale occurrence of wildfire; fire control; pest and disease outbreaks; and conversion to non-forest use, particularly agriculture and pastures. At the same time, some areas of harvested and degraded forests or agricultural and pasture lands are abandoned and revert naturally or are converted to forests or plantations. In high latitudes, the area of forests is undergoing little change (Kolchugina and Vinson, 1995). In mid-latitudes, there is a net gain of about 0.7 Mha/yr of forests, mostly in Europe and China (Dixon *et al.*, 1994a). Furthermore, many of the forests in high and mid-latitudes have been harvested (clear cut or selective cut) in the far to near past and are now generally in a stage of regeneration and regrowth (Apps and Kurz, 1991; Birdsey, 1992; Heath *et al.*, 1993; Kauppi *et al.*, 1992, 1995; Kolchugina and Vinson, 1993, 1995).

Low-latitude forests are experiencing high rates of loss — currently estimated to be about 15.4 Mha/yr during 1980–90, but with large uncertainties (FAO, 1993). Much of the deforested area is converted to new agricultural or pasture lands, which often replace degraded agricultural lands that may or may not be capable of supporting tree cover (Brown, 1993; Dale *et al.*, 1993). However, in a few tropical countries, deforestation has decreased during the last decade [e.g., India (Ravindranath and Hall, 1994; see also Section 24.3.1.1), Brazil (Skole and Tucker, 1993), and Thailand (Dixon *et al.*, 1994a)]. In addition to deforestation, large areas of forests are harvested and degraded. For example, about 5.9 Mha/yr of low-latitude forests were logged during 1986–90, and most logging occurred in mature forests (83%) rather than secondary forests (FAO, 1993). These harvested forests can regenerate and accumulate C if they are protected or are relatively inaccessible to human populations, but many of them become degraded (e.g., Lanly, 1982; Brown *et al.*, 1993b, 1994). Forest degradation, resulting in a loss of biomass C, occurs through damage to residual trees and soil from poor logging practices, log poaching, fuelwood collection, overgrazing, and anthropogenic fire (Goldammer, 1990, 1993; Brown *et al.*, 1991, 1993b; FAO, 1993; Flint and Richards, 1994). Similar anthropogenic disturbances most likely have occurred and are still occurring in other forest regions of the world. This means that few forested areas in the world are presently undisturbed by humans; this fact has implications for their present role in the global C cycle and future C sequestration potentials (Lugo and Brown, 1986, 1992; Brown *et al.*, 1992; Wood, 1993).

24.2.2. Forest Carbon Pools and Flux

The world's natural forests contain vast quantities of organic C, with an estimated 330 Gt C in vegetation (live and dead, above and belowground), 660 Gt C in soil (mineral soil plus organic horizon) (Table 24-1), and another 10 Gt C in plantations. Estimates of all C pool components, using published factors (see Dixon *et al.*, 1994a), were made in arriving at these C pool estimates. However, some components are poorly known, such as the C pool in woody detritus and slash and dead roots — which undoubtedly adds to the uncertainty in the estimated total C pool. Most of the C pool in vegetation is located in the low-latitude forests (64%), whereas most of the soil C pool is located in high-latitude forests (52%). Country-level analyses demonstrate that forests already play an important role in the C budget of some countries by offsetting significant amounts of fossil fuel emissions (Box 24-1).

Table 24-1: *Estimated C pools and flux in forest vegetation (above and belowground living and dead mass, including woody debris) and soils (O horizon and mineral soil to 1-m depth) in forests of the world. Dates of estimate vary by country and region, but cover the decade of the 1980s. Estimates are based on complete C budgets in all latitudes, using data from original source or from adjustments for completeness.*

**Box 24-1. Estimates of Current C Sequestration Rates by Forests in Relation
to the Size of their C Pool and Annual Emissions from Fossil Fuel Burning**

Some countries that signed the Framework Convention on Climate Change have made detailed calculations of the amounts of C currently being sequestered by their forests, taking into account the historic rates of forest planting and harvesting, and the dynamics of forest growth and the flow of C to litter and forest product pools (see Table 24-2 for a sampling). In Britain, New Zealand, and India, C is being sequestered as a result of recent forestation programs—whereas in Finland, C is being sequestered by natural regeneration and regrowth of forests because the annual growth is greater than the annual harvest. In Canada, carbon sequestration is occurring as a result of recovery from previous fires. In 17 West European countries, forestry offsets from 1–2% (The Netherlands, Britain, Germany) to about 90% (Sweden) of fossil fuel emissions (Burschel *et al.*, 1993; Kauppi and Tomppo, 1993).

Table 24-2: Carbon storage and C sequestration rates in forests, and national C emissions.

Country	Year	Carbon Stored in Trees and Litter (Mt)	Fossil Fuel–C Emissions (Mt/yr)	Rate of C Removed by Forests (Mt/yr)[1]	Source
Britain	1990	60[2]	164	2.5 (1.5)	Cannell and Dewar, 1995
New Zealand	1990	113	8	3.5 (44)	Maclaren and Wakelin, 1991

Germany	1990	1500–2000	268	5.4 (2)	Federal Ministry for Env., 1994
Canada	1986	12000	136	51.0 (37.5)	Kurz *et al.*, 1992
India	1986	10000	137	5.0 (3.6)	Makundi *et al.*, 1996
Poland	1990	1113	131	8.0 (6)	Galinski and Kuppers, 1994
USA	1990	18585	1300	80 (6)	Turner *et al.*, 1995a

[1]Value in parentheses is the percentage of fossil fuel emissions removed by forests.
[2]Plantation forests only; all forests and woodlands contain ~87 Mt C in the trees alone (Milne, pers. comm.).

Mid- and high-latitude forests are currently estimated to be a net C sink of about 0.7 ± 0.2 Gt/yr because forests at these latitudes are, on average, composed of relatively young classes with higher rates of net production as they recover from past disturbances such as abandonment of agricultural land, harvesting, and wildfires; a larger proportion of these forests are actively managed (i.e., established, tended, and protected); and some areas may be responding to increased levels of atmospheric CO_2 and nitrogen (N) (fertilization effect) (Apps and Kurz, 1991; Birdsey, 1992; Kauppi *et al.*, 1992, 1995; Xu, 1992; Heath *et al.*, 1993; Kolchugina and Vinson, 1993, 1995; Kurz and Apps, 1993; Turner *et al.*, 1995a). Because secondary forests in the mid-and high latitudes are rebuilding C pools, there is a finite potential over which this C sequestration can occur. For example, the current C sink in European forests may disappear within 50 to 100 years (Kauppi *et al.*, 1992), although others suggest that it may take forests as long as several centuries to millennia to reach a C steady state in all components (Lugo and Brown, 1986).

Low-latitude forests are estimated to be a relatively large net C source of 1.6 ± 0.4 Gt/yr in 1990 (Table 24-1), caused by deforestation, harvesting, and gradual degradation of the growing stock. Although this is the best estimate available in the literature, we use this value with recognition that there are many reasons to believe that the uncertainty is larger than shown

(Lugo and Brown, 1992). Unlike the high- and mid-latitude forests—where estimated C fluxes are based, for the most part, on data from periodic national inventories (i.e., field measurements)—the estimated C flux for low-latitude forests is based on a model that tracks only forests that are cleared or harvested with regrowth. In the model, C accumulates in regrowing forests for up to 50–100 years. Furthermore, the model assumes that all other forests not reportedly affected by humans during the period of model simulation (about 1850–1990) are in C steady state (Houghton *et al.*, 1987). Recent work questions this steady-state assumption and implies that the net tropical C flux could be higher or lower than that reported here, depending upon the relative contribution of forest lands that are still gaining C through recovery from past human disturbances or are losing C through continued human use (Brown *et al.*, 1992; Lugo and Brown, 1992).

The error terms associated with the C flux estimates in Table 24-1 are derived from the range of values resulting from the use of different assumptions in the C budgets for a given country or region. They do not represent errors derived from statistical procedures. Error enters the flux estimation procedure through uncertainties and biases in the primary data, and these compound as the data are combined to draw inferences (Robinson, 1989). Many estimates for components of the forest-sector C budget are probably known no better than ±30% of

their mean, and others may be known no better than ± 50% or more of their means (Robinson, 1989). These errors are compounded in making global estimates of C flux—perhaps to large proportions—but to what extent is presently unknown. Clearly, there is a need to apply error-estimation techniques to calculations of the forest-sector C budgets to provide more precise estimates of the C flux.

The global average net C flux and uncertainty term from the world's forests reported here of -0.9 ± 0.5 Gt/yr (a net C source; Table 24-1) is less than that reported in Schimel *et al*. (1995) of -1.1 ± 1.1 Gt/yr. The main reason for this difference is in the interpretation and use of results from the literature. A major difference exists between the respective estimates used for the C flux of boreal forests, particularly for the FSU. In this chapter (Table 24-1), the studies of Kolchugina and Vinson (1993, 1995) were used, which include a complete forest-sector C budget and use more current data; Schimel *et al*. (1995) relied more on the work by Melillo *et al*. (1988) and Krankina and Dixon (1994). These two latter studies were not used in arriving at the estimate in Table 24-1 for the mean C flux for boreal forests because the Melillo *et al*. (1988) results were for an earlier period (prior to 1980) and the Krankina and Dixon (1994) study did not consider all components of the C budget. The main source of difference in the uncertainty term is the error assigned to the tropical net flux: We report an uncertainty term around the tropical flux of ± 0.4 Gt/yr based on Houghton (1995), whereas Schimel *et al*. (1995) report a term of ± 1.0 Gt/yr based on an assumption that the uncertainty was greater than 50% for reasons given above. However, as discussed above, none of these uncertainty terms may reflect the true precision of the estimates.

Substitution of the net C flux for forests reported here (Table 24-1) into the global C budget (Schimel *et al*., 1995) results in an imbalance of 1.2 ± 1.0 Gt/yr. Because the primary data for C budgets for temperate and boreal countries originate from national forest inventories, any increased growth of forests due to CO_2 and N fertilization and climatic effects is already included in the net flux estimates. In other words, the reported C sink for mid- to high-latitude forests (Table 24-1) includes all these factors already because the data, for the most part, come from repeated forest inventories. In contrast, the tropical forest C flux is based on a model and not on repeated forest inventories. Furthermore, the model does not include effects of CO_2 and N fertilization and climate. This leads to the conclusion that a large part of the imbalance in the global C budget must be due to a C sink in tropical latitudes, which also has been suggested by others (Lugo and Brown, 1992; Taylor and Lloyd, 1992; Schimel *et al*., 1995). This could be due to a combination of stimulated regrowth from CO_2 and N fertilization and climate, as well as more extensive forest regrowth. It is clear that to resolve this issue, repeated national forest inventories, with permanent plots, are needed in tropical latitudes.

Most biomass burning in tropical forests is intentional and is associated with land-clearing practices. However, wildfires also occur in tropical moist and dry forests; these also are largely of anthropogenic origin (Goldammer, 1990). Factors contributing to increased wildfires in tropical moist forests are the drying of organic materials (fuel) on the forest floor of degraded forests (increased exposure to solar radiation) and changes in the microclimate of forest remnants surrounded by deforested areas (Fearnside, 1990; Kaufman and Uhl, 1990). Significant areas of temperate and boreal forest also are burned by wildfires of natural or anthropogenic origin or prescribed (controlled) fires (Levine, 1991; Auclair and Carter, 1993; Dixon and Krankina, 1993).

The destruction of forest biomass by burning releases, in addition to CO_2, GHGs that are byproducts of incomplete combustion—namely, methane (CH_4), carbon monoxide (CO), nitrous oxide (N_2O), and nitrogen oxide (NO_x), among others. Whereas complex accounting models and forest inventories are needed to estimate the losses and gains of C over different timescales, the emissions of these other gases from biomass burning are instantaneous, absolute transfers from the biosphere to the atmosphere (Crutzen *et al*., 1979; Crutzen and Andreae, 1990). Globally, biomass burning contributes about 10% of total annual CH_4 emission, 10–20% of total annual N_2O emission, and about half of the CO emission—and so has a significant effect on atmospheric chemistry, especially on tropospheric ozone levels (Houghton *et al*., 1992). Biomass burning also transfers a fraction (up to 10%) of the C to an inert form (charcoal) with a turnover time that is practically infinite.

Many boreal forests grow on peat or organic soils that contain very large amounts of C. Undisturbed anaerobic, northern peatlands are sinks for CO_2 and sources of CH_4 (Matthews and Fung, 1987; see Chapter 6). Drainage of these soils to improve forest productivity virtually stops CH_4 emissions but initiates rapid CO_2 loss by aerobic decomposition. Draining peat soils for forest establishment can produce a C loss from these soils that exceeds C stored in the forest if 20–30 cm of peat decompose as a result of the drainage (Cannell *et al*., 1993). There also are vast areas of forested peatlands in the tropics; how they will be affected by drainage is largely unknown (see Chapter 6).

In addition to managing forest vegetation to conserve or sequester C, there also is an opportunity to manage forest soils for the same purposes (Johnson, 1992; Lugo and Brown, 1993; Dixon *et al*., 1994a). Regional and national programs to conserve soil, including organic matter, have been implemented worldwide (Dixon *et al*., 1994a). Management practices to maintain, restore, and enlarge forest soil C pools include (after Johnson, 1992) enhancement of soil fertility; concentration of agriculture and reduction of slash-and-burn practices; preservation of wetlands; minimization of site disturbance during harvest operations to retain organic matter; forestation of degraded and nondegraded sites; and any practice that reduces soil aeration, heating, and drying. Several long-term experiments demonstrate that C can accrete in the soil at rates of 0.5 to 2.0 t/ha/yr (Dixon *et al*., 1994a).

24.3.   Carbon Mitigation Options

It should be emphasized at the outset that the objective of the practices presented here—that is, to foster C conservation and sequestration in forests—is but one of a variety of objectives for forest management that needs to be balanced with other objectives. However, most forest-sector actions that promote C conservation and sequestration make good social, economic, and ecological sense even in the absence of climate-change considerations. Other objectives for managing forests include sustainable development, industrial wood and fuel production, traditional forest uses, protection of natural resources (e.g., biodiversity, water, and soil), recreation, rehabilitation of damaged lands, and the like; C conservation and sequestration resulting from managing for these objectives will be an added benefit. For example, although the primary reasons for the establishment of plantations on non-forested land have been economic development, provision of new wood resources (e.g., Portugal, Swaziland), replacement of diminishing or less-productive natural forests (e.g., Australia, Brazil, Malaysia), import substitution (e.g., United Kingdom, Zimbabwe), generation of export income (e.g., Chile, New Zealand), or rehabilitation projects (Evans, 1990; Kanowski and Savill, 1992; Kanowski *et al*., 1992), they also are considered an important means for sequestering C.

There are basically three categories of forest management practices that can be employed to curb the rate of increase in CO_2 in the atmosphere. These categories are:

1) Management for conservation (prevent emissions)
2) Management for storage (short-term measures over the next 50 years or so)
3) Management for substitution (long-term measures).

The goal of conservation management is mainly to conserve existing C pools in forests as much as possible through options such as controlling deforestation, protecting forests in reserves, changing harvesting regimes, and controlling other anthropogenic disturbances such as fire and pest outbreaks. The goal of storage management is to expand the storage of C in forest ecosystems by increasing the area and/or C density of natural and plantation forests and increasing storage in durable wood products. Substitution management aims at increasing the transfer of forest biomass C into products (e.g., construction materials and biofuels) that can replace fossil-fuel-based energy and products, cement-based products, and other building materials.

24.3.1.   Conservation Management

24.3.1.1. Controlling Deforestation

Slowing the rate of loss and degradation of existing forests could reduce CO_2 emissions substantially. The most significant C conservation clearly would occur in the tropics, where each Mha of deforestation produces about a 0.1 Gt C net flux (flux from Table 24-1, divided by area of deforestation of 15.4

Mha/yr). Because the burning of biomass usually accompanies deforestation, slowing deforestation also would reduce emissions of other GHGs.

Reducing tropical deforestation and forest degradation rates would require action to reduce the pressures for land and commodities while increasing the protection of remaining forests for the purposes of conservation and timber production. Most deforestation and degradation is caused by the expansion and degradation of arable and grazing lands and subsistence and commodity demand for wood products—which in turn are a response to the underlying pressures of population growth, socioeconomic development, and political forces. Thus, programs to reduce deforestation must be accompanied by measures that increase agricultural productivity and sustainability, as well as initiatives to slow the rate of population growth (Grainger, 1990; Waggoner, 1994; see also Chapters 13, 15, and 23) and deal with the socioeconomic and political issues.

Although reducing deforestation in the tropics may appear to be a difficult task, there are countries where this is happening (e.g., Brazil, India, Thailand). An example of note is India, where net deforestation has been reduced significantly. Despite its high population density and growth rate, India has succeeded in stabilizing the area under forest during the last decade at about 64 Mha, about 19% of its land area (Ravindranath and Hall, 1994). This stabilization does not mean deforestation of native forests has ceased but rather that loss of native forests is balanced by establishment of plantations (see Chapter 15). This has been achieved by strong forest conservation legislation, a large forestation program, and community awareness.

Past international efforts to curb deforestation, such as the Tropical Forestry Action Plan, have met with limited success (Trexler and Haugen, 1995). Major factors are the absence of comprehensive agricultural policies that meet the needs of resource-poor farmers and the growing global demand for food, fiber, and fuel for the increasing human population (Brown, 1993; Grainger, 1993). Deforestation has been viewed as largely a forestry and conservation problem, and tackling the symptoms rather than the root causes is an incomplete strategy. Global action to mitigate emissions of C by conserving C pools may lead to more interest and success in controlling deforestation and making agriculture more sustainable.

24.3.1.2. Protection and Conservation of Forests

In recent years, there has been significant expansion of "protected areas" into areas of both mature and secondary forests for conservation of biodiversity and sustainable timber production (presently about 10% of the forest land; World Conservation Monitoring Centre, 1992). Carbon pools should remain the same or increase in size in these areas, depending on their present age-class distribution. New protected areas should include those that contain large C pools, such as forests growing on peat soils at high and low latitudes, and high-biomass old-growth forests.

Two biologically significant forest regions that have received attention as C reservoirs in recent years are the Amazon Basin of Brazil and the forests of the FSU (Fearnside, 1992; Kolchugina and Vinson, 1993, 1995; Krankina and Dixon, 1992). The largest contiguous area of C-dense forests in the world is found in the FSU. These forests are subject to future environmental degradation and harvesting, accelerating the loss of C (Brown *et al.*, 1996). Protection of these forests from harvest without regeneration, uncontrolled fires, and pollutants is a priority of the FSU, but infrastructure and resources there are underdeveloped.

The management of tropical forests for sustainable timber production is likely to increase over the coming decades due to collective action under the auspices of the second International Tropical Timber Agreement (agreed to in January 1994). It also is likely that a trend toward management for sustainable timber production in all of the world's forests will occur in the future. Using forests for sustainable timber production—including extending rotation cycles, reducing waste, implementing soil conservation practices, and using wood in a more C-efficient way—ensures that a large fraction of forest C is conserved. Paper recycling is another strategy with the potential to reduce harvest levels and promote greater C conservation (Turner *et al.*, 1995b).

24.3.2. Storage Management

Storage management means increasing the amount of C stored in vegetation (living, above and belowground biomass), soil (litter, dead wood, mineral soil, and peat where important), and durable wood products. Increasing the C pool in vegetation and soil can be accomplished by protecting secondary forests and other degraded forests whose biomass and soil C densities are less than their maximum value and allowing them to sequester C by natural or artificial regeneration and soil enrichment. Other approaches are to establish plantations on non-forested lands; promote natural or assisted regeneration in secondary forests, followed by protection; or increase tree cover on agricultural or pasture lands (agroforestry) for environmental protection and local needs. The C pool in durable wood products can be increased by expanding demand for wood products at a faster rate than the decay of wood and by extending the lifetime of wood products. These measures include timber treatment and the production of long-lasting particle boards (Elliott, 1985).

Sequestering C by storage management produces only a finite C sequestration potential in vegetation and soils, beyond which little additional C can be accumulated. The process may take place over a time period on the order of decades to centuries, depending upon the present age-class of forest, the attainable maximum C density, forest type, species selection, and latitudinal zone. In the long run, this is less helpful than substitution options (see Section 24.3.3), given the expected continuous need to offset future C emissions.

Expansion of C pools through the establishment of plantations is becoming less socially and politically desirable, especially with the global concern for biodiversity and other social, cultural, land-tenure, and economic factors (Nilsson and Schopfhauser, 1995). However, in many situations plantations are the only option, and they can increase local biodiversity through the reestablishment of native species in the understory when they are established on highly degraded lands and are subject to no further management (Lugo *et al.*, 1993; Parrotta, 1993; Allen *et al.*, 1995). These forests can then contribute to the development goals of national forest sectors. Furthermore, if more native forests are to be protected and/or harvesting levels reduced, plantation establishment may become more necessary to offset wood reductions (see Chapter 15).

24.3.3. Substitution Management

Substitution management, which has the greatest mitigation potential in the long term (>50 years) (Marland and Marland, 1992; Swisher, 1995), views forests as renewable resources. It focuses on the rate of C sequestration or the transfer of biomass C into products that substitute for or lessen the use of fossil fuels, rather than on increasing the C pool itself (Grainger, 1990; Mixon *et al.*, 1994). This approach involves extending the use of forests for wood products and fuels obtained either by establishing new forests or plantations or by increasing the growth of existing forests through silvicultural treatments (Table 24-3). However, a consideration of growth rates and initial standing stocks of biomass C is critical in determining which existing forests should be used for this purpose (Marland and Marland, 1992). For example, it is better not to convert forests with a large initial standing biomass C and slow growth rates (e.g., old-growth forests) to managed stands because it may take a very long time (up to centuries) until the net C sequestered returns to its initial value (Harmon *et al.*, 1990; Marland and Marland, 1992)—or never, if they are harvested on a rotational basis (Dewar, 1991; Vitousek, 1991; Dewar and Cannell, 1992; Cannell, 1995). In contrast, forests with high growth rates and low-to-medium initial biomass C standing stocks are amenable for conversion to managed forests, with considerable quantities of C sequestered if the harvested wood is directly used (Marland and Marland, 1992). When presented with cleared or disturbed forest lands, any forest management practice that increases the C pools and cycles the C by harvesting wood for substitution of energy-intensive products or fossil fuels will remove CO_2 from the atmosphere on a continuing basis.

In the case of forests established on non-forested lands for energy products such as fuelwood, not only is there an increase in the amount of C stored on the land (Grainger, 1990; Schroeder, 1992) but, if the wood burned as fuel displaces fossil fuel usage, it creates an effective rate of C sequestration in unburned fossil fuels (Hall *et al.*, 1991; Sampson *et al.*, 1993; see also Chapter 19). There must, however, be a net energy return in the total system (Hall *et al.*, 1986; Herendeen and Brown, 1987). The extent to which fuelwood plantations are able to displace fossil fuel use in developed countries will depend on the continued development of highly efficient technologies (e.g., Williams and Larson, 1993) for converting

Table 24-3: *Sequestration potential of different forest types (from Nabuurs and Mohren, 1993).*

Forest Type	Long-Term Average Quantity of C in All Living Biomass and Forest Products (t/ha)	Long-Term Average Quantity of C in Litter, Dead Wood, and Soil to 100 cm (t/ha)	Average Net Annual Rate of C Accumulation[1] (t/ha/yr)

[1] C sink over first rotation through net primary production minus decomposition of soil organic matter, litter, dead wood, logging slash, and products.

wood into clean forms of energy like electricity. The extent to which fuelwood plantations will be established on degraded lands in developing countries for the generation of electricity will depend more on other incentives such as rural employment and income generation.

When forests are used to produce sawtimber, plywood, or other industrial wood products, C can be sequestered for long periods. The length of time depends on how the timber is treated and used. The production of wood products often requires much less energy than does production of alternative products like steel, aluminum, and concrete, and there can be a large energy return on investment in wood products. For example, the substitution of composite solid-wood products with load-bearing capacities for steel and concrete can save large amounts of fossil fuels. However, an analysis of the full life cycles of wood products is required to appreciate the impact on net C storage and net C emissions. Over long time periods, the displacement of fossil fuels either directly or through production of low-energy-intensive wood products is likely to be more effective in reducing C emissions than physical storage of C in forests or forest products. For example, substitution of wood grown in plantations for coal in the generation of electricity can avoid C emissions by an amount up to four times the amount of C sequestered in the plantation, depending upon the time period over which coal resources are expected to last

(Ravindranath and Hall, 1995). Furthermore, if the wood resource is derived from sustainably managed plantations, other benefits, such as rural jobs and land rehabilitation (if the project is on degraded lands), will accrue (Ravindranath and Hall, 1995).

24.4. Assessment of C Mitigation Options

The potential land area available for the implementation of forest management options for C conservation and sequestration is a function of the technical suitability of the land to grow trees and the actual availability as constrained by socioeconomic factors. Determining the technical suitability of land is conceptually less difficult, being based generally on the region's climatic and edaphic characteristics. However, moving from what is suitable to what is actually available is more difficult because of institutional, economic, demographic, and cultural factors—all of which influence present and future land-use decisions (Trexler and Haugen, 1995).

This section is divided into two parts: steady-state potential, based on estimates of the amount of C that could be conserved and sequestered when all actually available lands (in some cases, only technically suitable lands are considered) are under management and contain their maximum C density for a given

practice; and transient potential, based on estimates of the amount of C that could be conserved and sequestered on all available land subject to reasonable rates of establishment of forest management practices over time.

24.4.1. Steady-State Potential

Most previous estimates of the C sequestration potential are simply the product of the suitable or available land area and the maximum or time-averaged C density (e.g., Grainger, 1988; Postel and Heise, 1988; Sedjo and Solomon, 1989; Winjum *et al.*, 1992a). Using this approach and approximate estimates of areas of land available for reforestation and natural and assisted regeneration, Winjum *et al.* (1992a) estimate that 2.2–5.6 Gt C could be sequestered in the entire high-latitude zone over a 50-year period. In Russia alone, Krankina and Dixon (1994) estimate a potential sequestration of 4.5 Gt C over a 50-year period by replacing hardwood stands with conifers, increasing the productivity of existing forests, and establishing plantations on technically suitable lands. Furthermore, they estimate that exercising fire management and reducing harvest could account for an additional potential C savings of 7.2 Gt over a 50-year period.

On estimates of available land in mid-latitudes, 13.5–27.0 Gt C could be sequestered by forestation and natural regeneration over a 50-year period (Winjum *et al.*, 1992a). In the United States alone, an aggressive program of tree planting on marginal agricultural lands (crops and pastures), increasing windbreaks and shelter belts, and forest management could sequester up to 15 Gt C over about a 40-year period (Sampson, 1992).

At low latitudes, a combination of forestation, agroforestry, and natural or assisted forest regeneration on an estimated 300 to 600 Mha of land considered to be available by Winjum *et al.* (1992a) could conserve and sequester about 36–71 Gt C over 50 years. If all technically suitable lands are considered, more than double this amount could be conserved and sequestered by plantation establishment, converting arable/degraded lands to agroforestry, and protecting existing forests (Houghton *et al.*, 1993; Iverson *et al.*, 1993; Unruh *et al.*, 1993).

Recent country-specific estimates for China, India, Mexico, and Thailand indicate that the available land for establishment of plantations and agroforestry is 172 Mha, 175 Mha, 44 Mha, and 7 Mha, respectively (Masera *et al.*, 1995; Ravindranath and Somashekar, 1995; Wangwacharakul and Bowonwiwat, 1995; Xu, 1995). These estimates of land availability are based on national forest-cover targets for China and India and on technical availability for the other two countries. The C sequestration potential on these lands could be up to about 5 Mt/yr.

24.4.2. Transient Potential

Although the studies cited in Section 24.4.1 set a useful upper bound for the potential for C conservation and sequestration, only a few studies consider the issues of land availability,

socioeconomic barriers, the timescale over which C may be sequestered, or realistic or feasible rates of forest establishment or regeneration. At the present rate of successful plantation establishment in the tropics of only 1.8 Mha/yr (FAO, 1993), it would take many decades to achieve the levels of sequestration suggested by Winjum *et al.* (1992a). Similar time frames would be needed for the establishment of agroforestry, as well as large areas of mid- and high-latitude plantations. Once established, reaching maximum C storage would then take up to many decades.

A study by Grainger (1990) focuses on the tropics only. He considers a range of scenarios for conserving and sequestering C, including a combination of forestation and deforestation control, and assumes that all wood harvested from the new plantations would be converted into long-term storage as industrial wood. The study does not consider woody detritus or belowground C, is not regionally explicit, and gives only a partial treatment to land availability. The analysis suggests that sequestering about 3 Gt C/yr (the rate at which it was increasing in the atmosphere in 1980) would require 600 Mha of new forest plantations—roughly the area of degraded lands regarded by Grainger (1988) as physically suitable for plantation establishment.

24.4.2.1. Analytical Approach

Nilsson and Schopfhauser (1995) and Trexler and Haugen (1995) are the only studies suitable for global analysis of the mitigation potential of forests. These studies have been chosen because they are global in nature, include an extensive literature review of the land availability issue, and include feasible rates of establishment of management options. These two studies have been combined to arrive at a global estimate of the potential amount of C that could be conserved and sequestered by different regions of the Earth on an annual and cumulative basis between 1995 and 2050. Nilsson and Schopfhauser (1995) estimate the potential for C sequestration through a feasible global forestation program (Table 24-4). Trexler and Haugen (1995) focus on the tropics only and include the options of slowing deforestation and natural or assisted regeneration of land (followed by protection). Both studies assume aggressive, but unspecified, policy and financial interventions in the forestry sectors, with no future change in climate that might interfere with the proposed strategies. The combined analysis uses data for forestation from Nilsson and Schopfhauser (1995) and data for slowing deforestation and regeneration from Trexler and Haugen (1995).

Nilsson and Schopfhauser (1995) estimate for different countries/regions the amount of land likely to be available, feasible annual planting rates, likely growth rates, and rotation lengths (Table 24-4). They use a growth model, without intensive management, to estimate the quantity of C fixed in aboveground and belowground biomass, litter, and soil organic matter for the period 1995 to 2100. Because the focus of the study was to estimate how much C could be sequestered by a global forestation

Table 24-4: Regional estimates of land availability, average mean annual increment (MAI), rotation length, and planting rate for a global forestation program, including establishment of plantations and agroforestry, to sequester C (data from Nilsson and Schopfhauser, 1995).

Region/ Country	Land Available[1] (Mha)	MAI (m^3/ha/yr)	Rotation Length (yr)	Planting Rate[2] (Mha/yr)
High Latitudes

[1]Full details of sources are provided in Nilsson and Schopfhauser (1995); many of the sources originate from individual countries.

[2]Includes rate of establishment of both plantations and agroforestry systems.

[3]Canada includes not satisfactorily restocked (NSR) forest areas in addition to marginal agricultural lands (Van Kooten, 1991); the low end of the MAI was used for NSR forests.

program only, they make no assumptions about the life expectancy of the wood produced. Further, the amount of C sequestered by this program will be realized only if the forests are harvested at their designated rotation lengths. Considerably higher yields than those reported in Table 24-4, though often possible in plantations, require more intensive management than is likely to be achieved for a large-scale program such as that proposed by Nilsson and Schopfhauser (1995). Similar arguments can be made for shortening the rotation times.

For most high- and mid-latitude countries, the area of actually available land is equated with that technically suitable, or about 215 Mha (Table 24-4). The rather large amount of land available in Canada is from a combination of large areas of not satisfactorily restocked forest lands (19.7 Mha) and marginal agricultural lands (8.6 Mha; Van Kooten, 1991). In low-latitude countries, Nilsson and Schopfhauser estimate actual availability (130 Mha) to be only 6% or so of those lands deemed suitable (2,228 Mha) because of additional cultural, social, and economic constraints (Trexler and Haugen, 1995). The global

estimate of 345 Mha of actually available lands for plantations and agroforestry is similar to the low end of the estimated range of 375 to 750 Mha offered by Winjum *et al.* (1992a) for the same forestry practices.

The assumed establishment rates of 8.3 Mha/yr for plantations and 1.4 Mha/yr for agroforestry [estimated from land available, plantation period, and rotation length; see Nilsson and Schopfhauser (1995) for more details] are not unrealistic based on present establishment rates. For example, the assumed annual rate of plantation establishment in the tropics used in Nilsson and Schopfhauser is about 65% of the actual rate for 1980–90 (FAO, 1993). For China, the assumed rate of 2.5 Mha/yr also is lower than the reported rate of 3.9 Mha/yr (Xu, 1992).

Trexler and Haugen (1995) use country-level estimates for each decade from 1990 to 2050 for 52 tropical countries accounting for virtually all of the tropical forests. For each country and decade (based on detailed country-by-country analysis), they estimate current and projected future deforestation rates, the potential reduction in deforestation based on feasible implementation of alternative land uses, and the area presently available for natural or assisted forest regeneration (native forests) followed by protection, as well as likely rates of implementation. Based on these estimates, Trexler and Haugen (1995) project that by the year 2050, deforestation could be reduced by only 20% of the business-as-usual scenario—equivalent to about 138 Mha—and a further 217 Mha of land will be available for natural or assisted regeneration. They also estimate the change in aboveground biomass C associated with each land-use change. We have added estimates of belowground biomass, soil, and litter C (see footnote 2 to Table 24-5) to be consistent with the study of Nilsson and Schopfhauser (1995).

24.4.2.2. Quantities of C Conserved and Sequestered

Together, the studies suggest that 700 Mha of land might be available globally for C conservation and sequestration programs (345 Mha for plantations and agroforestry, 138 Mha for slowed tropical deforestation, and 217 Mha for natural and assisted regeneration of tropical forests). This amount of land could conserve and sequester 60 to 87 Gt C by 2050 (Table 24-5). Globally, forestation and agroforestry account for 50% of the total (38 Gt C), with about 20% of this accumulating in soils, litter, and belowground biomass (Nilsson and Schopfhauser, 1995). The amount of C that could be conserved and sequestered by forest-sector practices by 2050 under baseline conditions is equivalent to about 12 to 15% of the total fossil fuel emissions over the same time period (IPCC 1992a scenario).

The tropics have the potential to conserve and sequester by far the largest quantity of C (80%), followed by the temperate zone (17%), and the boreal zone (3% only). More than half of the tropical sink would be caused by natural and assisted regeneration followed by forest protection and slowed deforestation. Other analyses have shown that forest conservation and natural regeneration is potentially easier, cheaper (see Section 24.5), and more

acceptable to the local population than plantation-based forestation (Deutscher Bundestag, 1990; Grainger, 1990). Forestation and agroforestry would contribute less than half of the tropical

Table 24-5: *Global estimates of potential amount of C that could be sequestered and conserved by forest management practices between 1995 and 2050 (from Nilsson and Schopfhauser, 1995; Trexler and Haugen, 1995).*

[1] This estimate differs from the one made by Maclaren (1996), because it includes multiple rotations and different data for the C budget components.

[2] Includes an additional 25% of aboveground C to account for belowground C in roots, litter, and soil (based on data in Nilsson and Schopfhauser, 1995; Brown *et al*., 1993b); range in values is based on the use of low and high estimates of biomass C density resulting from the uncertainty in these estimates.

total, but without them, regeneration and slowed deforestation would be highly unlikely (Trexler and Haugen, 1995).

The total quantity and annual rates of C conservation and sequestration would vary among countries or regions (Table 24-5; Figure 24-1). The FSU accounts for more than 70% of the C sequestration potential in the boreal zone (Table 24-5). At mid-latitudes, the greatest potential for sequestering C would be in the United States (about 3.4 Gt), followed by temperate Asia (about 2.2 Gt), and China and New Zealand (1.7 Gt each) (Figure 24-1a). In low latitudes, tropical America would have the greatest potential for C conservation and sequestration (27 Gt), followed by tropical Asia (20 Gt) and tropical Africa (12 Gt) (Table 24-5; Figure 24-1b). Forestation and regeneration would likely have the greatest potential in tropical America and Asia, whereas agroforestry would be the most important activity in tropical Africa (Nilsson and Schopfhauser, 1995).

Figure 24-1: Average annual rates of C conservation and sequestration per decade through implementation of forest management options listed in Table 24-5 (a) by four countries or regions of the high- and mid-latitudes with the highest total sequestration rates and (b) for the three tropical (Tr.) regions.

Annual rates of C conservation and sequestration from the practices listed in Table 24-5 would increase over time and reach 2.2 Gt/yr by 2050 (Figure 24-2a), with C accretion in the tropics dominating the flux. Carbon savings from slowed deforestation and regeneration would be the highest initially, but from 2025 onwards—when plantations would reach their maximum C accretion—they would sequester practically identical amounts as forestation (Figure 24-2b). During this period, tropical deforestation would continue, and the tropics would remain a net C source, albeit gradually diminishing. By about 2030, the tropics would become a C sink (Trexler and Haugen, 1995). On a global scale, forests could turn from a source to a sink by about 2010 due to C conserved in other zones.

In summary, the tropics appear to have the greatest long-term potential for C conservation and sequestration by—in decreasing order of importance—protecting lands for natural and assisted regeneration, slowing deforestation, forestation, and agroforestry. The mid-latitudes also could make a significant contribution, but the potential for the high latitudes appears to be limited. The uncertainty in the estimated mitigation potential of forests has not, at present, been estimated. Like the uncertainty associated with the estimated C flux from the world's forests (see Section 24.2.2), the uncertainty in the estimated mitigation potential is likely to be high. The factors causing the highest uncertainty are the estimated land availability for forestation projects and regeneration programs and the rate at which tropical deforestation can be actually reduced. The next most uncertain term is the amount of C that can be conserved or sequestered in tropical forests; there is considerable debate about how much biomass C tropical forests contain (Brown and Lugo, 1992). The net amount of C per unit area that can be sequestered in a global forestation program is more certain. However, as discussed in Section 24.2.2, all errors are certain to be compounded when making global estimates.

The contribution of forestry to mitigation of CO_2 emissions would be considerably higher if the wood produced were assumed to be used as a substitute for fossil fuels (Section 24.3.3; Hall *et al.*, 1991; Sampson *et al.*, 1993). For example, for the forestation program described here (Table 24-5), the quantity of biomass that could potentially be produced over the 55-year period was 147 billion m³, which is equivalent to about 39 billion tons of coal (W. Schopfhauser, pers. comm.). If the wood were substituted for coal over the same time period, the C emissions avoided would be about 29 Gt, or about 77% of the C sequestered in the forestation program (37.6 Gt) (Table 24-5).

A number of projects to conserve and sequester C along the lines described above are now being jointly implemented between developed and developing countries. They vary from C conservation by protecting forests or developing sustainable forest management practices to increasing C pools through forestation and agroforestry (Box 24-2).

24.5.   Project Costs and Benefits of C Conservation and Sequestration

The previous IPCC assessment (IPCC, 1992) reported regional average annual costs of about $8/t C for tropical forestation and reduction of deforestation, increasing to about $28/t C for forestation in non-U.S. OECD countries. Costs for establishing a forest plantation, excluding the opportunity cost of land, were estimated to range between $230 and $1000/ha (Sedjo and Solomon, 1989), with an average cost of $400/ha.

Unit cost estimates have been improved since the earlier IPCC report (see also Chapter 8, *Estimating the Costs of Mitigating Greenhouse Gases*, and Chapter 9, *A Review of Mitigation Cost Studies*, of the IPCC Working Group III volume): (1) They have been estimated for individual countries rather than by regions or for the globe as a whole; (2) they have been developed for several types of mitigation options; (3) other cost

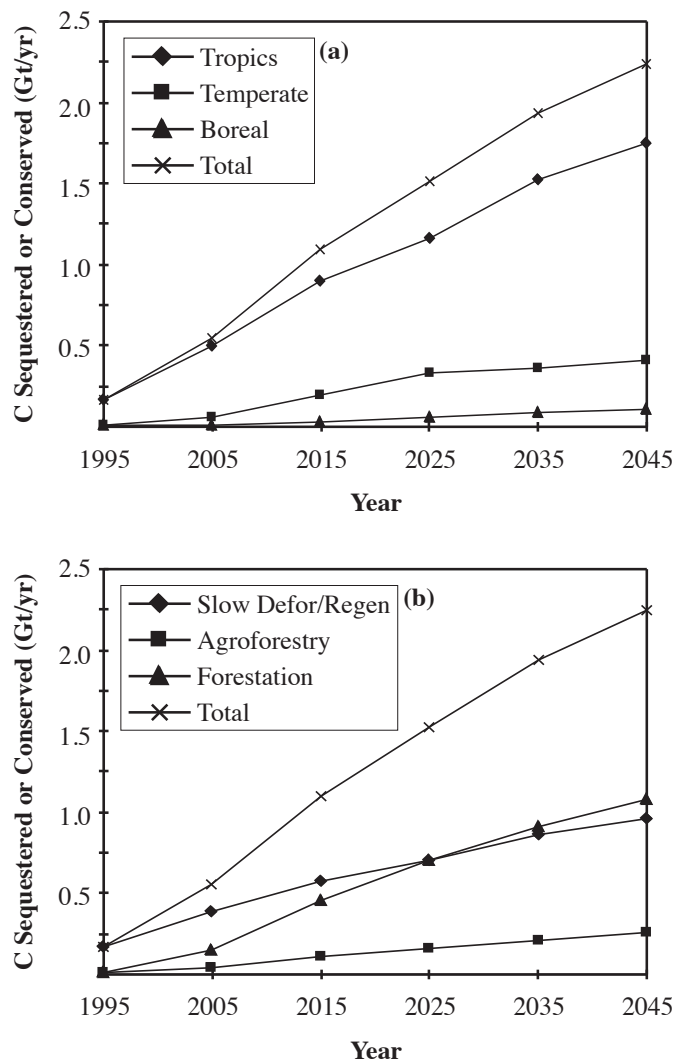

Figure 24-2: Average annual rate of C sequestration and conservation per decade through implementation of the forest management options listed in Table 24-5 by (a) latitudinal region and (b) forest management practice. Note that Defor = deforestation and Regen = natural and assisted regeneration.

Box 24-2. Jointly Implemented Forestry Offset Projects to Sequester C Emissions

There are several examples of C-offset projects around the world; the main characteristics of six of these projects are highlighted in Table 24-6 (adapted from Dixon *et al*., 1993a; Kinsman and Trexler, 1993).

Table 24-6: *Jointly implemented forestry offset projects.*

Location	Main Sponsor[1]	Forestry Option	Total Cost (10^6 US$)	Carbon Sequestered (Mt)	Duration (yr)
Guatemala	AES Thames	Sustainable Agroforestry	14	15.5–58	10
Malaysia (1)	ICSB/NEP	Harvest Modification	0.45	0.3–0.6	2–3
(2)	ICSB/FACE	Forest Rehabilitation	14	5–7.5	25
Paraguay	AES Barbers Point	Protection, Sustainable Agroforestry	2–5	13	30
Russia (Saratov)	USEPA/OSU	Forestation	0.2	0.04	50
USA (Oregon)	PacifiCorp	Sustainable Forestry	0.1/yr	0.06/yr	65

[1]AES Thames is a subsidiary of Applied Energy Services (AES) Corporation (Virginia, USA); NEP = New England Power (Massachusetts, USA); FACE = Forest Absorbing Carbon Dioxide Emissions, a project of the Dutch Electricity Generation Board; ICSB = Innoprise Corporation Sdn Bhd (Yayasan Sabah, Malaysia); USEPA/OSU = U.S. Environmental Protection Agency in cooperation with Oregon State University (T. Vinson, pers. comm.); PacifiCorp is an electric utility company in Oregon, USA.

Brief details of two of these offset projects follow:

- The cooperative venture between Innoprise Corporation Sdn Bhd (ICSB), the largest logging concession holder in the state of Sabah, Malaysia, and the Forest Absorbing Carbon Dioxide Emissions (FACE) Foundation promotes the planting of trees to absorb CO_2 from the atmosphere and offset emissions from power stations. The objective is to rehabilitate 25,000 ha of degraded logged forests by enrichment planting with dipterocarps—long-lived local tree species valued for their timber—and by reclaiming degraded areas using indigenous fast-growing pioneer trees. Forest fruit trees also are being interplanted to improve the forest's value for wildlife. Over a 60-year rotation, the rehabilitated forest is expected to sequester at least 200 t C/ha more than degraded logged forest; thus, a total of 5 Mt C will be sequestered. Results achieved so far are very encouraging, with survival rates around 87% and growth rates of 1.2 cm dbh per year (P. Moura Costa, pers. comm.). The long-term nature of the project (25 years) will allow the maintenance and silvicultural treatments required to sustain the growth rates to be achieved.
- For the Reduced-Impact Logging Project, New England Power (NEP) provided funds to ICSB to train personnel and implement a set of harvesting guidelines in 1,400 ha of ICSB concessions. In return, NEP can claim the C retained due to these efforts as a C offset. The project aims to reduce by half the damage to residual trees and soil during timber harvesting. Thus, less woody debris will be produced, decompose, and release CO_2, meaning more C will be retained on-site in living trees (Putz and Pinard, 1993). Conventional selective logging in the concession provides the base for comparison. Controlling logging damage is expected to result in the retention of 25–45 t C/ha after 2 years, and a total of 35–63 kt C are expected to be sequestered, at a cost of $8–14/t C.

---

components, including maintenance, land rental (opportunity costs), and monitoring and evaluation, are now being addressed; (4) incremental costs have been estimated by some researchers; and (5) analytical methods have been improved to provide better insights and techniques for the evaluation of costs and benefits. Despite these improvements, most estimates do not discount the C flows. Thus, net C storage occurring at any time has the same economic value.

The IPCC (1992) report does not attempt to quantify the benefits of mitigation options to reduce or store C. The valuation of C and other benefits is essential to the successful implementation of mitigation options—particularly for developing countries, where C storage may not be a sufficient inducement for local dwellers to maintain forestation projects. There is no global consensus at present on the monetary value of reducing a unit of atmospheric C.

Incremental costs of comparable projects or programs are defined as the difference between the total costs of an alternative and those of a baseline project that satisfies the same service, such as the demand for food, fuel, fiber, watershed protection,

and habitat (Ahuja, 1993; K. King, 1993). Under the UN Framework Convention on Climate Change, a developing country may seek the incremental costs of a project to reduce C emissions or sequester C from developed countries. For the forest sector, however, few estimates are available for the incremental costs of GHG emissions reduction.

24.5.1. *Reducing Deforestation and Protecting Forests*

The unit cost of reducing C emissions by decreasing deforestation and protecting forests tends to be low (Table 24-7) as the C density of forested areas tends to be relatively high. Cost estimates, often obtained from government budgets, include the small direct cost of protection but generally not the comparatively larger opportunity cost of land. None of the estimates includes the potentially substantial, though as yet unknown, cost of providing an alternative livelihood and a viable lifestyle to those responsible for deforestation. Furthermore, present-day costs of forest protection will likely increase in the future as the amount of land put under protection increases (Adams *et al.*, 1993; Moulton and Richards, 1990).

Most of the costs reported in Table 24-7 are under \$3/t C, but range from tens of cents/t C to about \$15/t C. These costs exclude the value of local benefits that may be derived from protected forests, such as watershed protection, maintenance of biodiversity, education, tourism, and recreation; their inclusion would further offset some of the costs and in many instances

Table 24-7: *Cost of forest protection or reducing deforestation.*

Country	Cost (\$/t C)
Brazil	2.3[1]–4[2]
Cote d'Ivoire	8[1]

[7]Krankina and Dixon, 1994.

result in net benefits (Dixon *et al.*, 1993b). For example, in Thailand, local benefits are estimated at \$2/ha—which would almost offset the \$2.1/ha direct cost of protection (Wangwacharakul and Bowonwiwat, 1995). Because direct benefits offset direct costs, the opportunity cost of land (present value \$44–89/ha) represents the cost of avoiding deforestation.

24.5.2. *Expansion of C Pools and C Transfer to Products*

Subsequent to the IPCC report (1992), several studies have been done that better determine the cost of expanding C pools and C transfer to products (Table 24-8). The studies have focused on deriving cost estimates of mitigation options for individual countries. The costs generally include initial or establishment costs per ton of C but do not include opportunity costs or maintenance, monitoring, and evaluation costs. The methods for obtaining cost figures include literature surveys, government sources, personal questionnaires, and some field data. At the same time, researchers have refined the methodology for estimating the amount of C sequestered by a particular mitigation option and better identified the individual components of the total cost (Sathaye *et al.*, 1995). This identification has helped improve the transparency of reported cost estimates.

Earlier studies had reported point estimates for cost of C sequestration. Moulton and Richards (1990), however, developed a cost function to reflect the rise in costs associated with large-scale tree planting rather than a simple point estimate, and refined the tree plantation establishment cost estimates by differentiating costs associated with location and site considerations. Based on their data, Cline (1992) estimates costs as rising from \$12/t C for the first 100 Mt of C sequestered to \$41/t C for sequestering between 700 and 800 Mt/yr. Adams *et al.* (1993) report somewhat higher costs than Moulton and Richards (1990) (Table 24-8). The Moulton and Richards (1990) analysis has been expanded by adding the potential effects of forestation on altered timber supply, stumpage prices, harvest levels, and ultimately C sequestration (Turner *et al.*, 1995b). The latter approach couples a forest economics model, a forest inventory model, and a forest C model to make a 50-year projection of the forest sector of the U.S. economy. Coupling of models permits analysis of more-complex mitigation options such as increased paper recycling, alternative harvesting schemes, and tree planting on agricultural land. One drawback of these models is that they ignore new uses of wood—such as for power or heat generation—that would minimize the impact on traditional timber markets.

Several studies conducted for developing countries (Table 24-8) evaluate the cost of sequestering C using options such as agroforestry, long- and short-rotation plantations, natural regeneration, forest management, and silvicultural practices. Based on an estimate of the technically available land area in a given country, the tropical studies have developed cost curves that show increasing marginal costs (\$/t C) with higher sequestration. The curves for India, China, and Thailand, for example, indicate that the unit cost for sequestering C on 80% of the technically available area would be less than \$10/t C.

[1] Forest components for sequestering C vary by source: Dixon *et al*. (1994b), Krankina and Dixon (1994), and Winjum *et al*. (1993) include only C in vegetation; Xu (1995), Ravindranath and Somashekhar (1995), Wongwacharakul and Bowonwiwat (1995), and Masera *et al*. (1995) include vegetation and soil C; Swisher (1991), Moulton and Richards (1990), and Adams *et al*. (1993) account for C in vegetation, soil, and litter.

[2] Values in parentheses are interquartile ranges.

[3] Figures vary depending on land rental costs per ha from $400 to 1,000; FLORAM = Florestales Amazonia.

[4] Marginal costs include planting and land rental costs.

[5] Includes land rental costs.

24.5.2.1. Carbon Components

All the above cost estimates account for above and below-ground biomass C, but not all account for C in soil, fine and woody detritus, understory, and wood products. Estimates of the distribution of C between aboveground vegetation and soils vary significantly by ecosystem and by bioclimatic and edaphic conditions (Brown *et al.*, 1993a; Sampson *et al.*, 1993). By excluding many of the other C components, the studies reported in Table 24-8 overestimate the unit costs.

The studies summarized in Table 24-8 ignore another potentially large C benefit—that is, the possibility of substituting wood from sustainable plantations for fossil fuels (see Section 24.3.3; Hall *et al.*, 1991; Sampson *et al.*, 1993; see also Chapter 19). The extent to which wood products can displace fossil fuel depends on the products and applications for which wood is substituted. Fossil fuel savings may be considerable when wood is substituted for energy-intensive aluminum, steel, or concrete in construction (Burschel *et al.*, 1993). When harvesting wood to directly displace fossil fuels, the critical elements become the rate of tree productivity and the efficiency with which wood can be harvested and substituted for fossil fuels (Marland and Marland, 1992; see also Section 24.3.3).

24.5.2.2. Cost Components

The unit cost estimates reported in Table 24-8 include the cost to initiate a forest sector project—such as planting stock costs, planting labor, and supervision—but do not include the opportunity cost of land and growing stock, annual maintenance costs, and monitoring and evaluation costs. Of these, the latter two are generally a small fraction of the initial cost. The opportunity cost of land and growing stock, however, could significantly increase the unit cost estimates. Land rental costs are estimated at \$148/ha by Moulton and Richards (1990) for the United States; a land purchase price is estimated between \$400 and \$1,000/ha by Sedjo and Solomon (1989). Land prices are likely to be lower in developing countries. For example, in Thailand, the present value of the opportunity cost of land is estimated to be between \$44 and \$89/ha (Wangwacharakul and Bowonwiwat, 1995). For degraded lands that are suitable for reforestation, which are widespread across many countries, the land price may be close to zero.

Winjum and Lewis (1993) demonstrate the significance of including the opportunity cost of the forest stock. Using the value of growing stock and revenues (i.e., negative costs), they show that without including growing stock costs, the median values (negative costs) of storing C are -\$48/t C for temperate and -\$32/t C for tropical plantations. With the growing stock costs included, the median values of storing C increase to -\$22 and -\$24/t C, respectively. Inclusion of the opportunity cost of land and of forest stock therefore may increase the cost in developed countries two to threefold, but the increase may be smaller in developing countries where degraded lands are available.

24.5.2.3. Monetary Benefits

Implementation of mitigation options will result in direct benefits derived from timber and non-timber forest products. The commercial value of these products will vary with the site and location of a project—particularly in tropical countries, where non-timber forest products provide sustenance to the local dwellers. Additional indirect benefits (nature conservation, recreation, etc.) will add to a project's value. Appropriate distribution of the total benefits among the project beneficiaries, however, is necessary to ensure the project's survival.

Trading in C credits can serve to offset the cost of an international project. Several forest sector C offset projects (Box 24-2) have been established and maintained at costs well below, or at net benefits to, the modeled estimates reported by Dixon *et al.* (1993a).

Monetary timber benefits alone often can more than offset the project costs (Winjum and Lewis, 1993). The cost offset varies depending on inclusion of indirect benefits, such as forest stock value. Other estimates of the benefit of C sequestration for developing countries (Ravindranath and Somashekar, 1995; Roslan and Woon, 1995; Wangwacharakul and Bowonwiwat, 1995; Xu, 1995) confirm that product revenue from many plantation and agroforestry projects could completely offset costs. Schroeder (1992) points out that agroforestry projects could be implemented for C sequestration across many ecological zones and practices at a positive present value of net benefit ranging from \$54/ha to \$6,000/ha, assuming that product prices remain unchanged in the future. The above estimates suggest that it would be possible to achieve C sequestration at a net benefit or negative cost.

The distribution of benefits plays an important role in assuring the success of either large forestation programs or individual projects. Adams *et al.* (1993) illustrate that a U.S. forestation program to sequester C on agricultural land will bestow higher benefits to agricultural producers and landowners from higher commodity prices, but the decline in timber prices will reduce timber-sale profits for private forest owners. If the distribution of benefits is to be equitable, the government will have to compensate private commercial tree planting to prevent farmers from displacing present tree plantations. For example, Saxena (1989) has shown that the losers in a rural forestry development program in India will be the local forest officers, whereas both the rural rich and the poor will gain to varying degrees from non-timber benefits and timber sales.

It is important that participants in a program aimed at sequestering C gain appropriate and adequate benefits to ensure sustained C storage. Winnett *et al.* (1993) suggest that there is a risk that the behavior of landowners will change if increased wood supply lowers stumpage prices. The result is less incentive to invest in intensive forest management. These studies, however, do not consider the case where wood is sold in energy markets rather than in traditional markets for timber.

Not harvesting timber from a forestation program is another way to avoid the impact on timber prices. For example, Barker

et al. (1995) estimate that converting 4 Mha of marginal cropland to forests and allowing 2 Mha of bottomland cropland to revert to hardwood wetlands would sequester 850 Mt C in the United States over a 50-year period, at the same time extending wildlife and wetland habitats (non-timber benefits). This example is estimated to cost about $45/t C. There are similar opportunities in Europe, where about 15% of cropland currently is set aside to reduce agricultural surpluses.

24.5.3. Carbon Sequestration through Silviculture

Silvicultural practices (thinning, fertilization, improved harvesting, genetic tree improvement, etc.) are directed to increasing both the growth and the quality of the forest resource. Increased growth *per se* does not increase mean C storage and, indeed, may decrease C storage over a given area if the growth increase is associated with a shift to a younger age-class distribution (Turner *et al.*, 1995b). Many silvicultural practices are designed to improve some aspect of the wood and/or tree form and may do little to increase C sequestration, but the longer-term, indirect effects may have significant C implications. For example, management techniques that allow greater portions of the forest to be harvested and converted to long-lived wood products may sequester a greater mass of C in the long term in both the forest itself and in the forest product stock.

Some silvicultural practices—such as thinning, extending rotation ages, and retaining high levels of coarse woody debris after harvesting—increase or at least stabilize soil C pools and tend to maintain more C on forest lands. These practices have received considerable attention in relation to maintaining biodiversity and soil productivity (Swanson and Franklin, 1992), but their C storage benefits have not been well characterized. Reduction of logging damage to residual trees can also reduce the associated releases of C (see Box 24-2).

A few studies have examined the economics of C sequestration by silvicultural practices. Hoen and Solberg (1994) assessed the efficiency of various strategies to sequester C in biomass of Norwegian forests. Carbon sequestration attributable to thinning and fertilization of stands was $71/incremental ton of C

captured, even where current logging levels were maintained. Modeling efforts by Marland and Marland (1992) demonstrate that the relative C benefit of different silvicultural strategies can change dramatically depending on site-dependent characteristics such as forest growth rate, site occupancy at the time management is implemented, and the manner and efficiency with which forest products will be used.

24.5.4. Global Costs

The IPCC report (1992) estimates that the forestation costs (undiscounted) for offsetting between 5 and 26% of the 5.5 Gt C being released annually from fossil fuel combustion would range from $2.4 billion/year to $12 billion/year if accomplished over a 10-year planting period, with declining costs for longer planting periods. Dixon *et al.* (1991) report that the marginal initial cost to sequester global C increases gradually to $10/t C for a storage level of 70 Gt C, which was about 90% of the identified storage potential. Beyond 70 Gt C, the marginal cost increases rapidly. The corresponding total cost to store 70 Gt C amounts to $230 billion. Country-specific marginal cost estimates for Brazil, Russia, and the United States (Dixon *et al.*, 1991) and for India (Ravindranath and Somashekhar, 1995), China (Xu, 1995), Central America (Swisher, 1991), and Thailand (Wangwacharakul and Bowonwiwat, 1995) confirm that between 50 and 90% of the C storage potential can be tapped at an initial cost of less than $10/t C.

Using the mean unit costs for individual options by latitudinal region (from data in Tables 24-7 and 24-8), the cumulative cost (undiscounted) of conserving and sequestering the quantity of C given in Table 24-5 (for individual options, corrected for vegetation only) ranges from $247 billion to $302 billion, at an average unit cost ranging from $4.6 to $3.7/t C, respectively (Table 24-9). Average unit cost decreases as more C is conserved by slowing deforestation and forest regeneration because these are the lowest-cost options. For the forestation program alone, the unit cost would be $6.4/t C, and the total cost would decrease to $253 billion. The estimated unit cost in Table 24-9 for the forestation program is higher than that reported by Nilsson (1995), but it is consistent with new findings by others (e.g.,

Table 24-9: *Global costs of conserving and sequestering C based on the estimates in Table 24-5.*

	Zone/Forestry Options[1]						
	Low			**Mid**		**High**	
	D/R	AF	PL	AF	PL	PL	**Total**
Cost ($/t C)	2	5	7	5	6	8	3.7–4.6[2]
Total Costs (10⁹ $)							
– Low estimate	44[3]	27	97	3	60	17	247
– High estimate	99[3]	27	97	3	60	17	302

[1] D/R = slowing deforestation and regeneration; AF = agroforestry; PL = plantations.
[2] Weighted average cost per unit (total costs/total C).
[3] Total costs based on low and high C conservation estimates given in Table 24-5.

Table 24-8). However, Nilsson (1995) argues that these costs may be underestimated by severalfold if additional costs such as establishing infrastructure, protective fencing, education and training, and tree nurseries were included. On the other hand, if timber and other products generate revenue, then the capital investment for the second and subsequent rotations will be derived from the revenue from the previous rotation, and the incremental capital investment will be a fraction of the cost. Discounting future costs also significantly reduces the total and average costs estimated above. Assuming an annual discount rate of 3% reduces the range of total costs to $77 to $99 billion and the average unit cost to $1.4 to $1.2/t C.

Land costs still tend to be excluded from cost analyses; their inclusion could increase the cost severalfold. In addition, the cost and benefit estimates presented here do not cover indirect or nonquantifiable items, such as changes in biodiversity, water resources and soil erosion, and the livelihood of forest dwellers. Their inclusion would provide a more realistic picture of the dislocation caused by strategies to protect forests or reforest suitable lands. However, even if present cost estimates for C mitigation by forestry were doubled or tripled, they would still be considerably lower than a proposed U.S. fossil-fuel tax of $100–350/t C (Rubin *et al.*, 1992).

24.6. Impacts of Future Climate, Atmospheric CO_2, Land Use, and Human Population on C Conservation and Sequestration

The direct (increased concentration of CO_2) and indirect (changes in temperature, moisture regime, growing season length, etc.) effects of a changing atmosphere and climate on forest ecosystems are discussed in more detail in Chapters 1 and A. This section discusses how these changes and future changes in human demographics are likely to affect amounts and rates of C conservation and sequestration. Because projections concerning the effects of climate change and human activities are very uncertain, only their likely range of impacts is presented here.

Environmental factors such as future climate change, increases in atmospheric CO_2, increased mobilization of other elements such as nitrogen and sulfur, and other pollutants such as NO_x and tropospheric ozone are likely to have the greatest impacts on mid- and high-latitude forests (Apps *et al.*, 1993). In the low latitudes, human factors such as changing demographics, increased demand for agricultural land, economic growth, technology, and resource management policies—all of which have the potential to lead to high rates of land-use change—are expected to be the dominant forces on forests and could overwhelm any changes caused by future environmental conditions (Brown *et al.*, 1993a; see also Chapters 1 and 15).

Each of the promising forest management options for mitigation of C emissions is likely to be affected differently under a changed climate and human population density. For regeneration and slowed deforestation in the tropics, demand by an increasing human population for more land for agriculture and wood products (e.g., for industrial and energy use) at the expense of forest cover is likely to have a major effect on land availability; direct and indirect effects of climate change on land-use potentials may be less important in comparison (Brown *et al.*, 1993a). In the mid and high latitudes, where changes in land use are relatively stable at present, the direct and indirect effects of climate change are likely to be more important (see Chapters 1 and 15). For forestation, the key factors are how a changed climate and atmosphere will affect the suitability and availability of lands for plantation and agroforestry establishment, as well as the effects on species selection, rates of tree growth, and other pathways for sequestering C (in soil, litter, roots, etc.). The impacts of the various factors are discussed briefly in Sections 24.6.1 and 24.6.2.

24.6.1. *Impact on Land Suitability and Availability*

The effects of future climate change on the redistribution of global forest biomes are uncertain; consequently, there are large differences in projected changes in forest area for a 2 x CO_2 climate (see Chapters 1 and 15). Furthermore, most models project instantaneous change in potential vegetation distributions only. The development of the IMAGE 2.0 model—which is one of the first efforts to link submodels of the terrestrial system, atmosphere-ocean system, and energy-industry system with geographical specificity—attempts to overcome some of the problems in projecting changes in distribution of vegetation (Alcamo, 1994). Output from the "conventional wisdom" scenario of this model (akin to the IPCC 1992a scenario with respect to projected fossil fuel use; for other aspects of the model, see Alcamo, 1994, and Chapter 25) has been used to address the possible impacts of changed land-cover patterns on C conservation and sequestration potentials. Model output has been used to provide an estimate of likely changes in land suitability (i.e., potential vegetation based on the ability to grow trees, determined by climatic and edaphic factors) and land availability (a reduction in land suitability based on the need for land to grow crops, provide fuels, and so forth for the increasing human population) (see also Chapter 15). The area of land suitable for forest-sector practices for mitigation could increase globally, with the larger gains occurring in high and low latitudes mainly because of warmer temperatures and an extended growing season (Table 24-10; see also Chapter 1). However, the potential increase in suitable lands is based on climatic factors alone and does not consider whether soils will be suitable for forest establishment. This is potentially problematic in the high latitudes, where the boreal forests are projected to migrate into the tundra; tundra soils have characteristics that can retard forest establishment.

Considering the possibility of climate change, forest-sector programs aimed at C conservation and sequestration should be targeted toward those areas, tree species, and practices that are most likely to succeed, even if climate change occurred. The best targets from this perspective of risk may be the humid tropical zone and, to a lesser extent, the boreal zone, where conditions are most likely to become favorable for tree growth in new

Table 24-10: *Likely change in areas of land suitability (technically suitable to grow trees based on edaphic and climatic factors) and availability (technically suitable lands constrained by social, cultural, economic, and political factors) by 2050, brought about by changes in climate and human demographics (data are from the "Conventional Wisdom" scenario, a simulation of the IMAGE 2.0 model[1]).*

	Change in Land[2]	
Latitudinal Belt	Suitability	Availability
High (>50°)	1.21	1.08
Mid (25–50°)	1.15	1.05
Low (0–25°)	1.31	0.64

[1] Alcamo, 1994; model outputs grouped as in table provided by R. Leemans, RIVM, The Netherlands.
[2] Change computed as area of lands in 2050 divided by area in 1990.

plantations (but see discussion above regarding soils) (G.A. King, 1993; Table 24-10). However, in the tropical zone, a consideration of the human element and its impact on forests could change this risk perspective. Almost all of the increase in suitable lands in the high and mid-latitudes has the potential to become available (Table 24-10). In contrast, gains in land suitability in low latitudes might be unrealized because of the need for their use for agriculture, and so forth; potentially, half of the present available lands could be lost (Table 24-10). Based on the change in land availability alone, the amount of C that can potentially be sequestered in mid and high latitudes would likely change little, with possible slight gains. The potentially large decrease in land availability in low latitudes could significantly reduce the amount of C conserved or sequestered in this region.

It has been proposed that during the transient response—in the first 100 years or so following climate warming—the processes

of forest dieback and other disturbances could have major impacts on the C balance of forests (Smith and Shugart, 1993; see also Chapter 1). Gains in C sequestration from forestation programs at mid and high latitudes could be offset in the transient period by the release of C from unmanaged forests, resulting from the processes of migration and regeneration being slower than dieback and other disturbances. However, dieback problems in plantation forests are likely to be relatively less important because these will be managed forests with relatively short rotations, and species substitution could occur.

24.6.2. Impact on Rates of C Conservation and Sequestration

Results from the IMAGE 2.0 model—which incorporates the effects of CO_2 fertilization, temperature, and moisture on plant growth and soil processes—are used as examples of how these factors may affect C conservation and sequestration rates (Klein Goldewijk *et al*., 1994; also see Chapter 25 for more details on IMAGE 2.0). A discussion of the effects of these factors on ecosystems also is presented in Chapters 1 and A. The values in Table 24-11 are derived from the IMAGE 2.0 model to indicate how much the net C flux from forest ecosystems (or net ecosystem production) could change (percent change from baseline conditions) by 2050; it is assumed that plantations would respond in the same manner. The percent changes in this table do not include regions where land-cover change occurred; they include only those that affect the cycling of C in regions that were forested in 1970 and still forested in 2050 (referred to as stable forested regions). Differences between simulations are governed by interactions among land cover, the biosphere, climate, and CO_2 concentrations.

Forests growing in mid- and high-latitudinal belts could potentially increase their net C uptake in response to a changed climate and atmosphere (Table 24-11, compare entries 1 and 8). In contrast, the net C uptake in low-latitude forests under the

Table 24-11: *Estimates of magnitudes of direct and indirect effects of global change on net C flux from stable forested regions (i.e., areas that were forested in 1970, the baseline, and still forested in 2050). Data were generated by the IMAGE 2.0 model (van Minnen et al., 1995).*

	Latitudinal Belts (% Change)[1]		
Effect	Low	Mid	High
1. Baseline—all feedbacks to 1970 values	202	-2	-21
2. CO_2 fertilization and water-use efficiency	215	10	-11
3. Temperature and moisture feedback on plant growth	129	143	212
4. Temperature feedback on soil respiration	193	-46	-87
5. 2 and 4	210	-32	-75
6. 3 and 4	154	117	190
7. 2 and 3	136	153	220
8. 2, 3, and 4	174	129	202

[1] All net C fluxes are from the atmosphere to the biota; change in net flux was calculated as the difference between net C flux in 2050 and 1970, divided by the net flux in 1970 x 100.

combined effect of all factors (entry 8) could be lower than under baseline conditions. In other words, the region of the world that has the greatest potential for C conservation and sequestration (Table 24-5) under present climate conditions has the potential to lose some of this benefit under a changed climate and atmosphere. Although tropical forests have the largest potential to respond to CO_2 fertilization and water-use efficiency (Table 24-11, entry 2), this could be potentially offset by the response of plant growth and soil respiration to changed temperature and soil moisture (Table 24-11, entry 6).

In mid and high latitudes, a changed climate could have a large effect on the net C uptake rates of forests and thus rates of C sequestration due mostly to greater stimulation by increased temperatures and moisture on plant growth (Table 24-11, entry 3) than of soil respiration (Table 24-11, entry 4). Under no change in climate, the contribution by forests in these latitudes to the future global amount of C sequestered and conserved would be about 20% (Table 24-5). The results in Table 24-11 suggest that a potential exists to increase this share substantially, particularly given that the amount of land available is likely to increase or at least remain constant (Table 24-10).

In conclusion, under the conditions simulated by the IMAGE 2.0 model, which considers the entire suite of global change factors, there is a potential that C conservation and sequestration by forest management in the tropical region would become less important in the future, mainly due to loss of available land—unless policies are instituted to secure the required land areas for mitigation measures. In contrast, sequestration of C in temperate and boreal forest lands could play a larger role because available lands are likely to remain constant or increase and net rates of C uptake could increase.

24.7. Research and Data Needs

To improve our ability to estimate the mitigation potential of forestry practices, increased efforts are needed in the following areas:

- Realistic land-use modeling at national scales to determine trends in and constraints to forest cover, agricultural land needs, and land availability potentials. Variables such as present and projected population growth, agricultural productivity, forest growth rates, and energy demand should be linked with national trends in land use in these models so that assessments can be made of lands technically and actually available for C conservation and sequestration projects; possible interventions and their direct and indirect effects on future land uses; and key barriers that might be encountered in attempting to implement forestry options for mitigation.
- Improvements in the economic methodology for valuing all costs, including land, and especially benefits associated with forest management options for C conservation, storage, and substitution.

- Improved information about how different silvicultural and other management practices for major forest types and plantation species, growing under different climate/edaphic regimes, affect the dynamics, distribution, and retention of C in forests.
- Better understanding of the efficiency with which wood is converted into wood products, the life expectancy of wood products, and the energy balance of wood products versus that for alternative products that wood displaces.

CONTENTS

EXECUTIVE SUMMARY

Comprehensive evaluation of possible opportunities for mitigation of greenhouse gas (GHG) emissions requires consideration of a complex set of interlocking issues that together determine feasibility and implementability. Chapters 19 through 24 describe opportunities and challenges for GHG mitigation in six sectors of natural and socioeconomic systems, providing an encompassing summary of possible options. An important additional perspective comes from consideration of issues and opportunities that cut across the options presented for the individual sectors. These cross-cutting issues include whether energy end-use mitigation options can realistically reduce demands to levels that can be met by alternate supply systems at low emissions, whether the many competing pressures for the use of land can be reconciled, and whether nontraditional "geo-engineering" offers any plausible options that may be employed to intentionally counterbalance anthropogenic climatic forcings and change. This chapter summarizes the limited information that is available for addressing these questions.

Energy Implications for Low-Emissions GHG Scenarios

The energy supply and end-use sectors are collectively responsible for more than half of the world's total anthropogenic GHG emissions. For most situations, there are more candidate mitigation technologies and options than can be realistically adopted and implemented in a given national or regional setting. In addition to considering purely technological aspects of implementation, however, decisionmakers need to consider corollary benefits and potential side effects of individual mitigation measures. Additional factors to consider include how these options may complement or conflict with each other and with key national and subnational objectives, and which of the candidate options can be most readily implemented by the country's institutions and social and economic structure.

Many emissions-reduction estimates of individual mitigation measures draw from diverse studies based on limited data from specific countries or regions; they often use widely varying social and economic growth assumptions. It is not possible to predict future energy demand reductions in the aggregate with any certainty—as is indicated by the very large range of energy demands described in the end-use demand mitigation chapters in this assessment. However, studies indicate that it is feasible to reduce energy demand in individual end-uses and even in the aggregate—hence to reduce substantially fossil fuel-related emissions against baseline trends. The extent of actual reductions will depend on numerous factors, including energy prices, government policies, continued research and development of energy-efficient devices, and societal and behavioral trends, as well as other environmental concerns. Reductions in energy demand could be coupled with low-emissions energy supply systems to further reduce emissions. Current options in the energy supply arena that would be able realistically to meet energy demand at low emissions will be limited if energy demands are not constrained. Thus, a more flexible energy future is likely to be one where energy supply and end-use mitigation measures are used in conjunction to achieve low emissions.

Issues Related to Land Use and Land Cover

A wide range of future mitigation options and strategies involving various uses of land areas has been suggested. The primary issue in evaluating these options is whether the world can continue to support an increasing population with its growing needs for food and fiber and, at the same time, expand the amount of land used for production of biomass for energy. Analyses of land-use trends and patterns make clear that substantial land can be made available for biomass energy resources only if high rates of improvement in agricultural productivity continue throughout the world. Alternatively, moderate increases in agricultural productivity, reduced population growth rates, and reduced emphasis on meat consumption in the future could provide an adequate global food supply with reduced requirements for agricultural land. Even making optimistic assumptions, however, there will be regional dislocations and imbalances as demand for food, limitations in agricultural productivity, and increasing populations come into conflict. Important stresses on land availability for agriculture, biomass plantations, and other land uses will emerge if population growth continues unabated, high-meat dietary preferences remain stable or increase, the rate of increase in agricultural productivity slows or stops, land degradation continues, or the development and penetration of new technologies cannot be extended to developing countries.

A significant problem in more thoroughly documenting, understanding, and projecting the potential for demands on the world's land resources is that changes in the extent and patterns of land cover and land use are not well-documented. Different global databases indicate large differences for comparable classes of land use and/or land cover. To carry through a thorough assessment of global land resources and their (potential) uses and productivity, significant research is needed—beginning with the development of state-of-the-art land use and land-cover databases that span the world. With such information, assessments of possible mitigation options and strategies

related to land use and cover could be carried out using a geo-referenced framework that would enable determination of competing land-use activities and efficiently account for the effects of land degradation and the consequences for other environmental concerns, especially biodiversity.

Concepts for Counterbalancing Climatic Change

A review of conceptual approaches for counterbalancing anthropogenic climate change through geoengineering indicates that many options entail important adverse environmental consequences. Thus, these approaches do not provide an alternative that would readily permit the continued and expanded use of carbon-based fuels. Proposed concepts for geoengineering that have been examined include, for example, the deployment of solar radiation reflectors in space and the injection of sulfate aerosols into the atmosphere to mimic the cooling influence of volcanic eruptions. Most of these approaches are likely to be expensive to sustain and/or to have serious, but poorly understood, side effects, making them unattractive as possible mitigation options. Projections of the chemical and climatic effects of implementing such approaches are, for most options, at least as uncertain as those for future development of technologies and agricultural productivity. Geoengineering options also generally impose added costs on society and become essentially permanent commitments. Although it is perhaps appropriate to keep geoengineering approaches in reserve in case of unexpectedly rapid climatic change, investments in nontraditional approaches would seem much more effective if directed toward developing fossil fuel-free energy sources rather than at efforts to counterbalance the consequences of fossil fuel use.

Integrated Assessment of Mitigation Potential

Comprehensive assessment of different combinations of mitigation options can only be carried out in an integrated manner, considering both the direct and coupled implications of various choices—including, for example, the resulting changes in the fluxes of all greenhouse gases at local, regional, and global scales. The development and testing of capabilities for quantitative analysis, including integrated assessment modeling, are still in early stages of development. As a consequence, there is, at present, no single "right approach" to integrating an analysis across the various issues and disciplines. Models and related analyses, for example, must make tradeoffs between the level of sectoral detail they can include and the level of complexity and data requirements that can be realistically handled. Further, Integrated Assessment Models (IAMs) are only as good as the underlying socioeconomic assumptions and the necessary information on sectoral impacts, adaptation, and mitigation strategies. Across these issues information is lacking in many regions, particularly in developing countries. Over the next few years, the development of adequate databases and the improvement of analysis and assessment capabilities are essential to providing the information needed for the difficult choices that are being faced by decisionmakers.

25.1. Introduction

Mitigation options are measures, methodologies, and technologies to reduce emissions and enhance sinks of greenhouse gases or to otherwise limit climatic change and consequences resulting from human activities. This broad definition encompasses a large diversity of mitigation options. Chapters 19–24 of this volume present and discuss the most important options for a number of individual sectors, including energy supply, industry, transportation, human settlements, agriculture, and forestry. Such a compilation of information on specific measures to abate GHG emissions is an important first step in the analysis of mitigation options. In itself, however, it does not address the important need to analyze the overall, cross-sectoral potential for reduction of emissions within a country or region, the ways in which specific mitigation options interact with other options and with national or regional goals, and the implications of different combinations of mitigation options for the national or regional economy and resource base.

To address these broad cross-sectoral issues, integrated analysis of mitigation options is required. This chapter presents some of the cross-cutting themes central to such an analysis. Chapter 27 and its related appendices provide detailed information and methodologies that will be of use to national decisionmakers in analyzing mitigation options and developing national strategies for GHG emissions reduction. Within each country these options need to be integrated with other key national objectives—including, for example, promotion of rural development, increasing economic growth, generation of new employment opportunities, or improvement of environmental conditions.

There are several conceptual issues related to a cross-sectoral analysis of mitigation options. This chapter addresses some of these issues by focusing on four major questions:

- *What important cross-sectoral issues arise in efforts to reduce GHG emissions from the energy sector?*

  The energy sector is likely to be the major focus of GHG emissions mitigation in most countries. While an evaluation of options in individual sectors indicates that there are many opportunities to reduce fossil-fuel carbon emissions substantially below those in 1990 for particular activities or processes, it is not possible to determine how much total emissions can be reduced without combining these individual options into a comprehensive strategy or scenario. In the aggregate, how much can energy demand be reduced? What supply-side options can be relied upon to meet these energy demands? Which combinations of demand management options and alternative energy supply systems have the greatest potential for reducing emissions and meeting other national/regional goals? Section 25.2 describes the major challenges and approaches to analyzing mitigation options in the energy sector.

- *What specific constraints on land use and availability may limit mitigation options focusing on land management?*

  A wide range of future mitigation options and strategies have been suggested that involve various uses of land. The main issue is whether the world can continue to support an increasing population, with its growing needs for food and fiber, and, at the same time, expand the amount of land used for production of biomass for energy—while preserving environmental resources for other purposes, such as the maintenance of ecosystems, conservation of biodiversity, regeneration and storage of freshwater, assimilation of wastes, and so forth. Section 25.3 summarizes the issues and problems confronting efforts to assess land-use options and scenarios, including the lack of reliable global information on current and projected patterns of land cover and land use.

- *What ideas for large-scale "cross-sectoral" options exist for attempting to deliberately counterbalance potential human-induced climate change?*

  Suggested approaches to counterbalance anthropogenic climate change through geoengineering include, for example, the deployment of solar radiation reflectors in space and the injection of sulfate aerosols into the atmosphere to mimic the cooling influence of volcanic eruptions. Section 25.4 reviews what is known about these concepts, pointing out that based on current information, they appear to be very costly, very uncertain, and/or have significant side effects relative to measures to reduce GHG emissions.

- *Can we assess the overall effectiveness of mitigation options and strategies?*

  Comparison and assessment of different sets of mitigation options is best carried out in an integrated manner, considering fluxes of all GHGs at local, regional, and global scales. Such an assessment also should include the effects of economic activities and trade and potential climate-change feedbacks. Section 25.5 provides an overview of the issues that need to be considered as part of such a comprehensive assessment and includes a brief discussion of integrated models that are currently being developed.

25.2. Energy Implications for Low-Emissions Greenhouse Gas Scenarios

Energy supply and end-use sectors are collectively responsible for more than half of the world's total anthropogenic greenhouse gas emissions. Therefore, mitigation policies for these sectors are critical to achieving any reasonable future stabilization of GHG concentrations in the atmosphere. In 1990, the carbon (C) content

of fossil energy was about 6 Gt C. Energy supply and end-use demand sectors both contributed significantly: 2.4 Gt C were emitted during energy conversion and distribution, while about 3.6 Gt C were emitted at the point of end-use (see Chapter B).

Options for reducing energy-related emissions, therefore, fall under two broad categories: those that reduce GHG emissions while providing energy services at projected levels of demand and those aimed at reducing energy demand itself in key end-use sectors. Previous chapters of this report investigate many aspects of these measures in great detail: Chapters 20 through 22 examine options to reduce energy use and process-related GHG emissions in the industrial, transportation, and residential/commercial sectors, respectively, and Chapter 19 discusses technologies to enhance fossil fuel conversion efficiencies and describes Low Emissions Supply Systems (LESS) to meet future energy demands. Chapter 28 and its companion appendix contain a detailed inventory of more than one hundred GHG mitigation technologies for the energy supply and end-use sectors, providing information on key parameters such as performance and environmental characteristics, capital and operating costs, and infrastructure requirements. Also, while specific mitigation policy measures and implementation challenges are discussed in the individual sectoral mitigation chapters, a more generic assessment of decisionmaking under uncertainty, mitigation costs, and macroeconomic measures can be found in Chapters 2, *Decisionmaking Framework to Address Climate Change,* Chapter 9, *A Review of Mitigation Cost Studies,* and Chapter 11, *An Assessment of Economic Policy Instruments to Combat the Enhanced Greenhouse Effect,* of the Working Group III volume.

25.2.1. Cross-Sectoral Implications

While the energy-related mitigation discussion in this assessment is both exhaustive and reflective of the current "state-of-the-science," such a compartmentalized framework of analysis does not address three very important cross-cutting questions:

- How can national decisionmakers rank and choose among mitigation options?
- Can sets of end-use mitigation options taken together realistically reduce future energy demands to levels that are assumed in the construction of energy-supply scenarios that lead to low emissions?
- What are the implications of high-biomass energy futures on other land-use requirements, including the provision of food for the world's increasing population?

Sections 25.2.2 through 25.2.5 provide a roadmap of the kinds of cross-cutting issues and tradeoffs that need to be considered in attempting to answer these questions.

25.2.2. Selecting Mitigation Options

Mitigation agendas are typically laid out by national, regional, and project-level decisionmakers, often with limited resources.

A detailed description of mitigation options is therefore of limited use without a proper set of guidelines on how to select the promising options in a particular setting.

The first step in such an assessment is to establish the scope and overall goal(s) of the mitigation strategy. Considerations include whether the strategy is to meet particular emission reduction targets; assess specific technologies or policies; or identify measures that best integrate with key national and subnational objectives, such as increasing economic growth and self-reliance, reducing unemployment and social inequalities, or promoting rural development. Decisionmakers also must determine if they wish to target carbon dioxide (CO_2) only or several GHGs; which of the candidate options can be feasibly implemented by the country's institutional structure; and whether the options being considered will be available and cost-effective in their country within the timeframe under consideration.

25.2.3. Constructing Energy Demand Mitigation Scenarios

In the context of energy demand, the screening criteria described above can be used to identify, rank, and combine promising demand-side options into one or more scenarios. These mitigation scenarios can then be evaluated against the backdrop of a "no-policy," baseline scenario. Such disaggregated descriptive frameworks have been used for energy mitigation scenario analysis at national and regional levels (Lazarus *et al*., 1995). The question thus emerges whether the range of technology options discussed in the energy end-use chapters of the present report can be used to construct energy demand scenarios in different sectors and regions that can then be aggregated to global levels. Such an analysis has not been attempted here, for the following reasons:

- **Consistency of assumptions**: The end-use chapters in this report review a diverse set of studies on the mitigation potentials of various technologies and policies. These studies often are based on limited data from specific countries or regions and use widely varying social and economic growth assumptions [including gross domestic product (GDP), population growth, prices, productivity, exchange rates, technology diffusion, and market regimes]. Aggregating them or extrapolating their projections to other regions could produce misleading results.
- **Accounting for corollary benefits, potential side effects, and offsetting trends**: Sectoral mitigation strategies operate in a complex societal fabric where they may influence, or be influenced by, other social and environmental constraints and, in many cases, even other mitigation policies. Cleaner and more efficient vehicles, for example, will reduce local pollution and have beneficial impacts on human health; many demand-side management measures may also lower consumer expenditures on energy services. Such corollary benefits would make these options more attractive than from a purely GHG mitigation

standpoint. On the other hand, mitigation options also may have potential side effects. For example, heat cascading systems that result in better waste-energy utilization might require establishing industries and human settlements in close proximity and therefore might stress local water resources and possibly aggravate concerns about air, noise, and water pollution. In addition, the emissions reduction potential of many mitigation options can be offset by societal and behavioral trends. Improved household and car efficiency measures, for example, may have some of their mitigation potential offset by decreasing household size and car occupancy. This is because while less energy may be consumed on a per house or per car basis, more houses and cars will be required for a given number of people. A technology-based aggregation of mitigation potentials is unlikely to incorporate many of these interactions, which may play important roles in determining the feasibility, competitiveness, and achievable mitigation potential of various options in a given setting.

25.2.4. Consistency of Energy Supply Mitigation Scenarios with Energy Demand Projections

Many projections of future energy supply—such as the Low Emissions Supply Systems (LESS) described in Chapter 19—suggest that GHG emissions can be reduced substantially relative to 1990 levels by using a number of fuel-mix choices in the long term. However, these emissions futures hinge critically on the validity of the assumed set of future energy demands.

Future demands depend not only on a number of demographic and socioeconomic factors but also on the extent to which successful reductions can be achieved from the implementation of energy conservation and other demand-side management schemes. Many energy supply projections already assume substantial reductions in demand from baseline trends as a result of these end-use mitigation measures. The demand projections for the LESS constructions, for example, are based on a high economic growth, accelerated policy variant (i.e., including GHG mitigation policies) of the SA90 scenarios developed by the IPCC in 1990 (Bernthal, 1990). The long-term energy demands in this scenario are significantly less than those projected by IS92a, the median in the "nonintervention" (i.e., assuming no explicit GHG mitigation policies) scenario-set developed by the IPCC in 1992 (Leggett *et al.*, 1992). The SA90 scenarios did not consider the range of technological and societal options considered in the end-use chapters of the present report. The question thus emerges: Are the SA90 accelerated policy demands assumed in the construction of the LESS scenarios consistent with reductions achievable in various end-use sectors? If so, can these demand reductions be achieved through mitigation measures that have a net benefit to society, even in the absence of climate change, or are they likely to be realized only at significant cost to society?

To answer these questions adequately would require the development of energy demand scenarios based on the technological options discussed in the end-use mitigation chapters of this report. As explained earlier, such an analysis has not been attempted here. However, short of the development of such scenarios, some conclusions can still be drawn.

First, the end-use demand mitigation chapters indicate that the range of future sectoral demands is very wide indeed. In the transportation sector, for example, if small, energy-efficient cars become fashionable and desirable and if urban traffic congestion and other concerns drive policy leading to greater use of mass transit, then it might be possible to achieve energy demands for transport consistent with SA90 through mitigation options that benefit society even in the absence of climate change. The same, however, cannot be said in a world in which incomes rise, personal vehicles proliferate, car occupancies decline, fossil fuels remain inexpensive, and additional transportation networks are built to meet the growing numbers of vehicles. Similarly, end-use demands for residential and commercial buildings consistent with the SA90 accelerated policy case are conceivable if three conditions are met: (1) energy prices rise over time sufficiently to influence consumer behavior; (2) governments enact strong policies to promote energy efficiency; and (3) research and development of energy-efficient devices is supported and continues to yield viable new products. A number of reference energy scenarios with such variations have been constructed (Alcamo *et al.*, 1995).

Second, unconstrained energy demands are likely to limit the suite of energy supply options that realistically would be available to meet these demands at low emissions. This would lower the flexibility and may increase the vulnerability of the energy supply system. For example, the LESS projections include a "high-demand" variant based on demands similar to those in the median "nonintervention" IS92a scenario (Edmonds *et al.*, 1994). Conceivably, low-emissions supply systems still could be developed that meet IS92a demands for the year 2100 at annual emissions approximately half of the 1990 levels and one-fifth of the IS92a emissions projections for 2100. However, such low-emissions supply systems would need to rely on a substantial increase in coal production (e.g., coal production for LESS "high-demand" constructions for the year 2100 in Chapter 19 is almost five times the 1990 levels) and require extensive CO_2 sequestering in aquifers and natural gas fields—a situation that may not be sustainable as gas fields become filled to capacity. Besides, other energy sources, including biomass, are likely to be pushed close to the limits of their realizable potential to meet high demands. A more flexible and possibly lower-cost energy future is likely to be one where energy supply and end-use mitigation options are used in conjunction to achieve low emissions.

25.2.5. Low Emissions Energy Supply and Land Use

Many alternative energy supply futures require that a substantial portion of the world's future energy needs be met by

"modern" biomass. The biomass-intensive variant of LESS, in fact, targets almost 550 Mha of land for energy cultivation by the year 2100. This raises a number of concerns, including whether biomass plantations would conflict with land needed to meet regional food requirements for increasing populations, whether biomass cultivation on degraded lands would really be achievable at productivity levels assumed in the LESS constructions, and whether intensive cultivation practices would be needed that in turn might stress local water resources. As Section 25.3 shows, these concerns further complicate the gamut of issues concerning planning for current and future uses of land and land cover.

25.3. Issues Related to Land Use and Land Cover

Many mitigation options depend upon changes in land management, increasing carbon sequestration potential, and the use of renewable energy such as biomass (e.g., Chapters 19, 22, and 24). Many mitigation policies in the transportation sector also require changes in land-use patterns to reduce the need for goods, transport and travel. All of these mitigation options involve land, land use, and land cover. In the present context, "land" refers to the Earth's surface, including the soil and its geology and hydrology; the biosphere; and the lowest layer of the atmosphere. "Land cover" includes only the upper-soil layers and vegetation, while "land use" refers to the explicit purpose for which humans exploit land and its vegetative cover and consists of a series of activities that alter ecological and physical properties of land (Turner *et al.*, 1993). A clear distinction between land use and cover is important for assessing land-related mitigation options because the availability of land, water, and related commodities is limited, and different land uses compete with each other.

This section discusses issues related to competition for land. Although land required for human settlement, infrastructure, and other uses is important locally and regionally, the cumulative effect of these uses is of lesser importance globally. The following discussion focuses on land required for agriculture—the most important land use worldwide.

Land use and its changes are heterogeneous, both spatially and temporally. The global significance of land use arises as a result of the cumulative effects of local and regional changes in land cover. These changes are not necessarily land-cover conversions. An altered management could change the properties of land cover (e.g., enhance plant growth through fertilization) without changing the overall structure or vegetation category (Turner *et al.*, 1990). The consequences of such modifications seldom appear in regional and global environmental assessments but are important in altering emissions from land use (Leemans and Zuidema, 1995). Coarse land-cover patterns have been used most often to analyze historic and current land-cover change. These assessments are strongly limited by the quality of the available land-cover data. Nonetheless, some insights have emerged.

25.3.1. Patterns of Land Cover

Potential usage of land is determined by the local climate, soil, and land cover. Climate is the major constraint and controls the global patterns of vegetation structure and (potential) species composition (Walter, 1985; Woodward, 1987). Temperature and precipitation define the major latitudinal zones (e.g., boreal, temperate, and tropical), whereas seasonality of these factors largely defines the biomes (e.g., deserts, rangelands, and forests) within these zones. Variation between years, deviations

Box 25-1. Land-Cover Classifications

Research into many aspects of global change requires reliable, geo-referenced information on global land cover for a well-defined time period (Townshend, 1992). Several classification schemes have been developed to describe land-cover patterns. Schemes have been based on structural (e.g., trees vs. shrubs), physiognomic (e.g., deciduous vs. evergreen), floristic (e.g., oak-hickory forest), or bioclimatic (e.g., boreal forest) classes, or mixtures thereof. Imprecise terminology, such as "woodlands," is often used to label classes. Many classification schemes also include indices that are not directly related to land cover but to other environmental variables, such as climate (e.g., tropical rainforest). Such deficiencies are not problematic when a unique classification is applied throughout an analysis, but many global data sets are mixtures from different sources, using similar terminology but largely different criteria (Leemans *et al.*, 1995). One of the few globally comprehensive classifications is the hierarchical UNESCO classification (1973). This hybrid classification (physiognomic and structural characteristics at higher levels, species composition at lower levels) was specially developed for the description of natural vegetation at a climax stage; this is probably one of the reasons that it has never resulted in a global assessment of land cover. Despite their problems, UNESCO vegetation maps have been produced for several regions (e.g., White, 1983). Since the development of the UNESCO classification, no such generally accepted scheme for land cover has been developed, although several approaches are emerging, mainly based on technologies involving remote sensing (Running *et al.*, 1994). These approaches have led already to more comprehensive regional estimates of deforestation patterns (e.g., Skole and Tucker, 1993) and land-cover classifications (Defries and Townshend, 1994). Several international organizations, including UNEP and FAO, have recently formulated requirements for adequate land-use and land-cover classifications (Mücher *et al.*, 1993; UNEP/GEMS, 1993, 1994) and concluded that the implementation of such schemes should be prioritized in order to assure consistent land-use evaluations (Fresco *et al.*, 1994).
Figure 25-1: Global assessments for the extent of different land covers. The data are aggregated into coarse classes (i.e., Forest, Woodland, Grassland, Tundra, Desert, Wetland, Cultivated, and Other) from the original publications or data sets.

from climatic means, and extreme events (e.g., severe temperatures, storms, and droughts) influence plant growth and survival and lead to successional changes and further differentiate land cover locally. The history of natural events and human-induced changes determines the actual land cover in any region.

Several data sets of global land cover have been compiled. Most of these data banks are based on simple land-cover classification schemes, generally having between five and fifty classes worldwide (see Box 25-1). Despite their relative simplicity, significant differences exist among the different global land-cover databases. Figure 25-1 presents an aggregation of the different land-cover classes in each database into broad, but comparable, classes. These databases are derived from statistical sources, national maps, and/or other sources, such as climate atlases. This has led to the large variation in total extent of each class (Figure 25-1). The most apparent difference between these databases is for cultivated lands, for which estimates range from 0 to 55 x 10⁶ km². Databases without cultivated land have focused primarily on natural (or potential) vegetation prior to human activities (e.g., Prentice *et al*., 1992; Neilson *et al*., 1992), while the largest values for this class (e.g., Solomon *et al*., 1993) stem from evaluations of land that could potentially be used for cultivation. The most authoritative estimate for cultivated land at

present is likely that of FAO (1991), which gives 1450 Mha. Unfortunately, however, all of these estimates are only gross approximations. There are no accurate figures for many countries; much of the information is based on averages or ill-defined categories; and the global compilations are generated from a multitude of sources (Buringh and Dudal, 1987; Defries and Townshend, 1994; Leemans *et al*., 1995). One of the major limitations is that spatial patterns are often not well-depicted. Linkages between land-cover and other geo-referenced databases—such as climate, topography, and soils—could assist in removing some of the inconsistencies of the existing land-cover databases (Loveland *et al*., 1991; Running *et al*., 1994). Improvements in these linkages are a critical constraint in the use of land-cover data in mitigation assessments.

In spite of these shortcomings, many of these estimates are cited and used in different climate-change assessments. The differences in the estimates become important because the use of a different database can lead to significantly different results, and hence conclusions. Thus, global assessments always must be concerned with inconsistencies, limitations, and errors in these data sets. When used with care, these data sets can be used to determine possible impacts of climate change (e.g., Emanuel *et al*., 1985), simulate global carbon cycling (e.g., Melillo *et al*.,

1993; Prentice *et al.*, 1994), and parameterize land-surface properties in climate models (e.g., Hummel and Reck, 1979; Wilson and Henderson-Sellers, 1985). However, these data sets remain inadequate for describing local and regional properties of ecosystems fully, and consequently for assessing and evaluating mitigation potential accurately.

25.3.2. Societal Uses of Land

Land and land cover provide many resources—including food, fodder, fiber, and biomass—and functions, including biodiversity conservation, water regeneration, waste accumulation, and flood buffering. Human activities have led to significant changes in land cover, and such changes are expected to continue to change the land surface (Houghton, 1994; Table 25-1). On continental, regional, and local scales there are large differences in the rate and nature of changes in land cover (Turner *et al.*, 1990; Meyer and Turner, 1994).

Approximately 11% of the land surface has been converted to cropland, and roughly 25% is occupied by pasture (FAO, 1991); 6% is legally protected in conservation areas and reserves (Morris, 1995). About half of the remaining forests and woodlands are managed secondary forests or plantations. In addition to the readily apparent changes in land cover, much of the land has been degraded or is at risk of degradation, including topsoil loss, nutrient depletion, acidification, and compaction. Recent estimates are 750 Mha for light degradation, 910 Mha for moderate degradation, and 310 Mha for severe degradation (World Resources Institute, 1992; Oldeman, 1993). Damaged and degraded lands can generally be rehabilitated to a productive state, but not always restored to their desired use (Barrow, 1991; Brown and Lugo, 1994). All of these transformations have had a large impact on natural processes, biodiversity, and the resilience of ecosystems, and directly affect the potential for carbon storage and other mitigation options involving land cover.

How much land and water is needed to provide adequate food, fodder, and fiber? What are the competing demands on those resource bases? At what rate is land degradation reducing their availability? Such questions have to be considered when land-focused mitigation options compete with existing land uses.

Table 25-1: *Changes in land cover and population from 1700 to 1980 (from Houghton et al., 1983).*

Year	Forests and Woodlands (Mha)	Grassland and Pastures (Mha)	Croplands (Mha)	Population (millions)
1700	6220	6860	270	680
1850	5970	6840	540	960
1920	5680	6750	910	1650
1950	5390	6780	1170	2500
1980	5050	6790	1480	4500

In general, mitigation options in the agriculture and forestry sectors focus on moving toward a more sustainable use of available resources by enhancing the sequestration potential of the ecosystems involved. Many of these options could well have other positive side effects, including pollution reduction, slowing the rate of land degradation, and biodiversity conservation. The proposed increase in biomass utilization to offset fossil fuel use illustrates the potential for competing demands for land. The suggested quantities of biomass can theoretically be provided by ecosystems globally—for example, through biomass plantations that can be established on many types of lands (Hall and Overend, 1987). However, minimizing costs and energy used in transportation would favor growing biomass close to urban areas; it is in such places where the greatest demands on land will occur, creating a possible conflict between land for biomass plantations and for other uses.

25.3.2.1. Global Food Production

Food security has long been a major concern, and several analyses have been conducted to evaluate whether the future food supply will be adequate to feed the growing population (e.g., FAO, 1993; Bongaarts, 1994; Dyson, 1994; Kendall and Pimentel, 1994; Smil, 1994; Waggoner, 1994). Many of these studies suggest that the land could provide food for the increasing population if current trends in agricultural productivity driven by improved management, use of high-yielding varieties, and changed cropping systems can be sustained. Other studies, however, suggest that increasing land degradation, limited water supply, and dependence on energy-intensive fertilizers, combined with a growing population, have already started to lead to a decline in per capita food production and land availability (e.g., Kendall and Pimentel, 1994). Continued downward trends would render the global food supply much less secure than appears from many analyses (Kendall and Pimentel, 1994).

The results of the above analyses are particularly sensitive to assumptions about dietary preferences. Different consumption patterns can lead to very different gross requirements. The amount of food consumed per capita differs significantly by country and region. Diets consisting mainly of grains and vegetables (e.g., China; Table 25-2) require different quantities and types of agricultural land compared to diets containing more meat and dairy products (e.g., United States, Table 25-2). A meat-based diet for the entire world population would clearly exceed current agricultural capabilities (Waggoner, 1994). A conceptually simple means to provide food for the increasing population would be to alter dietary habits. Although a slight shift from red meat toward poultry is occurring in the developed world (thereby reducing total feed grain requirements), red meat consumption is increasing in many other parts of the world (World Resources Institute, 1992). Bringing about dietary changes may be difficult to implement.

Land suitability for agriculture is dependent upon environmental factors, including climate, terrain, soil, water resources, and nutrient availability. These suitability patterns will shift under

Table 25-2: *Regional and global consumption of foods and grain (from Kendall and Pimental, 1994).*

[b]In capita^{-1} day^{-1}.

climatic change. Although the consequences of climatic variability are not always adequately addressed (if at all), the potential global distribution of crops is well-understood and can be modeled for current and changed climate and atmospheric composition (e.g., Brinkman, 1987; Leemans and Solomon, 1993; Rosenzweig and Parry, 1994). Such studies indicate that 65% of the land area is suitable for agriculture (Leemans and Solomon, 1993; Solomon *et al.*, 1993) but that the amount of land actually available is considerably lower because of unsuitable soils and terrain. As a result, the land potentially available for agricultural production is about 3000 Mha (approximately 20% of total land area, of which about 50% is already cultivated; see FAO, 1991).

Potential biomass productivity and, consequently, yield (which is only a fraction of total biomass production) can be estimated from growing-season characteristics and plant type (e.g., C_3 or C_4 plants). These parameters help determine photosynthetic, respiratory, and direct CO_2 responses for a given land area. When suboptimal water and nutrient availability (mainly nitrogen and phosphorus) are accounted for, the attainable yield of biomass ranges from 60–90% of the theoretical potential yield (Figure 25-2). The attainable yield is further reduced by competition for resources (including light); weeds; diseases; pests; and local air, water, and soil pollution. Proper land management, however, can help alleviate some of these reductions. In most cases, less-efficient agricultural practices can explain the large differences in yield and potential increases therein for different countries (see Plucknett, 1994).

Considering that agricultural productivity for many regions is still far below attainable yield levels, there is a large potential to enhance food production (e.g., FAO, 1993), but land degradation

strongly affects attainable and actual productivities. The complex interactions among different environmental and management factors make it immensely difficult to project long-term sustainable agricultural productivities. Unfortunately, many future food and biomass assessments strongly focus on potential productivity (e.g., Hall and Overend, 1987; Waggoner, 1994), leading to overly optimistic conclusions.

25.3.2.2. Global Biomass Production for Energy

Biomass production competes with land required for food production and for other uses. Food production requires the most productive lands, whereas biomass crops can probably be grown on less-productive lands as well (Hall and Overend, 1987). However, growing these crops on less-productive land would lead (at least initially) to lower yields. It is often argued that biomass plantations can assist in the rehabilitation or improvement of degraded agricultural land and that these lands could be used in a profitable and sustainable manner (e.g., Bongaarts, 1994; Hall *et al.*, 1994). Although this is probably true for regions with lightly and moderately degraded soils (about 16.5×10^6 km^2), plantations are unlikely to be useful in regions with severely degraded soils (about 3.1×10^6 km^2). Rehabilitation in such regions is a long-term and difficult process, especially if the original functions of the system (i.e., biological productivity) are to be restored (Barrow, 1991; Brown and Lugo, 1994).

Biomass crops have been demonstrated to be economically feasible in many different regions (e.g., Hall, 1991; Carpentieri *et al.*, 1993). However, large increases in biomass requirements would require a significant quantity of additional land (Alcamo *et al.*, 1994). In many regions this would pose no problem—due to, for example, the use of existing biomass sources, such as municipal waste, and crop and forestry residues. However, in regions where food supply already is stressed and will continue to be stressed in the near future (e.g., sub-Sahelian zone: FAO, 1993), biomass probably is not a viable option.

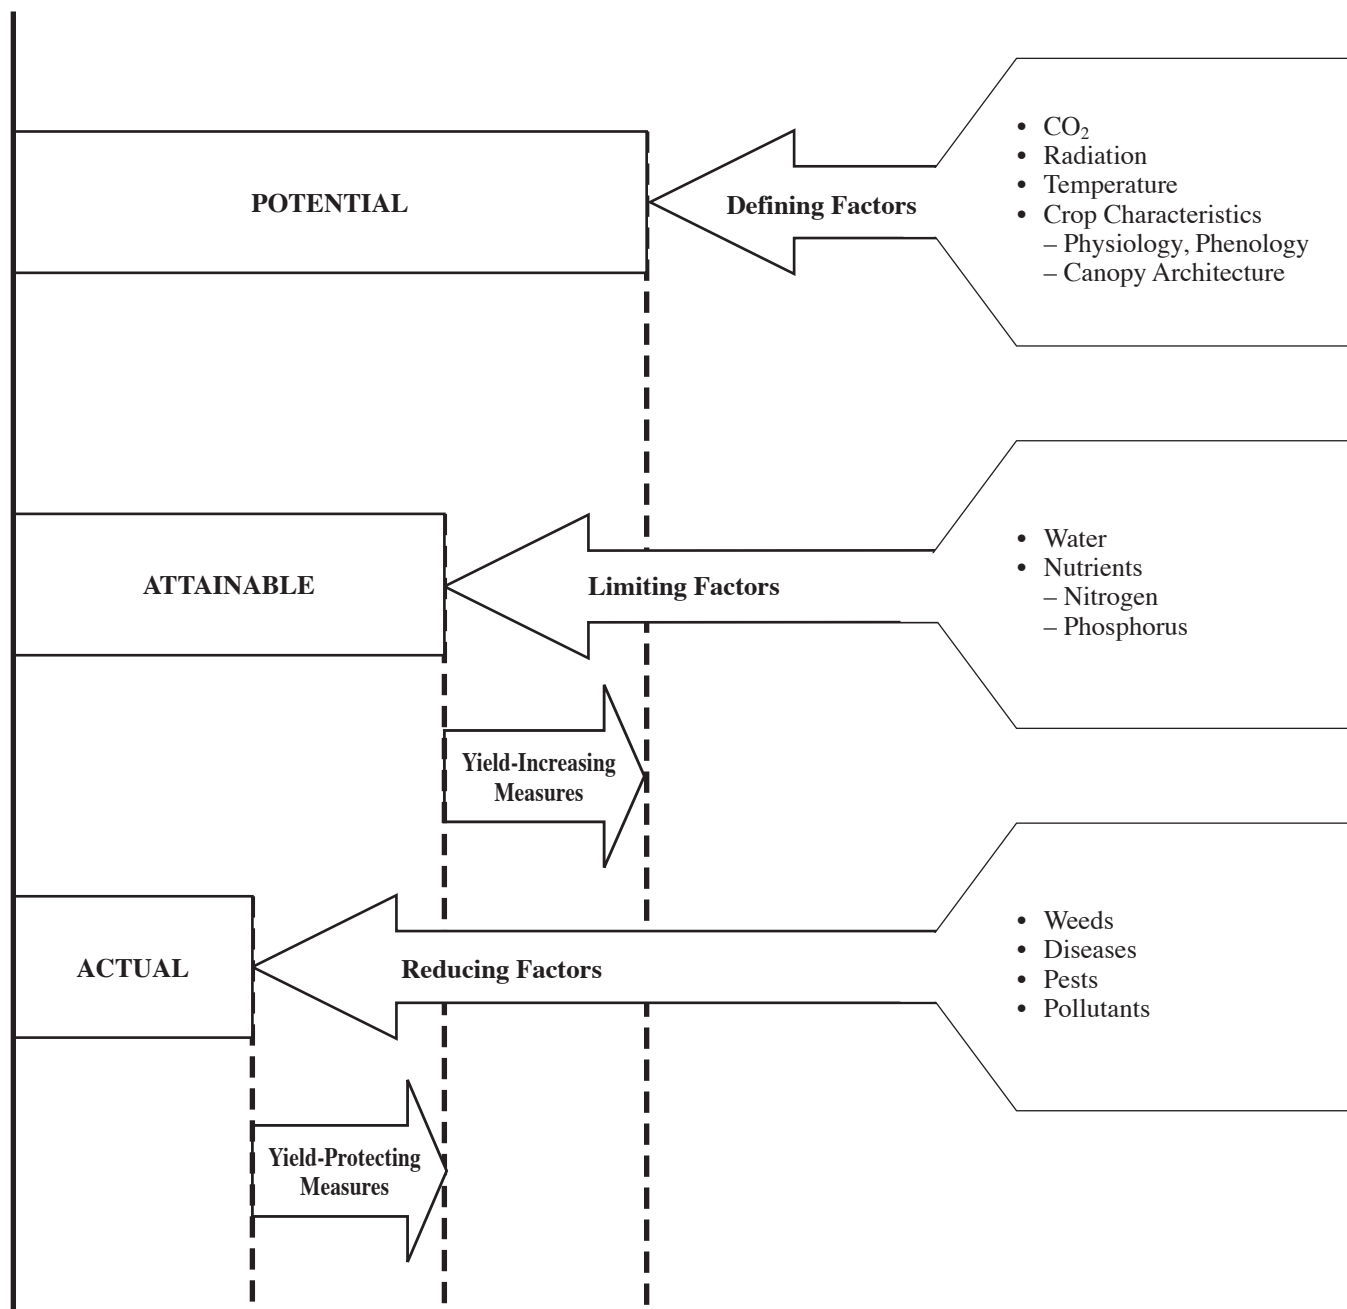
Whereas most emphasis in biomass energy has been directed toward terrestrial systems, proposed alternative sources include micro-algae, marine algae, and halophytes, which grow rapidly in saline lands. Micro-algae are single-celled, fast-growing plants that grow well over a wide range of environmental conditions. In regions with inexpensive flatlands, shallow ponds can be constructed where these algae can reproduce (Wyman, 1994), but this technique is currently quite expensive. Because their productivity is usually high, the potential use of marine algae for the conversion of solar energy is large (Orr and Sarmiento, 1992), but their natural extent is limited to regions of high nutrients (i.e., areas of upwelling). Currently, cultivation of marine algae is commercially viable only for specific purposes (pharmaceutical, chemical, and food products), because it is too expensive for large-scale biomass production (Bird, 1987). Saline lands in coastal zones and arid regions could produce biomass using halophytes (Glenn *et al.*, 1993). Although halophytes could assist in slowing or rehabilitating degraded


Figure 25-2: Different levels of agricultural productivity (after Rabbinge and van Ittersum, 1994).

arid lands, their productivity is too low for them to be a significant source of biomass in arid regions.

25.3.3. Land Use and Mitigation: An Assessment

Article 2 of the UN Framework Convention on Climate Change (FCCC) does not directly address the issue of mitigation. Mitigation options, however, are primary means for meeting the first part of the objective of the Article (i.e., stabilization of GHG atmospheric concentrations). Mitigation options also can help address the second part of the objective (i.e., ecosystem adaptive capabilities, food security, and sustainable

economic development). The land-use and land-cover consequences of mitigation options also are linked strongly with UNCED's Agenda 21 and international treaties on desertification, forests, and biodiversity.

The low quality of available land-use and land-cover data and the lack of understanding of the complex human driving forces behind changes in these properties limit the validity of analyses of current land uses and make future projections speculative (Riebsame *et al.*, 1994). Discussions on land availability for biomass production are therefore not yet compelling but are promising enough to support additional, more-comprehensive research. A preliminary conclusion is that if current trends in

agricultural production can be continued, competition for land is not likely to be a significant problem globally but could generate serious problems locally and/or regionally. The biggest challenge is to increase agricultural productivity in the least-productive regions and simultaneously to provide room for additional uses and functions for that land.

Much of the scientific effort required to improve these assessments needs to be directed toward integrating important social, economic, and cultural driving forces of land use with physical and ecological (including agricultural) options for land use and land cover (Turner *et al*., 1993; Meyer and Turner, 1994). For example, large-scale development of biomass plantations could limit degradation of dry lands (e.g., by desertification) and enhance C sequestration, but also could have negative impacts on biodiversity in other regions as a result of increased deforestation or restrictions on the types of afforestation that are feasible (Ramakrishnan *et al*., 1994). Unfortunately, such an integrated approach is only in the early stages of development (e.g., Alcamo, 1994; Edmonds *et al*., 1994; Morita *et al*., 1994; Rotmans *et al*., 1994).

25.4. Concepts for Counterbalancing Climatic Change

Climate change induced by GHG emissions is an accidental result of human activities. The question, therefore, arises as to whether there are practical, large-scale, deliberate actions that might be taken to counterbalance these inadvertent changes. Such actions, sometimes referred to as "geoengineering" the climate, differ from traditional mitigative actions—which attempt to reduce the causes of the perturbing influences—in that the geoengineering approaches allow the emissions but seek to negate or reverse their influence or effects. While some geoengineering options have been suggested, in general they would require significant efforts relative to implementing alternative energy technologies or to moderating and avoiding the actions causing the greenhouse emissions.

There are four fundamental approaches to geoengineering that have been suggested to limit the perturbing effects and impacts of GHG emissions: (1) accelerating the removal of greenhouse gases from the atmosphere; (2) altering the Earth's radiation balance to compensate for the effects of the increase in concentrations of GHGs; (3) moderating the climatic response to increasing GHGs by counteracting the positive feedback processes in the atmosphere-ocean-land surface system; and (4) counteracting the harmful effects of the changes that do occur.

In reviewing these options, it should be recognized that analysis of these concepts is only schematic. For several of these ideas, effectiveness cannot yet be evaluated, leaving much for further exploration. Coupled to the rather significant costs and potential environmental side effects that are likely to be involved, starting down such a path is most appropriately considered a "last resort" option.

25.4.1. Accelerating the Removal of Greenhouse Gases from the Atmosphere

Direct removal of GHGs from the atmosphere is generally impractical—the concentrations being so dilute that it would be comparatively more practical, although still quite costly, to remove GHGs from the emissions stream at their sources. As an example of the impracticality of such direct efforts, Viggiano *et al*. (1995) analyzed a proposal to remove chlorofluorocarbons (CFCs) already released to the atmosphere using negative-ion chemistry techniques and found that the energy requirements brought the cost of the proposal well above the costs of approaches such as limiting the uses and emissions of CFCs.

Proposed approaches for accelerating the natural removal processes for CO_2 include enhancing the storage of carbon by the terrestrial biosphere and enhancing the pumping of carbon to the deep ocean by the oceanic biosphere. In these schemes, solar energy and photosynthesis would be used to power a removal process facilitated by human intervention. The advantages and disadvantages of possible approaches involving the enhancement of terrestrial carbon storage (e.g., in forests or soils), and the potential for deriving biomass fuels through these efforts, are covered in Chapters 23 and 24; approaches focusing on enhancing ocean removal are addressed here.

The oceans cover more than twice as much area as the land, are uninhabited by humans, and contain much more carbon than the terrestrial biosphere (~40,000 vs. ~2,200 Gt C, respectively)—making the potential for enhancing oceanic storage seemingly significant. In the oceans, the biosphere acts to slowly pump carbon into the deep ocean, while the net effect of the oceanic circulation is to bring carbon back to the surface to be released into the atmosphere. In preindustrial (but postglacial) times, these biological and circulation fluxes were apparently in quite close balance, keeping the atmospheric concentration nearly constant. With human activities releasing about 7 Gt C per year to the atmosphere, the net flux to the deep ocean is estimated to have increased by about 2 Gt C per year (primarily by increased downward transport of carbon). Enhancing this circulation-based removal process to accommodate a greater fraction of fossil-fuel carbon emissions would reduce the atmospheric burden, but such changes would be very difficult to achieve (although the natural downward flux will rise slowly as the CO_2 concentration increases).

Because of the chemical buffering of the atmospheric CO_2 concentration by the ocean, reduction of the atmospheric concentration would require extensive fertilization of the ocean to promote biological carbon uptake. Studies indicate that iron fertilization of the Southern Ocean would lead to only modest additional oceanic uptake of carbon. A recent iron-fertilization experiment on an 8 x 8 km oceanic plot sought to enhance biological carbon uptake but concluded that, although growth was initially enhanced, the net effect was negligible due to losses in the food chain (Martin *et al*., 1994). However, preliminary results from a more recent iron-fertilization study

found a 30- to 40-fold increase in chlorophyll in the eastern equatorial Pacific (Monastersky, 1995a, 1995b); the extent of the potential long-term effects and the consequences for nutrient cycles are not yet known. Even a major fertilization effort might well be equivalent to only the increase in the CO_2 concentration occurring over about a 10-year period (Joos *et al*., 1991; Peng and Broecker, 1991). Such fertilization might also induce major side effects, further making this approach problematic.

Because carbon dissolved in the ocean also is present in inorganic form, a second conceivable means of increasing oceanic uptake would be by increasing oceanic alkalinity. However, this could be a practical possibility only if the weathering of rocks and river runoff were increased substantially (e.g., by a factor of 30: Flannery *et al*., 1995)—a solution that is unlikely to be feasible.

25.4.2. *Altering the Earth's Radiation Balance*

Several approaches have been suggested to counterbalance the additional trapping of infrared radiation of GHGs by reducing the available solar energy. A number of analyses (e.g., Manabe and Wetherald, 1980; Hansen and Lacis, 1990) have suggested an approximate equivalence in the influence of changes in radiative forcing by infrared and solar radiation; however, more-recent simulations that include the effects of the oceans show that the equivalence is less than perfect in terms of the latitudinal and seasonal patterns of the climatic response (Hansen *et al*., 1994). Nonetheless, at least some of the solar-reduction schemes could be latitudinally and perhaps seasonally tailored to achieve essential equivalence, so that the resulting radiative change would be nearly equal and opposite. Comparisons described below generally assume the need for a reduction in solar radiation of 1%, which would roughly counterbalance a 50% increase in CO_2 concentration. Note, however, that to be effective over time, the intensity of the counterbalancing effort would have to increase continuously to match the increasing GHG effect, requiring a continually increasing, and major, societal commitment.

Reducing solar radiation reaching the top of the atmosphere is conceptually possible by putting mirrors either in Sun-synchronous or near-Earth orbits. The first approach would involve placing a 2,000 km-diameter solar radiation deflector at the first Sun-Earth Lagrange point (1.5 million km from Earth), as suggested by Early (1989). Although this would require significant initial efforts—possibly including a construction base on the Moon—it would be relatively easy to sustain, would have few inadvertent consequences, and could be incrementally controlled or removed in the event of unexpected side effects. The National Academy of Sciences (1992) explored a near-Earth option involving orbiting mirrors. They estimated that counterbalancing the effects of a 50% increase in the CO_2 concentration would require placing about 55,000 mirrors, each measuring 10 x 10 km, into orbit; such objects—in addition to being difficult to control—would eclipse the Sun, the Moon, and the stars roughly 1% of the time from the view

of a person looking upwards. Placing reflecting or absorbing aerosols in orbit also would be possible, but the amounts would need to be continuously replenished to make up for relatively rapid removal by the solar wind and atmospheric reentry.

In addition to other disadvantages, these extraterrestrial geo-engineering options would require significant up-front funding that could be used alternatively to develop various renewable energy sources. For example, the funding could be used to develop extraterrestrial technologies such as solar-power satellites (NAS, 1981) or to locate solar collectors on the Moon that would beam energy to Earth to provide a substitute for fossil energy; the cost likely would be comparable to lofting satellites that would simply diminish incoming solar energy.

Within the atmosphere, several concepts have been suggested for reducing solar radiation by the requisite amount; each approach has its advantages and disadvantages (National Academy of Sciences, 1992; Flannery et al., 1995). About a trillion reflective balloons—each several meters in diameter and floating in the upper stratosphere—would neither create partial eclipses nor significantly affect stratospheric chemistry but likely would be hard to design and hard to keep near the equator. The multitude of injected aluminum particles from rocket exhaust and the burn-up of reentering spacecraft may already be having a very minor influence of this type; see Brady *et al*. (1994) and TRW (1994) for an evaluation of their effects on the ozone layer. Continuous injection of sulfate aerosols into the stratosphere could be carried out to create the equivalent of a very large volcanic eruption. While this could be achieved at low cost using large artillery pieces for injection (see National Academy of Sciences, 1992), volcanic aerosols have tended to deplete stratospheric ozone. The aerosols would also whiten the skies because they scatter radiation forward more effectively than they reflect it. Injection of sufficient amounts of sooty aerosols into the stratosphere would cause warming in the stratosphere while cooling the troposphere—much like a suggested "nuclear winter" (Turco *et al*., 1983; Pittock *et al*., 1989). Due to the infrared effects resulting from stratospheric warming, the amount of soot injected would need to be quite significant. In this case, the sky would dim rather than whiten. Even though direct effects on ozone chemistry might be avoided because pure soot particles can be made unreactive to stratospheric ozone, the increased temperatures in the stratosphere might tend to decrease ozone concentrations. Other inadvertent environmental consequences of such measures remain poorly researched.

As appears to be happening inadvertently as a result of sulfur dioxide emissions from fossil fuel combustion (Charlson *et al*., 1991; Kiehl and Briegleb, 1993; Taylor and Penner, 1994), injection of sulfate aerosols into the troposphere can lead to a counterbalancing effect to GHGs (National Academy of Sciences, 1992; IPCC, 1995; Flannery *et al*., 1995). Such aerosols act in the clear sky by reflecting and scattering radiation (creating the white haze so evident over industrial regions). They also may have an effect in cloudy regions by brightening the clouds or enhancing cloud extent or lifetime.

Due to the short lifetimes of tropospheric aerosols, this approach would require injection of sulfate aerosols in amounts much greater than those currently emitted by fossil fuel power plants—leading to acid deposition, visibility impairment, ecosystem damage, and structural damage.

Increases in the albedo of the surface could be used to increase reflection of solar radiation back to space. While this may be practical in cooling residences and urban areas (see Chapter 22), countering the effect of a 50% increase in CO_2 would require covering roughly 10% of the Earth's land area or 5% of the ocean with a substance as reflective as new snow; such a change would be virtually impossible and highly disruptive of the surface climate.

25.4.3. Altering Climatic Feedback Mechanisms

Much of the predicted climatic response to GHGs is due to the amplifying effects of positive climatic feedback mechanisms, particularly the increase in the atmospheric water-vapor concentration. If these feedback mechanisms could be countered, the extent of global warming could be greatly reduced.

Possible approaches have not been carefully considered, but might include reducing the rate of evaporation of water (e.g., by coating or covering water surfaces) to reduce the intensity of water vapor feedback; increasing the extent and reflectivity of clouds (e.g., adding sulfates to decrease cloud-droplet size); enhancing the intensity of the oceanic thermohaline circulation (which would cool low latitudes and might promote increased heat loss in high latitudes); or altering atmospheric chemistry (e.g., by reducing tropospheric ozone to reduce its positive greenhouse effect). These proposed ideas have not been studied in even a preliminary way; however, each of these concepts likely has important side effects (e.g., altering precipitation patterns) that are as significant as the inadvertent perturbation to be avoided. Moreover, the positive feedbacks that they are intended to counteract have been poorly quantified; therefore, it is not yet possible to assess the effectiveness of these approaches.

25.4.4. Countering Harmful Effects

Means to counter at least some of the harmful consequences of greenhouse warming also have been suggested. For example, the predicted sea-level rise could be reduced by coating the polar ice caps to reduce melting or by pumping sea-water up onto East Antarctica as part of a giant snow-making operation; however, such projects would create enormous energy demands. Alternatively, it might be possible (e.g., by manipulating sea ice cover) to redirect Southern Ocean storms to increase snowfall onto East Antarctica; in fact, such a snow build-up may happen naturally (see Chapter 7, *Changes in Sea Level*, in the Working Group I volume).

If warmer oceans increase typhoon intensity or frequency, it may be possible to alter their tracks or reduce their strength by cloud seeding or by limiting evaporation via releasing oil slicks on the ocean. Locally, increasing the reflectivity of the surface (urban whitening) can reduce warming influences. Overall, however, acting after nature has amplified the original direct forcing of the GHGs is a relatively difficult and very inefficient option, and one that could well lead to unintended side effects.

25.4.5. Assessment of Climate Adjustment Options

There are at least as many uncertainties and complications involved in pursuing geoengineering options as in projecting the inadvertent climatic change of GHGs. In addition to scientific uncertainties, the UN Convention on the Prohibition of Military or Any Other Hostile Use of Environmental Modification Techniques, which entered into force 5 October 1978, may introduce complications if some countries may be negatively impacted while others benefit. Geoengineering, therefore, should be considered a viable response option only if imminent and especially rapid or threatening inadvertent change be found as a result of projected greenhouse warming (e.g., if collapse of the polar ice caps and concomitant sea-level rise are imminent). For this reason, exploring the advantages and shortcomings of the range of approaches and alternatives is a useful precaution but is not justified at the expense of the development of more practical and economical approaches.

If undertaken as a complement to reducing or slowing an unexpectedly rapid onset of inadvertent influences, geoengineering activities might be required only for a few decades. However, if undertaken as an alternative to actions to limit increasing emissions of greenhouse gases, geoengineering options would have to continue for many centuries—becoming a new, formidable, and quite possibly very costly societal responsibility. Assumption of this responsibility would need to be considered very carefully because suddenly halting such actions, even unintentionally, would, at least for most approaches, cause a rapid climatic readjustment toward the higher temperature state projected as a consequence of the inadvertent activities (i.e., the Earth would face the "climatic shock" of sudden greenhouse warming). Such a situation might well lead to more detrimental impacts than the slower warming projected if geoengineering options were not undertaken.

25.5. Integrated Assessment of Mitigation Potential

A number of evaluations of the effectiveness of various mitigation options and strategies have been published (e.g., Nakícenovíc *et al.*, 1994). Many of these mitigation assessments are based on models with limited scope, often with a strong emphasis on the energy sector (e.g., Dowlatabadi, 1994). Although some of these models include rudimentary simulations of global biogeochemical and physical processes and are suited for the evaluation of specific sectoral mitigation options, they remain of little use for evaluating combinations of mitigation options and the relations with major cross-sectoral issues, such as land use and water availability.

Many of these assessments also focus only on CO_2, neglecting other GHGs. Such partial assessments can be misleading because—through well-established linkages with other biological, chemical, and physical processes—reduction of CO_2 emissions could lead to enhanced emissions of other trace gases such as CH_4 (e.g., Dacey *et al.*, 1994). Furthermore, competing land uses often are neglected or poorly evaluated. Determination of the effectiveness of mitigation options and strategies should be based on an approach involving the simultaneous evaluation of several trace gases, in which the diverse aspects of land use are guaranteed, and in which important physical and biogeochemical processes, linkages, and feedbacks are included (Leemans, 1995). This requirement should result in the combined analysis of the Earth system (Ojima, 1993), including technological and socioeconomic models (Meyer and Turner, 1994).

Such integration can be successful only if the relevant properties and dimensions of each domain (e.g., geosphere, biosphere, anthroposphere) are addressed. For example, early carbon-cycle models aggregated all land covers into a few classes characterized by globally averaged parameters (e.g., Goudriaan and Ketner, 1984). Although such an approach is straightforward to implement, it does not allow assessment of local and regional consequences of global change (see Chapter 24) and is therefore unsuitable for evaluation of the efficacy of mitigation options. In current assessment models, continental-scale regions are assumed to be homogeneous. Thus, these models are not capable of representing the wealth of socioeconomic components and market forces that cause and react to change at the community, state, and national level. Similar arguments can be developed for all other domains. To address the heterogeneous response of biogeochemical processes, a georeferenced approach has to be adopted. More-recent models have taken such an approach (e.g., Melillo *et al.*, 1993; Klein Goldewijk *et al.*, 1994). The integrated models required to evaluate mitigation options and strategies should be robust and convey confidence in their simulation of local to regional processes, while simultaneously considering regional to global characteristics.

25.5.1. Components of Integrated Assessment Models

Integrated Assessment Models (IAMs) can in principle serve three purposes: (1) They can help assess potential responses to climate change, either by comparing the costs of response options to the benefits of avoided impacts or by comparing the relative effectiveness and costs of alternate response options; (2) they provide an overview of the cross-sectoral linkages and tradeoffs that can facilitate a more systematic evaluation of policy options; and (3) they can help evaluate the importance of climate change relative to other socioeconomic concerns.

As discussed in Chapter 10, *Integrated Assessment of Climate Change: An Overview and Comparison of Approaches and Results*, of the Working Group III volume, a number of IAMs have been developed that are integrated over different dimensions

and to different degrees. "Full-scale" IAMs seek to address the linkages and feedbacks among human activities, managed and unmanaged ecosystems, emissions and atmospheric composition, and climate change and sea level. The various models differ in the level of detail and complexity considered both within and between the modules, the underlying socioeconomic assumptions used, and the manner in which physical and socioeconomic uncertainties are addressed.

25.5.2. Illustrative Examples and Results

IAMs can be used to evaluate the implications of extensive biomass plantations on land use and availability. This section discusses simulation results using two very different IAMs as examples: IMAGE 2.0 (Alcamo *et al.*, 1994) and MiniCAM 2.0 (Edmonds *et al.*, 1995). The basic structures of the models are described in Boxes 25-2 and 25-3, respectively. IMAGE 2.0 is a targets-based IAM with considerable regional and sectoral detail of potential physical impacts. These impacts, however, are not given economic values. Also, the model does not include explicit representations of uncertainty. It does, however, account for land use and changes in land cover through physical and biogeochemical feedbacks, such as changes in albedo, terrestrial carbon storage, and enhanced plant growth. MiniCAM 2.0, on the other hand, is designed to balance the costs and benefits of climate-change policies. In this model, constraints on human activities are explicitly represented and costed out. However, the model has a more aggregated representation of climate-change impacts.

The IMAGE 2.0 baseline scenario uses the population and economic growth assumptions from the IPCC IS92a scenario (Leggett *et al.*, 1992); other scenario input variables come from a variety of sources (Alcamo *et al.*, 1994). As part of this baseline, it is assumed that biomass is used for the generation of 208 EJ energy worldwide in 2100 (and 74 EJ in 2050), thereby reducing the dependence on fossil fuels. The basic assumption for this baseline is that most of this biomass would be taken from readily available sources, such as agricultural and forestry residues, municipal waste, and so forth. A second scenario assumes that only 60% of this demand is readily available, while the remaining 40% has to come from specific biomass crops. This "biomass crop scenario" results globally in an increased demand for agricultural land. A third scenario assumes that no modern biomass is used and that an equivalent amount of the energy demand would be satisfied by oil instead. This "no biomass scenario" does not alter land-cover patterns. The three scenarios differ in their regional and global patterns of fluxes, sources, and sinks of greenhouse gases (Table 25-3).

The three scenarios illustrate different possibilities for increases in the emissions of individual GHGs to the atmosphere as a consequence of interactions of land-use and energy options (Table 25-3). The biomass crop scenario would lead to a large increase in agricultural land cover, although there would be large regional differences in area and timing

Terrestrial Environment System (TES)

IMAGE 2.0 (Integrated Model to Assess the Greenhouse Effect) is a multidisciplinary, integrated model of climate change. The model is designed to provide support for comprehensive evaluations of national and international policies concerning the build-up of GHGs. The model consists of three fully linked components: Energy Industry System (EIS), Terrestrial Environment System (TES), and Atmosphere Ocean System (AOS). EIS divides the world into 13 regions and computes emissions in each as a function of energy consumption and industrial production. The EIS-models are designed to investigate the effectiveness of different fuel mixes and improved energy efficiencies. TES defines the role of the terrestrial biosphere using vegetation-climate-soil interactions and determining the impacts of land-use change. The dynamic simulation of land-use and land-cover change is an important component of TES. These changes are simulated on a 0.5-degree global grid. Each grid cell is characterized by its climate, topography, soil, and land cover. Changes in natural vegetation are simulated with the BIOME model (Prentice *et al*., 1992). Potential productivity for eight major crops is computed using the "agro-ecological zone" approach developed by UN-FAO (Brinkman, 1987; Leemans and Solomon, 1993). This approach provides the potential distribution and productivity of crops and natural vegetation over the grid. For each region, the demand for land-based commodities (crops, livestock, biomass, lumber, and fuelwood) is calculated. The per capita consumption is derived from an assumed elasticity between consumption and per capita income. Population, dietary preferences, and socioeconomic factors control changes in demand. Agricultural data for the period 1970–1990 from FAO were used to parameterize the demand functions and to calibrate the geo-referenced area of cultivated land from Olson *et al*. (1985) with observed regional productivities. TES then reconciles the demand for land with its potential through a set of heuristic rules that reflect key driving factors, including proximity to infrastructure, population, and productivity of land. This relatively simple model results in rich patterns of land use and cover change for each region. These changed patterns are used to calculate the GHG emissions and local responses of ecosystems with respect to the terrestrial carbon cycle. TES allows evaluation of the impact of environmental changes on ecosystems and agriculture and the effectiveness of mitigation policies. Such evaluation can be achieved comprehensively because of the systemic linkages with other components of IMAGE 2. TES is linked with EIS through the demand for fuelwood and biomass. TES and AOS are indirectly linked through changes in soil moisture and albedo, mediated by land-cover change. All emissions are combined in AOS to determine atmospheric concentrations of GHGs, while accounting for atmospheric chemistry and oceanic carbon uptake.

Box 25-3. The MiniCAM 2.0 Model

MiniCAM 2.0 is an integrated assessment model with four major components: Human Activities, Atmospheric Composition, Climate and Sea Level, and Ecological Systems. The model considers energy and land-use change both explicitly and interactively. The energy system model is the Edmonds-Reilly-Barns (ERB) model (Edmonds and Reilly, 1985), while the agriculture land-use model (ALM) was developed explicitly for MiniCAM 2.0. ALM partitions land into managed and less-managed systems. The managed lands are used intensively for human settlement and infrastructure and extensively for growing crops, raising livestock, managed forests, or biomass cultivation for energy use. Less-managed lands are partitioned into ecological categories. The allocation of lands to human settlement and infrastructure is determined by population and income, and this use of land takes precedence in the model over all other uses of managed land. Extensive land uses are determined by expected profitability—which in turn depends on plant productivities, product prices, technology, fertilization, atmospheric CO_2 concentrations, climate, population, income, taxes, tariffs, and subsidies. Less-managed lands include those that are "parked" (i.e., excluded from use for managed activities) and those that are potentially available for managed uses.

The boundary between the managed and less-managed systems is determined by the expected profitability of managed lands in general. Within ALM, global markets are established for each of the major traded commodities—crops, livestock, and forest products—and a world price is established that clears international markets. Biomass for energy use is determined interactively with the ERB. Because biomass is used as an energy resource, its demand and price are determined in the ERB while its supply is determined in the ALM. Changes in land allocations determine net trace-gas fluxes from the terrestrial biosphere, while the ERB determines energy-related emissions. Other emissions, such as those from cement manufacture and from CFCs and their substitutes, are handled exogenously.

(Alcamo *et al*., 1994). This increase would take up less carbon than the land cover the biomass crops replace. This would limit carbon sequestration in ecosystems and enhance emissions of CH_4 and other GHGs. The realized climate change does not necessarily differ significantly for these three scenarios.

The MiniCAM 2.0 model also has been used to address issues of conflicting land use in cases where low fossil fuel emissions objectives are pursued (Edmonds *et al*., 1995). The model was used to examine the implications for land-use competition resulting from the technologies described in the LESS constructions in Chapter 19. The principal finding of the analysis was that with biomass productivities as high as that considered in LESS, negative impacts from the competition for land use are minimal. That is, increases in emissions from land-use change are likely to be less than 10%, and per capita consumption of crops and livestock also are likely to be within 10% of their reference values. The results, however, are sensitive to several assumptions, such as the productivity of biomass energy plants, the rate of technological progress in agriculture, and the rates of population and income growth.

Table 25-3: *Globally averaged summary of IMAGE 2.0 results for the baseline, biomass crops, and no-biomass scenarios. The scenarios differ in the assumptions regarding the source of 74 or 208 EJ of energy in 2050 and 2100, respectively (after Alcamo et al., 1994).*

Year and Scenario	Change in Atmospheric Concentration (%)		Change in Agricultural Productivity (% ha⁻¹)	Change in Agricultural Area (%)	Change in Forest Area (%)	Change in Average Surface Temperature (°C)	
	CO_2	CH_4	(% ha^{-1})	(%)	(%)	N. Hemisphere	S. Hemisphere
1990	358 ppm	1.7 ppm	100	2670 Mha	4720 Mha	14.2	13.0
2050							
Baseline	+46	+47	+72	+9	-26	+1.4	+1.0
Biomass Crops	+49	+53	+72	+30	-32	+1.5	+1.0

No Biomass	+139	0	+108	+15	-27	+2.4	+1.9

25.6. Concluding Remarks

A number of cross-sectoral linkages become evident only when an integrated analysis of climate and socioeconomic systems is used to complement sectoral analyses. The field of integrated assessment modeling is still under development, with various models being used to investigate different plausible ways to integrate across various disciplines. At present there is no single "right" approach to integrated assessment modeling, and models often have to make tradeoffs between the level of sectoral detail they can include and the level of complexity and data requirements that can be handled realistically. Further, Integrated Assessment Models are only as good as the underlying socioeconomic assumptions and information on sectoral impacts, adaptation, and mitigation strategies. As discussed throughout this report, there are key gaps in the understanding of the climate system, how climate change would impact the various sectors, and the feasibility and possible ancillary impacts of various adaptation and mitigation options. Across these issues, information from developing countries is particularly lacking.

The discussion in this chapter is, at best, a roadmap of the types of cross-sectoral issues and tradeoffs decisionmakers will need to consider in evaluating the various mitigation options. While the analysis has focused on energy and land use—which are two key arteries cutting across the various sectors—issues relating to society's demands for water and how water resources would be affected by different mitigation strategies have not yet been addressed in the same level of detail. Further, many cross-cutting impacts of mitigation policies also would be transmitted through trade and market forces. An analysis of these, however, falls beyond the mandate of this Working Group.

CONTENTS

EXECUTIVE SUMMARY

Working Group II of IPCC has prepared Guidelines to assess the impacts of potential climate change and to evaluate appropriate adaptations. They reflect current knowledge and will be updated as improved methodologies are developed. The Guidelines outline a study framework which will allow comparable assessments to be made of impacts and adaptations in different regions/geographical areas, economic sectors, and countries. The Guidelines are intended to help contracting parties meet, in part, their commitments under Article 4 of the UN Framework Convention on Climate Change.

Impact and adaptation assessments involve several steps:

- Definition of the problem
- Selection of the method
- Testing the method
- Selection of scenarios
- Assessment of biophysical and socioeconomic impacts
- Assessment of autonomous adjustments
- Evaluation of adaptation strategies.

Definition of the problem includes identifying the specific goals of the assessment; the ecosystem(s), economic sector(s), and geographical area(s) of interest; the time horizon(s) of the study; the data needs; and the wider context of the work.

The selection of analytical method(s) depends upon the availability of resources, models, and data. Impact assessment analyses can range from the qualitative and descriptive to the quantitative and prognostic.

Testing the method(s), including model validation and sensitivity studies, before undertaking the full assessment is necessary to ensure credibility.

Development of the scenarios requires, firstly, the projection of conditions expected to exist over the study period in the absence of climate change and, secondly, the projection of conditions associated with possible future changes in climate.

Assessment of potential impacts on the sector(s) or area(s) of interest involves estimating the differences in environmental and socioeconomic conditions projected to occur with and without climate change.

Assessment of autonomous adjustments implies the analysis of responses to climate change that generally occur in an automatic or unconscious manner.

Evaluation of adaptation strategies involves the analysis of different means of reducing damage costs. The methodologies outlined in the Guidelines for analyzing adaptation strategies are meant as a tool only to compare alternative adaptation strategies and thereby identify the most suitable strategies for minimizing the effects of climate change were they to occur.

26.1. Objectives

These Guidelines, which are a further development of those previously published (Carter *et al*., 1992), provide a means for assessing the impacts of potential climate change and of evaluating appropriate adaptations. They reflect current knowledge and will be updated as improved methodologies are developed. They do not aim to prescribe a single preferred method, but provide an analytical outline composed of a number of steps. A range of methods is identified at each step. Where possible, the merits and drawbacks of different methods are briefly discussed, with some suggestions on their selection and use.

The ultimate purpose of the Guidelines is to enable estimations of impacts and adaptations, which will allow comparable assessments to be made for different regions/geographical areas, sectors, and countries. The Guidelines are intended to help contracting parties meet, in part, commitments under Article 4 of the UN Framework on Climate Change.

26.2. Approaches

A general framework for conducting a climate impacts and adaptations assessment contains seven steps:

- Definition of the problem
- Selection of the method
- Testing the method
- Selection of scenarios
- Assessment of biophysical and socioeconomic impacts
- Assessment of autonomous adjustments
- Evaluation of adaptation strategies.

At each step, a range of study methods is available. These are described and evaluated in the following sections. For reasons of brevity, however, only the essence of each method is introduced, along with references to sources of further information.

26.3. Step One—Definition of the Problem

This involves identifying the goals of the assessment, the exposure unit of interest, the spatial and temporal scope of the study, the data needs, and the wider context of the work.

26.3.1. Goals of the Assessment

It is important to be precise about the specific objectives of a study, as these will affect the conduct of the investigation. For example, an assessment of the hydrological impacts of future climatic change in a river catchment would have quite different requirements for data and expertise if the goal is to estimate the capacity for power generation than if it is to predict changes in agricultural income as a result of changes in the availability of water for irrigation.

26.3.2. Exposure Unit to be Studied

The exposure unit (i.e., the impacted object) to be assessed determines, to a large degree, the type of researchers who will conduct the assessment, the methods to be employed, and the data required. Studies can focus on a single sector or activity (e.g., agriculture, forestry, energy production, or water resources), several sectors in parallel but separately, or several sectors interactively.

26.3.3. Study Area

The selection of a study area is guided by the goals of the study and by the constraints on available data. Some options are reasonably well-defined, including governmental units, geographical units, ecological zones, and climatic zones. Other options requiring more subjective selection criteria include sensitive regions and representative units.

26.3.4. Time Frame

The selection of a time horizon for study is also influenced by the goals of the assessment. For example, in studies of industrial impacts the planning horizons may be 5–10 years, while investigations of tree growth may require a 100-year perspective. However, as the time horizon increases, the ability to accurately project future trends declines rapidly. Most climate projections and scenarios rely on general circulation models (GCMs), which are subject to uncertainties. Projections of socioeconomic factors such as population, economic development, and technological change need to be made for periods exceeding 15–20 years.

26.3.5. Data Needs

The availability of data is probably the major limitation in most impact and adaptation assessment studies. The collection of new data is an important element of some studies, particularly for monitoring purposes regarding expected climate changes, but most rely on existing sources. Thus, before embarking on a detailed assessment, it is important to identify the main features of the data requirements—namely, the variables for which data are needed, the time period, spatial coverage and resolution of the required data, the sources and format of the data and their quantity and quality, and the data availability, cost, and delivery time.

26.3.6. Wider Context of the Work

In order to assist policymakers in evaluating the wider significance of an assessment, it is important to place it in the context of similar studies and of the political, economic, and social system of the region.

26.4. Step Two—Selection of the Method

A variety of analytical methods can be adopted ranging from qualitative descriptive studies, through more diagnostic and semi-quantitative assessments, to quantitative and prognostic analyses. Any single impact assessment may contain elements of one or more of these types. Four general methods can be identified: experimentation, impact projections, empirical analog studies, and expert judgment.

26.4.1. Experimentation

In the physical sciences, a standard method of testing hypotheses or of evaluating processes of cause and effect is through direct experimentation. In the context of climate impact and adaptation assessment, however, experimentation has only a limited application. Clearly it is not possible physically to simulate large-scale systems such as the global climate. Only where the scale of impact is manageable, the exposure unit measurable, and the environment controllable can experiments be usefully conducted (e.g., gas enrichment experiments with plants).

26.4.2. Impact Projections

One of the major goals of climate impact assessment, especially concerning aspects of future climatic change, is the prediction of future impacts. A main focus of much recent work has been on impact projections, using an array of mathematical models to extrapolate into the future. First-order effects of climate are usually assessed using biophysical models, and second- and higher order effects using a range of biophysical, economic, and qualitative models. Finally, attempts also have been made at comprehensive assessments using integrated systems models.

26.4.2.1. Biophysical Models

Biophysical models may be used to evaluate the physical interactions between climate and an exposure unit. There are two main types: Empirical-statistical models and process-based models. Empirical-statistical models are based on the statistical relationships between climate and the exposure unit. Process-based models make use of established physical laws and theories to express the dynamics of the interactions between climate and an exposure unit.

26.4.2.2. Economic Models

Economic models of several types can be employed to evaluate the implications of first-order impacts for local and regional economies. The main types of models are firm-level (which depict a single firm or enterprise), sectoral (which simulate behavior within a specific economic sector), and macroeconomic (which simulate entire economies).

26.4.2.3. Integrated Systems Models

Integrated systems models represent an attempt to combine elements of the modeling approaches described above into a comprehensive model of a given regionally or sectorally bounded system. Two main approaches to integration can be identified: the aggregate cost-benefit approach, which is more economically oriented, and the regionalized process-based approach, which focuses more on biophysical effects.

26.4.3. Empirical Analog Studies

Observations of the interactions of climate and society in a region can be of value in anticipating future impacts. The most common method employed involves the transfer of information from a different time or place to an area of interest to serve as an analogy. Four types of analogy can be identified: Historical event analogies, historical trend analogies, regional analogies of present climate, and regional analogies of future climate.

26.4.4. Expert Judgment

A useful method of obtaining a rapid assessment of the state-of-knowledge concerning the effects of climate on given exposure units is to solicit the judgment and opinions of experts in the field. Literature is reviewed, comparable studies identified, and experience and judgment used in applying all available information to the current problem.

26.5. Step Three—Testing the Method

Following the selection of the assessment methods, it is important that these are tested in preparation for the main evaluation tasks. Three types of activity may be useful in evaluating the methods: feasibility studies, data acquisition and compilation, and model testing.

26.5.1. Feasibility Studies

These usually focus on a subset of the study region or sector to be assessed. Such case studies can provide information on the effectiveness of alternative approaches, of models, of data acquisition and monitoring, and of research collaboration.

26.5.2. Data Acquisition and Compilation

Data must be acquired both to describe the temporal and spatial patterns of climate change and their impacts and to develop, test, and calibrate predictive models. Data collection may rely on existing information obtained and compiled from different sources, or require the acquisition of primary data through survey methods, direct measurement, or monitoring.

26.5.3. Model Testing

The testing of predictive models is, arguably, the most critical stage of an impact assessment. Most studies rely almost exclusively on the use of models to estimate future impacts. Thus, it is crucial for the credibility of the research that model performance is tested rigorously. Standard procedures should be used to evaluate models, but these may need to be modified to accommodate climate change. Two main procedures are recommended: validation and sensitivity analysis. Validation involves the comparison of model predictions with real world observations to test model performance. Sensitivity analysis evaluates the effects on model performance of altering its structure or parameter values, or the values of its input variables.

26.6.   Step Four—Selection of the Scenarios

Impacts are estimated as the differences between two states: environmental and socioeconomic conditions expected to exist over the period of analysis in the absence of climate change, and those expected to exist with climate change.

26.6.1. Establishing the Present Situation

In order to provide reference points with which to compare future projections, three types of "baseline" conditions need to be specified: the climatological, environmental, and socioeconomic baselines.

26.6.1.1. Climatological Baseline

The climatological baseline is usually selected according to the following criteria:

- Representativeness of the present-day or recent average climate in the study region
- Of sufficient duration to encompass a range of climatic variations
- Covering a period for which data on all climatological variables are abundant, adequately distributed, and readily available
- Including data of sufficient quality for use in evaluating impacts.

It is recommended that the current standard World Meteorological Organization (WMO) normal period (1961–90) be adopted in assessments where appropriate.

26.6.1.2. Environmental Baseline

The environmental baseline refers to the present state of other nonclimatic environmental factors that affect the exposure unit. Examples include groundwater levels, soil pH, extent of wetlands, and so on.

26.6.1.3. Socioeconomic Baseline

The socioeconomic baseline describes the present state of all the nonenvironmental factors that influence the exposure unit. The factors may be geographical (e.g., land use), technological (e.g., pollution control), managerial (e.g., forest rotation), legislative (e.g., air quality standards), economic (e.g., commodity prices), social (e.g., population), or political (e.g., land tenure). All of these are liable to change in the future, so it is important that baseline conditions of the most relevant factors are noted.

26.6.2. Time Frame of Projections

A critical consideration for conducting impact experiments is the time horizon over which estimates are to be made. Three elements influence the time horizon selected: the limits of predictability, the compatibility of projections, and whether the assessment is continuous or considers discrete points in time.

26.6.2.1. Limits of Predictability

The time horizon selected depends primarily on the goals of the assessment. However, there are obvious limits on the ability to project into the future. Climate projections, since they are a key element of climate impact studies, define one possible outer limit on impact projections. GCM estimates seldom extend beyond about 100 years, due to the uncertainties attached to such long-term projections and to constraints on computational resources. This fixes an outer horizon at about 2100. In many economic assessments, on the other hand, projections may not be reliable for more than a few years ahead.

26.6.2.2. Compatibility of Projections

It is important to ensure that future climate, environment, and socioeconomic projections are mutually consistent over space and time. It is important to be clear about (i) the relative timing of increases in greenhouse gas concentrations and climate change, and (ii) the relative timing of a 2 x CO_2 compared to a 2 x CO_2 "equivalent" atmosphere.[1] With regard to the former, there is a lag time of several decades in the response of the climate system to increases in greenhouse gas concentrations. With regard to the latter, a 2 x CO_2 "equivalent" atmosphere occurs earlier than a 2 x CO_2 atmosphere because gases such as CH_4, N_2O, and tropospheric O_3 also contribute to radiative forcing.

---

[1] A 2 x CO_2 "equivalent" atmosphere is one where the radiative forcing due to changes in all greenhouse gases (CO_2, CH_4, N_2O, O_3, halocarbons) is the same as that of an atmosphere where the concentration of CO_2 has doubled with the concentration of other greenhouse gases remaining unchanged.

26.6.2.3. Point in Time or Continuous Assessment

A distinction can be drawn between considering impacts at discrete points in time in the future and examining continuous or time-dependent impacts. The former are characteristic of many climate impact assessments based on doubled-CO_2 equivalent scenarios. In contrast, transient climatic scenarios allow time-dependent phenomena and dynamic feedback mechanisms to be examined and socioeconomic adjustments to be considered.

26.6.3. Projecting Environmental Trends in the Absence of Climate Change

The development of a baseline describing conditions without climate change is crucial, for it is this baseline against which all projected impacts are measured. It is highly probable that future changes in other environmental factors will occur even in the absence of climate change, which may be of importance for an exposure unit. Examples, as appropriate, include changes in land use, changes in groundwater level, and changes in air, water, and soil pollution. Most factors are related to, and projections should be consistent with, trends in socioeconomic factors. Greenhouse gas concentrations may also change, but these would usually be linked to climate (which is assumed unchanged here).

26.6.4. Projecting Socioeconomic Trends in the Absence of Climate Change

Global climate change is projected to occur over time periods that are relatively long in socioeconomic terms. Over that period it is certain that the economy and society will change, even in the absence of climate change. Official projections exist for some of these changes, as they are required for planning purposes. These vary in their time horizon from several years (e.g., economic growth, unemployment), through decades (e.g., urbanization, industrial development, agricultural production), to a century or longer (e.g., population).

26.6.5. Projecting Future Climate

In order to conduct experiments to assess the impacts of climate change, it is first necessary to obtain a quantitative representation of the changes in climate themselves. No method yet exists of providing confident predictions of future climate. Instead, it is customary to specify a number of plausible future climates. These are referred to as "climatic scenarios," and they are selected to provide climatic data that are spatially compatible, mutually consistent, freely available or easily derivable, and suitable as inputs to impact models.

There are three basic types of scenario of future climate: synthetic scenarios, analog scenarios, and scenarios from general circulation models.

26.6.5.1. Synthetic Scenarios

A simple method of specifying a future climate is to adjust the baseline climate in a systematic, though essentially arbitrary, manner. Adjustments might include, for example, changes in mean annual temperature of ±1, 2, 3°C, etc., or changes in annual precipitation of ±5, 10, 15%, etc., relative to the baseline climate. Adjustments can be made independently or in combination. In this way information can be obtained on the following:

- *Thresholds or discontinuities* of response that might occur under a given magnitude or rate of change. These may represent levels of change above which the nature of the response alters (e.g., warming may promote plant growth, but very high temperatures cause heat stress).
- *Tolerable climate change*, which refers to the magnitude or rate of climate change that a modeled system can tolerate without major disruptive effects (sometimes termed the "critical load"). This type of measure is potentially of value for policy, as it can assist in defining specific goals or targets for limiting future climate change.

One of the main drawbacks of the approach is that adjustments to combinations of variables may not to be physically plausible or internally consistent.

26.6.5.2. Analog Scenarios

Analog scenarios are constructed by identifying recorded climatic regimes that may serve as analogs for the future climate of a given region. These records can be obtained either from the past (temporal analogs) or from another region at the present (spatial analogs).

Temporal analogs are of two types: those based on past instrumental observations (usually within the last century) and those based on proxy data, using paleoclimatic indicators such as plant or animal remains and sedimentary deposits (from the more distant past geological records). The main problem with this technique concerns the physical mechanism and boundary conditions that would almost certainly be different between a warmer climate in the past and a future greenhouse gas-induced warming.

Spatial analogs require the identification of regions today having a climate analogous to the study region in the future. This approach is severely restricted, however, by frequent lack of correspondence between other nonclimatic features of two regions that may be important for a given impact sector (e.g., daylength, terrain, soils, or economic development).

26.6.5.3. Scenarios from General Circulation Models

Three-dimensional numerical models of the global climate system (including atmosphere, oceans, biosphere, and cryosphere) are the only credible tool currently available for simulating the

physical processes that determine global climate. Although simpler models also have been used to simulate the radiative effects of increasing greenhouse gas concentrations, only GCMs, possibly in conjunction with nested regional models, offer the possibility to provide estimates of regional climate change, which are required in impact analysis.

GCMs produce estimates of climatic variables for a regular network of grid points across the globe. Results from about 20 GCMs have been reported to date (e.g., see IPCC, 1990, 1992). However, these estimates are highly uncertain because of some important weaknesses of GCMs. These include poor model representation of cloud processes; a coarse spatial resolution (at best employing grid cells of some 250-km horizontal dimension); generalized topography, disregarding some locally important features; and a simplified representation of land-atmosphere and ocean-atmosphere interactions. As a result, GCMs are currently unable to reproduce accurately even the seasonal pattern of present-day climate at a regional scale. Thus, GCM outputs represent, at best, broad-scale sets of possible future climatic conditions and should not be regarded as predictions.

GCMs have been used to conduct two types of experiments for estimating future climate: equilibrium-response and transient-forcing experiments. The majority of experiments have been conducted to evaluate the equilibrium response of the global climate to an abrupt increase (commonly, a doubling) of atmospheric concentrations of CO_2. A measure that is widely used in the intercomparison of various GCMs is the climate-sensitivity parameter. This is defined as the global mean equilibrium surface air temperature change that occurs in response to an increase in radiative forcing due to a doubling of atmospheric CO_2 concentration (or equivalent increases in other greenhouse gases). Values of the parameter obtained from climate model simulations generally fall in the range 1.5–4.5°C (IPCC, 1992). Knowledge of the climate sensitivity can be useful in constructing climate change scenarios from GCMs.

Recent work has focused on fashioning more realistic experiments with GCMs—specifically, simulations of the response of climate to a transient forcing. These simulations offer several advantages over equilibrium-response experiments. First, the specifications of the atmospheric perturbation are more realistic, involving a continuous (transient) change over time in greenhouse gas concentrations. Second, the representation of the oceans is more realistic, the most recent simulations coupling atmospheric models to dynamic ocean models. Finally, transient simulations provide information on the rate as well as the magnitude of climate change, which is of considerable value for impact studies.

The following types of information are currently available from GCMs for constructing scenarios:

- Outputs from a "control" simulation, which assumes fixed greenhouse gas concentrations, and an "experiment," which assumes future concentrations. In the case of equilibrium-response experiments, these are values from multiple-year model simulations for the

control and 2 x CO_2 (or equivalent increases in other greenhouse gases) equilibrium conditions. Transient-response experiments provide values for the control equilibrium conditions and for each year of the transient model run (e.g., 1990 to 2100).

- Values of surface or near-surface climatic variables for model grid boxes characteristically spaced at intervals of several 100 km around the globe.

- Values of air temperature, precipitation (mean daily rate), and cloud cover, which are commonly supplied for use in impact studies. Data on radiation, windspeed, vapor pressure, and other variables are also available from some models.

- Data averaged over a monthly time period. However, daily or hourly values of certain climatic variables, from which the monthly statistics are derived, may also be stored for a number of years within the full simulation periods.

26.6.6. *Projecting Environmental Trends with Climate Change*

Changes in environmental conditions not due to climatic factors already should have been incorporated in the development of the environmental trends in the absence of climate changes; the only changes in these trends to be incorporated here are those solely to climate change. The two factors most commonly required in assessments are greenhouse gas concentrations and sea-level rise. Future changes in these are still under discussion, but the estimates reported by the IPCC may serve as a useful basis for constructing scenarios (IPCC, 1990). Other factors that are directly affected by climate (such as river flows, runoff, erosion) would probably require full impact assessments of their own, although some might be incorporated as "automatic adjustments" in projections.

26.6.7. *Projecting Socioeconomic Trends with Climate Change*

The changes in environmental conditions that are attributable solely to climate change serve as inputs to economic models that project the changes in socioeconomic conditions due to climate change both within the study area and, where relevant and appropriate, outside it over the study period. All other changes in socioeconomic conditions over the period of analysis are attributable to nonclimatic factors and should have been included in the estimation of socioeconomic changes in the absence of climate change.

26.7. **Step Five—Assessment of Impacts**

Impacts are estimated as the differences over the study period between the environmental and socioeconomic conditions projected to exist without climate change and those that are projected with climate change. Assessments may include the elements described in the following subsections.

26.7.1. Qualitative Description

The success of this method rests on the experience and interpretive skills of the analyst, especially the analyst's ability to consider all factors of importance and their interrelationships. Formal methods of organizing qualitative information also exist (e.g., cross-impact analysis).

26.7.2. Indicators of Change

These are particular regions, activities, or organisms that are intrinsically sensitive to climate, and that can provide an early or accurate indication of effects due to climate change.

26.7.3. Compliance to Standards

This may provide a reference or an objective against which to measure the impacts of climate change. For example, the effect on water quality could be gauged by reference to current water quality standards.

26.7.4. Costs and Benefits

These should be estimated quantitatively to the extent possible and expressed in economic terms. This approach makes explicit the expectation that a change in resources and resource allocation due to climate change is likely to yield benefits as well as costs. It can also examine the costs or benefits of doing nothing to mitigate potential climate change.

26.7.5. Geographical Analysis

Impacts vary over space, and this pattern of variation is of concern to policymakers operating at regional, national, or international scales because these spatial differences may have consequent policy and planning implications. The geographical depiction of the effects of climate change using geographical information systems is one method of describing impacts.

26.7.6. Dealing with Uncertainty

Uncertainties pervade all levels of a climate impact assessment, including the projection of future greenhouse gas emissions, atmospheric greenhouse gas concentrations, changes in climate, their potential impacts, and the evaluation of adjustments. There are two methods that attempt to account for these uncertainties: uncertainty analysis and risk analysis.

26.7.6.1. Uncertainty Analysis

Uncertainty analysis comprises a set of techniques for anticipating and preparing for the impacts of uncertain future events.

It is used here to describe an analysis of the range of uncertainties encountered in an assessment study.

26.7.6.2. Risk Analysis

Risk analysis deals with uncertainty in terms of the risk of impact. Risk is defined as the product of the probability of an event and its effect on an exposure unit. Since extreme events produce the most significant impacts, there is value in focusing on the changing probability of climatic extremes and of their impacts. Another form of risk analysis—decision analysis—is used to evaluate response strategies to climate change. It can be used to assign likelihoods to different climatic scenarios, identifying those response strategies that would provide the flexibility, at least cost (minimizing expected annual damages), that best ameliorates the anticipated range of impact.

26.8. Steps Six and Seven—Assessment of Autonomous Adjustments and Evaluation of Adaptation Strategies

Impact experiments are usually conducted to evaluate the effects of climate change on an exposure unit in the absence of any responses that might modify these effects and that are not already automatic or built in to future projections. Two broad types of response can be identified: mitigation and adaptation.

26.8.1. Mitigation and Adaptation

Mitigation or "limitation" attempts to deal with the causes of climate change. It achieves this through actions that prevent or retard the increase of atmospheric greenhouse gas concentrations by limiting current and future emission from sources of greenhouse gases and enhancing potential sinks. The evaluation of mitigation policies is outside the scope of these Guidelines.

Adaptation is concerned with responses to both the adverse and positive effects of climate change. It refers to any adjustment—whether passive, reactive, or anticipatory—that can respond to anticipated or actual consequences associated with climate change. It thus implicitly recognizes that future climate changes will occur and must be accommodated in policy.

26.8.2. Steps in Evaluation of an Adaptation Strategy

A broad framework for the evaluation of adaptation strategies to cope with climate change can be identified:

1) Define the objectives
2) Specify the climate impacts of importance
3) Identify the adaptation options
4) Examine the constraints
5) Quantify measures and formulate alternative strategies
6) Weigh objectives and evaluate tradeoffs
7) Recommend adaptation measures.

26.8.2.1. Defining the Objectives

Any analysis of adaptation must be guided by some agreed over-all goals and evaluation principles. Two examples of general *goals* commonly propounded are (i) the promotion of sustainable development and (ii) the reduction of vulnerability. These are open to various interpretations however, so specific objectives need to be defined that complement the goals. *Objectives* are usually derived either from public involvement, from stated public preferences, by legislation, through an interpretation of goals such as those stated above, or any combination of these.

26.8.2.2. Specifying the Climatic Impacts of Importance

This step involves an assessment, following the methods outlined elsewhere above, of the possible impacts of climate variability or change on the exposure unit. Where climatic events are expected that will cause damage, these need to be specified in detail so that the most appropriate adaptation options can be identified.

26.8.2.3. Identifying the Adaptation Options

The main task of assessment involves the compilation of a detailed list of possible adaptive responses that might be employed to cope with the effects of climate. The list can be compiled by field survey and interviews with relevant experts, and should consider all practices currently or previously used, as well as possible alternative strategies that have not been used, and newly created or invented strategies.

Six types of strategy for adapting to the effects of climate have been identified:

- *Prevention of loss*, involving anticipatory actions to reduce the susceptibility of an exposure unit to the impacts of climate
- *Tolerating loss*, where adverse impacts are accepted in the short term because they can be absorbed by the exposure unit without long-term damage
- *Spreading or sharing loss*, where actions distribute the burden of impact over a larger region or population beyond those directly affected by the climatic event
- *Changing use or activity*, involving a switch of activity or resource use to adjust to the adverse as well as positive consequences of climate change
- *Changing location*, where preservation of an activity is considered more important than its location, and migration occurs to areas that are more suitable under the changed climate
- *Restoration*, which aims to restore a system to its original condition following damage or modification due to climate.

Numerous options exist for classifying adaptive measures; but generally, regardless of the resources of interest (e.g., forestry,

wetlands, agriculture, water), the prospective list may include among other management measures the following:

- Legal
- Financial
- Economic
- Technological
- Public education
- Research and training.

26.8.2.4. Examining the Constraints

Many of the adaptation options identified in the previous step are likely to be subject to legislation or to be influenced by prevailing social norms, which may encourage, restrict, or totally prohibit their use. Thus, it is important to examine closely, possibly in a separate study, what these constraints are and how they might affect the range of feasible choices available.

26.8.2.5. Quantifying the Measures and Formulating Alternative Strategies

The next step is to assess the performance of each adaptation measure with respect to the stated objectives. It may be possible, if appropriate data and analytical tools exist, to use simulation models to test the effectiveness of different measures under different climatic scenarios. Historical and documentary evidence, survey material, or expert judgment are some other alternative sources of this information. Uncertainty analysis and risk assessment are also considered at this stage. This step is a prelude to developing strategies that maximize the level of achievement of some objectives while maintaining baseline levels of progress toward the remaining objectives.

26.8.2.6. Weighing Objectives and Evaluating Tradeoffs

This is the key evaluation step, where objectives must be weighted according to assigned preferences, then comparisons made between the effectiveness of different strategies in meeting these objectives. Standard impact accounting systems can be used in the evaluation. For example, a four-category system might consider (i) national economic development, (ii) environmental quality, (iii) regional economic development, and (iv) other social effects. Selection of preferred strategies then requires the determination of tradeoffs among the categories.

26.8.2.7. Recommending Adaptation Measures

The results of the evaluation process should be compiled in a form that provides policy advisors and decisionmakers with information on the best available adaptation strategies. This should include some indication of the assumptions and

uncertainties involved in the evaluation procedure, and the rationale used (e.g., decision rules, key evaluation principles, national and international support, institutional feasibility, technical feasibility) to narrow the choices.

CONTENTS

27.1. Introduction

This chapter is substantially different in focus from most of the preceding chapters on greenhouse gas (GHG) mitigation options. The preceding chapters focus on characterizing, from a global perspective, the full array of available mitigation options. This chapter instead addresses the analytical methods and processes for selecting and analyzing those mitigation options that best suit the specific needs, conditions, and national goals of individual countries. Its purpose is to help policy analysts and decisionmakers, especially in developing countries and countries with economies in transition, to obtain the objective information they need on mitigation options and to assist them in developing coherent national plans and strategies.[1]

This chapter is a summary of a broader set of mitigation guidelines entitled *Methods for Assessment of Mitigation Options*, which is being published as a separate appendix to this report. The chapter summarizes several key points from these guidelines:

- The broad challenges facing decisionmakers and analysts in conducting an effective mitigation options assessment
- The mitigation assessment process, including organizational issues and analytical steps
- Some of the key cross-cutting issues involved in the mitigation assessment process
- The range of analytical methods available to meet most countries' needs and capabilities.

The full guidelines in *Methods for Assessment of Mitigation Options* contain the following documents:

- **Technical Report**—A detailed examination of the methods and issues involved in an assessment of mitigation options and the development of national mitigation plans and strategies
- **Appendix I: Technical Methods**—A catalog of analytical methods, describing in detail their purpose, appropriate applications, potential drawbacks, and references for further information
- **Appendix II: Resources Guide**—A detailed reference guide to other climate-related studies and programs, including a guide to databases and analytical models commonly used for mitigation options assessments
- **Appendix III: Case Studies**—A set of case studies illustrating mitigation assessment processes and key analytical methods and approaches employed by different developing and transition countries
- **Appendix IV: Mitigation Assessment Handbook**—Detailed descriptions of a limited set of basic models that most countries could use in assessing their mitigation options.

As mentioned, the chapter focuses on the analytical needs of developing countries and countries with economies in transition. Because these countries have many other pressing national issues that take precedence over global-environment concerns, they often lack basic information and analytical capabilities for assessing mitigation options or organizing them into coherent national plans and strategies. For that reason, this chapter and its accompanying guidelines emphasize simple, readily available analytical methods and procedures (while not ignoring more sophisticated methods).

It should be pointed out that this chapter and the accompanying guidelines do not prescribe particular analytical methods or approaches to assessing mitigation options. Rather, the material presents a range of methods and approaches from which countries can select to meet their own needs and conditions. Developing countries and countries with economies in transition that need more practical assistance and support selecting and using these methods may be able to obtain such support through one of several multilateral and bilateral climate country-study programs being conducted.[2]

Before proceeding, it is worth defining a few key terms as they are used in this chapter:

- **Mitigation option**: A technology, practice, or policy that reduces or limits emissions of GHGs or increases their sequestration (This chapter does not consider measures to adapt to climate change.)
- **Mitigation options assessment**: The analytical process of identifying, selecting, and organizing mitigation options into a coherent national plan
- **Mitigation methods**: Analytical tools used to assess the impact and performance, costs and benefits, and social/political/institutional desirability of a mitigation option.

27.2. Challenges in a Mitigation Options Assessment

Before discussing specific methods or analytical steps, some of the broad challenges that analysts and policymakers face in organizing an assessment of mitigation options are worth noting. We have organized these into three broad categories:

- **Strategic challenges**: Strategic challenges affect the overall objectives of a mitigation options assessment and the process of selecting and implementing preferred options. Four strategic challenges stand out:
  - Integrating climate-change mitigation with other key national objectives which can require a clear set of national priorities, along with an analytical

---

[1] More specific information on methods for analyzing options that involve land-use changes—especially in the forestry and agriculture sectors, including biomass energy—is provided in Chapter 25.

[2] Climate country-study programs support developing countries and countries with economies in transition in developing national climate responses. A few examples include the UNEP/RISØ Climate Country Studies effort, the Asian Development Bank ALGAS project, and bilateral activities including those of the United States, Germany, Japan, and the Nordic countries.

process that consistently assesses options in light of these priorities

– Recognizing institutional constraints and deciding whether to fit a mitigation assessment process within these constraints or to seek additional institutional resources

– Relying on regional cooperation to address transboundary issues and to pool resources to lead to more effective assessments.

– Planning for future financing of mitigation options, particularly for developing and transition countries, and the role that the Global Environment Facility and others will play in providing these resources.

• **Analytical challenges**: Analytical challenges are those directly related to assessing mitigation options. Much of this chapter is about specific analytical issues, but analysts may face at least three broad challenges:

– Employing the appropriate analytical methods effectively to address the specific needs, conditions, and capabilities of a country

– Accommodating particularly dynamic economies and economies in transition in order to apply specific methods, especially forecasting, effectively

– Accounting for ancillary costs and benefits and efficiency and equity issues to enhance the acceptability of options.

• **Informational challenges**: Several informational challenges often must be addressed in conducting comprehensive mitigation options assessments:

– Gaining access to sources of information about technologies, costs, and country specific performance factors

– Extracting useful data or information from the sources that are available

– Accurately converting "imported" data or other information to properly reflect the operating conditions of the country in which the information is used.

27.3. Analytical Framework and Levels of Decisionmaking

We have chosen to organize the discussion of methods by national, cross-sectoral, sectoral, program, project, and technology decisionmaking levels, as illustrated in Figure 27-1. This framework is intended to reflect the links between different levels of an economy, the types of decisions made at those different levels, the information required to make those decisions, and, finally, the methods needed to obtain that information. Different organizational approaches are possible, but this framework highlights the importance of understanding the types of decisions to be made when selecting methods.

The four shaded levels in Figure 27-1 (i.e., the cross-sectoral, sectoral, program, and project levels) are the primary focus of this chapter. The national goals level—which addresses a country's national priorities and policies—is outside the

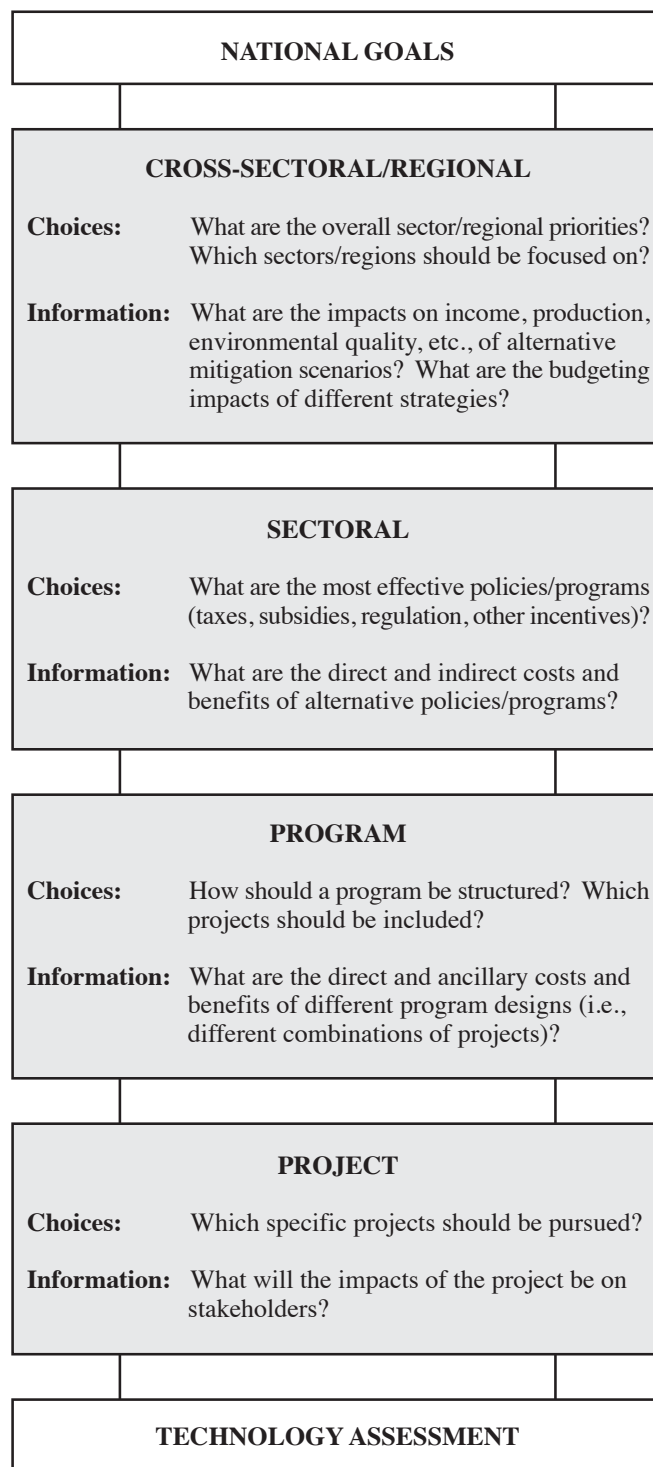
purview of this report, although clear priorities and policies contribute to the effectiveness of a mitigation options assessment. Additional information on methods and issues associated with setting national priorities and policies can be found in the IPCC Working Group III volume of the Second Assessment Report. The technology assessment level is covered by the other mitigation chapters in this report and the Technology Characterization Inventory appendix. The decisionmaking levels of direct concern are described below


Figure 27-1: Levels of decisionmaking for assessing mitigation options.

(more specific discussion of the methods themselves is contained in Section 27.6):

- **Cross-sectoral level**: At the cross-sectoral level, alternative sectoral and cross-sectoral (e.g., recycling) mitigation options are compared to determine their impact on an economy and other national interests or goals. Typically this involves compiling information on sectoral activities that produce GHGs, such as energy production, or sequester those emissions, such as forestry activities. This information is integrated with national goals and priorities, and resources and responsibilities are allocated to produce a comprehensive, workable plan. The types of methods used to assess and compare options at this level include macroeconomic models, decision-analysis tools, costing methods, and forecasting tools.

- **Sectoral level**: The sectoral level involves analysis to compare the impacts of individual programs or large-scale projects within a specific sector principally for the purpose of prioritizing options and determining sectoral resource requirements. For example, the emission reduction potential and cost per ton of carbon dioxide (CO_2) reduced might be compared for options such as energy-efficiency standards, building codes, and rebates on high-efficiency appliances. As in the cross-sectoral level, costing and forecasting tools are important, although they focus on more detailed program and project information. In addition, integrated analytical tools are becoming available for certain sectors such as energy and forestry that can compare relatively disparate options on a more common basis.

- **Program level**: Program-level analysis compares the costs and impacts of individual projects or bundles of projects for the purpose of developing mitigation programs. A program might consist of a series of projects to introduce improved forestry-management practices into a region. As in cross-sectoral and sectoral analysis, project costing and forecasting tools are important. Technology costing and performance, market research, and monitoring and evaluation tools also are important.

- **Project level**: At the project level, the purpose of analysis is typically to identify and characterize specific project options in terms of their financial costs, technical performance, environmental characteristics, and so forth. Identifying options may involve literature reviews, case studies, and expert judgment. Characterizing options often relies extensively on engineering estimates, performance assessments, and project evaluations, for example.

27.4. Organizing a Mitigation Options Assessment

27.4.1. *Organizational Steps*

A systematic approach to organizing an assessment process can contribute significantly to the quality and effective communication of results and effective implementation of recommended options. The approach can be developed by addressing four key questions:

- **How should assessment objectives be prioritized and who should be involved?** Mitigation options should be measured not only on the basis of their effectiveness in reducing GHGs but also on the basis of their contribution to other national objectives, such as sustainable development, rural development, or local environmental protection. Multiple stakeholders will be affected by these choices, so involving them in the process can be important.

- **What are the questions being answered by the analysis?** Effective decisionmaking requires the proper information; thus, mitigation analysis must focus on the proper questions. These questions will be defined broadly by national objectives but will vary depending on the decisionmaking level.

- **Which organizations will have institutional responsibility for the analysis?** Institutional capabilities are needed to gather data, select options to analyze, apply the necessary analytical methods, and communicate results. Key tasks involved in assigning the appropriate institutions to the assessment include identifying the available institutional resources, matching institutions to the research questions to be asked, coordinating among institutions, linking the analysis to the decisionmaking process, and designing feedback on the process to possible stakeholders.

- **Which organizations will have responsibility for implementing results?** Although the focus of this chapter is on methods for analysis of mitigation options, implementation issues cannot be completely separated in the discussion. Four factors to consider in the selection of options include the adequacy of implementation capabilities, institutional support for implementation, coordination of implementation, and evaluation and accountability.

27.4.2. *Analytical Steps*

Typically, a mitigation assessment process will follow a series of steps, each of which produces information for decisionmakers at different levels. The manner in which these steps are performed will reflect each country's resources, objectives, and decisionmaking process. Generally, these steps can be characterized as follows:

- **Baseline development**: Baselines, or "business-as-usual" scenarios, describe the growth in emissions expected as a result of economic growth, population growth, and other factors, assuming that no explicit mitigation policies are adopted.

- **Identification and characterization of alternative technologies and policies**: This may include ranking options with respect to costs, energy consumption, carbon sequestered, and ancillary impacts, among others.

- **Development of alternative scenarios**: Alternative scenarios include future projections of emissions [usually based on the global warming potential (GWP) of all GHGs] and costs, assuming that mitigation actions are taken.
- **Estimation of incremental costs and benefits of options**: Incremental costs and benefits are the difference between the baseline and alternative scenarios.
- **Assessment of the impacts of alternative GHG mitigation scenarios**: Impacts to consider could include macroeconomic, social, and environmental costs and benefits, and equity.
- **Sensitivity analysis**: The sensitivity of results to uncertainties in data or alternative assumptions is often assessed to ensure that the results are reliable and credible.

27.5. Key Methodological Issues

The choice and use of most analytical methods involve a number of methodological issues that decisionmakers and analysts should be aware of when considering a mitigation options assessment. Some of these issues are unique to certain methods, while others cut across many methods. This section outlines nine key methodological issues that span a number of methods:

1) **Top-down versus bottom-up analysis**: Significant controversy has existed between top-down and bottom-up approaches to estimating the costs of mitigation options. Each approach estimates mitigation costs differently, often with significantly different results. The top-down approach generally looks at macroeconomic impacts of alternative mitigation scenarios on income, consumption, or gross domestic product (GDP). A key assumption in the top-down approach is that economies are in equilibrium and that mitigating GHGs, therefore, generally entails some net cost to an economy. This assumption is often questioned by bottom-up analysts. Top-down models also have had problems accounting for different rates of technological change. The bottom-up approach looks at the microeconomic costs of and changes in demand due to individual mitigation options. It generally assumes that there are inefficiencies in the marketplace that allow for cost-effective mitigation options. Bottom-up models have had problems accounting for consumer behavior and administrative costs. In general, the top-down approach yields higher cost estimates for GHG mitigation than the bottom-up approach. Both approaches can serve important purposes, however, and improvements in both approaches are leading to more balanced results (Borero *et al.*, 1991; Krause *et al.*, 1993; UNEP, 1992). See IPCC Working Group III volume, Chapter 8, *Estimating Costs of Mitigating Greenhouse Gases,* Section 8.3.3., for a more thorough description of this issue.

2) **Matching method to objective**: Choosing the appropriate method for the analytical task depends on matching methods to objectives. For example, one objective for an expanding economy may be minimizing the impacts of GHG mitigation on the industrial sector. Sectoral impacts may be more appropriately measured using a macroeconomic analysis of options rather than an engineering cost approach. Alternatively, if an objective is to identify all technologies or policies that are cost-effective, a combination of engineering and cost-effectiveness methods may provide the best approach.

3) **Specifying the baseline and alternative scenarios**: Scenarios are used to portray future GHG emissions and economic activity without mitigation options in place (baseline or business-as-usual scenarios) or with policies in place (mitigation scenarios). Several issues in developing scenarios include the degree to which all sources and sinks are covered; the reasonableness of assumptions on economic growth, technology change, and market imperfections; the consistency of assumptions across analytical steps; and the capacity to incorporate feedbacks. Clearly defined scenarios are important for providing decisionmakers with useful guidance on the allocation of national resources. Scenarios also can play a significant role in the allocation of international funding for climate mitigation projects— for example, through the Global Environment Facility and through joint implementation projects.

4) **Accounting for uncertainty**: Most analyses are affected by uncertainty due to poor data quality, dynamic economies, economies with little historical market data, and so forth. Taking this uncertainty into account in estimating costs and impacts may be more practical than trying to achieve complete accuracy. This can be done by using "range" rather than "point" estimates, using expert judgment where good quantitative data are lacking, use of sensitivity analyses, and so on. Using these approaches will not eliminate uncertainty but will allow decisionmakers to attach greater confidence to those options and policies that yield favorable results (Stokey and Zeckhauser, 1978).

5) **Defining a common measure for comparing options**: A comprehensive and internally consistent assessment requires a common measure or "metric" for option comparison where different types of costs are involved or relevant impacts extend beyond the direct GHG reductions.

6) **Accounting for time in the analysis of costs and benefits**: The flows of costs and benefits from different mitigation options over time are often discounted to their present values so that they can be compared in consistent, present-value terms. The choice of discount rates has important implications but can be difficult to make in practice. Selection of a discount rate may depend on how displaced private uses are estimated, how imperfections in capital markets are

accounted for, and, perhaps most importantly, to what extent a country is willing to forgo current consumption and investment in favor of future environmental protection. Higher discount rates generally favor current consumption, while lower discount rates generally favor future environmental protection. Sensitivity analyses with different discount rates often are employed to estimate their different impacts (Stokey and Zeckhauser, 1978).

7) **Accounting for externalities and ancillary impacts**: Virtually every mitigation option will produce some positive or negative externality and/or ancillary impact. Whether quantifiable or not, these impacts represent real costs or benefits and should be factored into the assessment process.

8) **Data requirements**: A comprehensive mitigation assessment can require detailed information on literally hundreds of options. Few industrialized countries have access to all the data that would be required, but data availability is an even more serious constraint on developing countries. The cost of data collection is an important factor to weigh in developing a mitigation assessment.

9) **Understanding the limits of models**: Quantitative models, from simple spreadsheet costing models to sophisticated macroeconomic models, can be very useful for managing complex analytical tasks. However, the accuracy of the results from these models depends on the quality of data, the choice of assumptions, the appropriateness of the model to the analytical task, and so forth. All of these require good judgment and skill on the part of the analyst. The simple conclusion is that models are not a substitute for good analysis.

27.6. Analytical Methods

Table 27–1 illustrates the relationship between analytical methods and the different decisionmaking levels at which they are used. As shown, the same types of methods often are used at various decisionmaking levels (although the way methods are applied may be different at different levels). This section provides an overview of key analytical methods, including a brief description of the types of information the methods provide:

- **Macroeconomic analysis**: Macroeconomic analysis often is used to describe the current structure of an economy, to predict future economy-wide conditions and their impact on GHG emissions, and to analyze changes in these conditions that could arise from taking actions to mitigate GHG emissions (Borero *et al.*, 1991; Cline, 1992).
- **Decision analysis**: Decision-analysis methods provide a structure for integrating sectoral and cross-sectoral GHG mitigation objectives with other national priorities. Basic decision analysis involves identifying potential options, measuring the potential impacts of

those options (i.e., valuing the outcomes of various policy scenarios), and, based on this information, selecting the best options.

- **Costing analysis**: Mitigation costing methods estimate and compare costs and benefits of mitigation options to identify the set of actions that maximizes economic, social, and environmental benefits or minimizes the analogous costs of reducing GHGs. Four basic costing methods for ranking mitigation options are cost-benefit, cost-effectiveness, financial, and cost or supply curve analysis. More advanced methods include simulation and optimization models (Beaver and Huntington, 1991; Borero *et al.*, 1991; Cline, 1992; NAS, 1991; Stokey and Zeckhauser, 1978; UNEP, 1992, 1993). See the IPCC Working Group III volume for a detailed discussion of costing issues.
- **Forecasting**: The acceptability of a mitigation strategy, program, or project is determined by calculating the difference between "what would happen anyway" and "what would happen if mitigation measures were undertaken." The definition and development of these scenarios play a significant role in mitigation assessment. Forecasting is used here as a general term applied to methods used in developing time-dependent scenarios, such as econometric, time-series analysis, and end-use forecasting models.
- **Integrated planning**: Integrated planning approaches provide a structure for complex regional or sectoral assessments of multiple mitigation options. These methods typically are process or decision analytic-based and

Table 27-1: *Matching methods to decisionmaking levels.*

can be designed to produce both quantitative and qualitative results. A variety of quantitative methods can be used to support integrated planning. Integrated planning methods include integrated resource planning (IRP), used increasingly in the power sector; integrated transportation planning (ITP); and integrated forestry and agriculture planning (IIEC, 1994; Sathaye *et al.*, 1994). (For more information on integrated planning in forestry and agriculture, see Chapter 25.)

- **Market research**: Market research is an important analytical method in program design. Market research gathers information from prospective consumers of a particular product or service through focus groups, survey techniques, product testing, and so forth.

- **Monitoring and evaluation**: Mitigation programs and projects should be monitored and evaluated for their actual costs and impacts. The methods used often are the same used to assess a program or project in the first place, such as cost-effectiveness analysis and surveys. The key difference is the need to establish a monitoring and evaluation system during program or project design. This information can help determine whether initial objectives or targets are being achieved, how the program or project can be redesigned to improve results, and how future projects should be designed.

- **Options identification**: Many different mitigation options are available, as this report demonstrates. The analyst needs to identify those options that are most likely to suit the needs and conditions of his or her country. Typically, options are screened against a series of criteria such as technological maturity, commercial availability, and technical performance. Information on potentially suitable options can come from case studies, literature reviews, general opportunity studies, and the judgment of specialized experts.

- **Options characterization**: Once data have been obtained on specific mitigation options, a system is needed for characterizing options to ensure that the data obtained can provide usable information. A variety of methods are available to analysts, including cost curve analysis, estimates of tons of GHG avoided, and engineering assessments.

27.7.   Conclusions

The information in this chapter and the accompanying technical documents provide a cross-section of the large body of knowledge and experience available to analyze mitigation options. The information demonstrates that:

- Methods are available to analysts and decisionmakers at different levels of government to assess technology and policy options to mitigate GHGs from all significant sources, as well as their sequestration by sinks. These methods address the energy, industry, transportation, agriculture, and forestry sectors.

- Analytical, technical, and institutional resources are available from many multilateral and bilateral organizations to assist developing countries and countries with economies in transition in assessing mitigation options and strategies. Other economic development assistance programs that support investment decisions in energy production and end-use efficiency, forestry management, transportation, and agriculture also may demonstrate ancillary GHG emission mitigation benefits.

- Mitigation analyses have been and are being applied in developed, developing, and transitional-economy countries. These experiences demonstrate that appropriate mitigation assessment methods can be applied to meet the individual needs and conditions of all countries.

As a result of the available information and the many international and national efforts to assess projects, programs, and national mitigation strategies—as described in more detail below—it is possible to conclude that:

- The availability of mitigation methods and assistance enables all countries to develop strategies and evaluate programs and projects that support national economic, social, and institutional development goals and can slow the rate of growth in GHG emissions. The process of conducting a mitigation options assessment presents challenges to all countries. Projects identified in assessments may be difficult to implement because of a variety of economic, social, and institutional barriers in all countries.

- Development and application of mitigation assessment methods in all sectors and at all levels is an ongoing effort that will result in further improvements in the tools and the capabilities of countries to assess mitigation options. The IPCC, in coordination with other multilateral institutions, could accelerate the dissemination of selected information on assessment methods through seminars, workshops, and educational materials.

Methods are available for assessing mitigation options: The total body of information and other resources available internationally on analytical methods is indeed extensive:

- The technical report accompanying this chapter identifies more than 40 often-used methods for analyzing mitigation options. Many more exist that can address specific issues or adapt to different levels of analytical capability. The technical report also provides countries with approaches for organizing a mitigation options assessment, from identifying national goals to estimating the costs of specific technology options. As with specific analytical methods, assessment processes can take many different forms, depending on the country's needs and conditions.

- From the accompanying appendices, countries also can obtain:
  - More detailed information on the actual application of many of the key methods, including information on appropriate uses for the different methods, potential pitfalls, and where to obtain further assistance
  - See how mitigation options analyses have been conducted in four case studies, ranging from actual experiences with mitigation costing techniques to the mitigation planning process of an individual developing country
  - Obtain step-by-step instructions in developing a mitigation plan using a well-defined set of analytical tools and planning approaches
  - Learn about the many mitigation assessment activities being conducted by other countries and international institutions.

Analytical and technical resources are available to support mitigation analysis. Experience demonstrates that methods are available and appropriate: The fact that mitigation analyses are being conducted in many types of countries and that resources are available to assist countries with their needs is demonstrated by the following:

- The United Nations Environment Programme (UNEP) and the United Nations Development Programme (UNDP) provide support to about twenty-nine developing countries to coordinate climate country studies that include mitigation options assessments. Additional countries are expected to be added. The assessments developed through these studies will provide models of different mitigation strategies, including least-cost mitigation strategies, that other countries will be able to follow.
- The UK, Germany, the Netherlands, and the United States together will have supported more than seventy-five climate country studies in developing countries and countries with economies in transition. (The total number of countries involved is somewhat fewer due to overlap.) Many of these studies are developing mitigation strategies as one component. It is also noteworthy that a number of the studies place significant emphasis on developing local institutional and analytical capabilities to assess and implement mitigation options.
- The pilot phase of the Global Environment Facility allocated about $250 million for more than thirty global-warming mitigation projects. These funds were leveraged with additional World Bank and bilateral assistance funds. These projects will soon begin to yield a wealth of information and practical experience with different approaches to mitigating GHGs.

Inventory of Technologies, Methods, and Practices

DAVID G. STREETS, USA

Principal Lead Authors:
W.B. Ashton, USA; K. Hogan, USA; P. Wibulswas, Thailand; T. Williams, USA

CONTENTS

28.1. Introduction

The inventory is a database containing information on technologies, methods, and practices that can help to limit emissions of greenhouse gases. The inventory contains information on performance characteristics and applications, capital and operating costs, environmental characteristics (including emissions of greenhouse gases), and infrastructure requirements. The information is compiled in a two-page, standardized format for each technology. The inventory contains information on 105 technologies, including energy supply technologies (44), energy end-use technologies (47), agricultural and forestry practices (12), and other techniques (2). Table 28-1 lists all the technologies in the inventory. The inventory is published as an appendix volume to the Second Assessment Report.

The rationale for the inventory is straightforward. As the global climate change debate shifts toward studying the need for action, it is increasingly important for energy and environmental planners to have access to technical and economic information on the options that are available to reduce emissions and mitigate climate change. This information should be current, consistent, reliable, and widely available. In some countries, very good technology data and sophisticated analytical tools already exist. Often, however, information available from national or regional studies cannot be directly compared or adapted to new conditions because it has been collected in different formats or is based on different assumptions. Some countries, particularly developing and newly industrializing countries, lack sufficient resources to explore the benefits of these technologies on their own. In these cases, planners may rely on data of uncertain provenance, which can lead to unbalanced assessments of technology options, questionable data quality, and, ultimately, poorly informed investments. The need for wide access to a standardized data set drove the assembly of this inventory.

The inventory is designed for use by planners and analysts needing to evaluate options for reducing greenhouse gas emissions that are potentially attractive for near- and medium-term applications (say, the next 5–15 years). Some applications for which the inventory would be well suited are:

- Selection of technological options for use in different parts of the world
- National or regional economic development planning
- National or regional studies of greenhouse-gas emission reduction policies
- Macroeconomic analyses of large-scale climate change mitigation policies.

Although the inventory can be of value in prescreening technological options for specific applications, it is *not* intended to support the following types of studies:

- Engineering design or installation studies
- Site-specific applications
- Detailed technology transfer evaluations.

The inventory does not make any recommendations concerning specific types of technological systems or vendors.

Information on experience with advanced technologies in industrialized countries has been supplemented with information on applications of these technologies in developing countries. As the inventory develops, the aim is to increasingly make it a global resource and make its ownership world-wide. In the interim, users may replace inappropriate data elements with country-specific information that meets their local needs. In the longer term, the inventory will be made available to users in a computerized version. The software will provide guidance and data to permit conversion of data elements, especially costs, to local conditions. The inventory will be improved and extended in the future as a result of applications studies, such as the U.S. Country Studies Program, and government reviews of the material presently included. These additional items will include greater regional discrimination of data ranges, efficiencies achieved in recent practice, and comparative indications of development status.

The following section includes three examples illustrating the type of information contained in the inventory. The format of information for each technology in the inventory follows the outline provided in Table 28-2.

28.2. Emission Reduction Technologies

Carbon dioxide is emitted in large quantities by human activities, mostly as a result of combustion of fossil fuels and vegetation. Many techniques have been demonstrated to limit emissions of carbon dioxide from fuel-burning activities by improving the efficiency with which stored energy is converted to useful energy. The inventory characterizes many such approaches that have higher energy supply efficiencies than conventional systems. These approaches cover direct energy production in the industrial sector, as well as electricity generation, transmission, and distribution. Some of the technologies described are particularly suitable for the kinds of fuel resources, energy demands, and infrastructure found in developing countries. Appropriate technologies for developing countries, such as efficient cook stoves, are included in the inventory. Additionally, energy supply technologies that can replace fuel-burning technologies and essentially eliminate the direct production of carbon dioxide are described. Emphasis is placed on renewable energy supplies (biomass, solar, hydro, and wind energy). However, because some industrializing countries are considering nuclear energy as an option to meet electricity demand without adding to carbon dioxide emissions, several advanced nuclear energy options are included.

A range of technologies can improve the efficiency with which energy is consumed in various applications. Energy end-use technologies for buildings, transportation, and industry are included. Many of these technologies can provide substantial improvements in energy efficiency over conventional approaches, and the capital investments often can be recovered

Table 28-1: *List of technologies contained in the inventory.*

A. Energy Supply—Fossil Fuel Technologies
A.1   Atmospheric Fluidized-Bed Combustion (AFBC)
A.2   Coal Beneficiation
A.3   Coal-Water Mixtures
A.4   Combined Cycle
A.5   Combustion Turbines
A.6   Diesel Cogeneration
A.7   Fuel Cells
A.8   Industrial Cogeneration
A.9   Gas/Oil-Fired Steam Units
A.10   Integrated Gasification Combined Cycle (IGCC)
A.11   Inter-cooled Steam Injected Gas Turbine (ISTIG/STIG)
A.12   Pressurized Fluidized-Bed Combustion (PFBC)
A.13   Pulverized Coal-Fired Power Plant
A.14   Slagging Combustors
A.15   Oil and Natural Gas: Reduced Venting and Flaring of
       Gas during Production
A.16   Oil and Natural Gas: Improved Compressor Operations
A.17   Oil and Natural Gas: Improved Leak Detection and
       Pipeline Repair
A.18   Oil and Natural Gas: Low-Emission Technologies and
       Practices
A.19   Coal Mining: Enhanced Gob Well Recovery
A.20   Coal Mining: Pre-Mining Degasification
A.21   Coal Mining: Integrated Recovery

B. Energy Supply—Renewable Energy Technologies
B.1   Biomass-Fired Power Generation
B.2   Flat-Plate Photovoltaics
B.3   Geothermal Electric
B.4   Municipal Solid Waste (MSW) Mass Burn
B.5   Pelletized Biomass Combustion
B.6   Biogas by Anaerobic Digestion
B.7   Small-Scale Hydro
B.8   Solar Ponds
B.9   Solar Thermal Electric-Parabolic Trough
B.10   Solar Thermal Electric-Central Receiver
B.11   Solar Thermal Electric-Parabolic Dish/Stirling Engine
B.12   Wind Energy Conversion Systems
B.13   Tidal Energy
B.14   Ocean Wave Energy
B.15   Landfills: Gas Recovery and Utilization Techniques

C. Energy Supply—Nuclear Technologies
C.1   Light Water Reactors
C.2   Heavy Water Reactors
C.3   Liquid Metal Fast Reactors
C.4   Gas-Cooled Reactors

D. Energy Supply—Energy Transfer Technologies
D.1   Efficient Electrical Transformers
D.2   Electric Transmission and Distribution Systems
D.3   Thermal Energy Storage Systems
D.4   High-Voltage Direct-Current Transmission

E. Energy End-Use—Transportation Technologies
E.1   Advanced Signalization
E.2   Battery Electric Vehicles (EVs)
E.3   Compressed Natural Gas (CNG) Vehicles
E.4   Continuously Variable Transmission (CVT)
E.5   Direct-Injection Diesel Engines
E.6   Efficient Jet Aircraft
E.7   Efficient Tires
E.8   Ethanol Vehicles

E.9   Fuel-Cell Electric Vehicles (FCVs)
E.10   Two-Stroke Spark-Ignition Engines
E.11   Urban Transit Systems

F. Energy End-Use—Buildings Technologies
F.1   Adjustable Speed Electric Motor Drives
F.2   Advanced Insulation: Gas Filled Panels
F.3   Compact Fluorescent Lights
F.4   Electronic Ballasts
F.5   Efficient Electric Motors
F.6   Efficient Refrigerators
F.7   Energy Management Systems (EMS)
F.8   Glazing: Daylight Control
F.9   Glazing: Insulating
F.10   Glazing: Solar Control
F.11   Glazing: Switchable
F.12   Heat Pump Water Heaters
F.13   High-Albedo Materials
F.14   Landscaping
F.15   Lighting Controls
F.16   Room Air Conditioners (Window-Type)
F.17   Solar Domestic Water Heaters
F.18   Efficient Cooking Stoves

G. Energy End-Use—Industrial Technologies
G.1   Anaerobic Biological Treatment of Waste
G.2   Biofiltration of Gases
G.3   Cement Particle High-Efficiency Air Classifiers
G.4   Ceramic Recuperators
G.5   Continuous Pulp Digesters
G.6   Continuous Steel Casters
G.7   Distillation Control Systems
G.8   Electric Motors Variable Speed Drives—Industrial
G.9   Gas Membrane Separators
G.10   Heat Exchanger Enhancement Techniques
G.11   High-Efficiency Welding Power Supply
G.12   Mechanical Dewatering
G.13   Metal Parts Cleaning
G.14   Pinch Technology
G.15   Pipe Cross Reactors
G.16   Plating Waste Concentrators
G.17   Pulse Combustion Boilers
G.18   Textile Dyeing Vacuum System

H. Agricultural and Forestry Practices
H.1   Reduction in Use of Nitrogen Fertilizer and Animal Manure
H.2   Reduction in Tillage of Agricultural Soils
H.3   Reforestation/Afforestation and Prevention of Deforestation
H.4   Increasing Efficiency/Intensity of Forest Management
H.5   Substitution of Fossil Fuels with Sustainably-Grown
       Fuelwood
H.6   Increasing Agroforestry Endeavors
H.7   Livestock: Improved Nutrition/Mechanical and
       Chemical Feed Processing
H.8   Livestock: Improved Nutrition/Strategic Supplementation
H.9   Livestock: Production-Enhancing Agents
H.10   Livestock Manure: Covered Lagoons
H.11   Livestock Manure: Small-Scale Digesters
H.12   Livestock Manure: Large-Scale Digesters

I. Other Techniques
I.1   Landfills: Reducing Landfilling of Waste
I.2   Wastewater Treatment

rapidly through energy cost savings and lower operating and maintenance costs. Improved products or better energy services often are ancillary benefits. In many cases, the technologies are easily transferred to developing countries and simple to install and use. The reduction in greenhouse gas emissions that can be gained through the use of higher efficiency end-use technologies depends on the type of fuel used to produce the displaced energy and the efficiency of the primary energy conversion process.

Although research is underway on a variety of techniques for capturing carbon dioxide once it has been produced and then utilizing it or disposing of it, such systems are not included in this inventory because they are not likely to be of significant commercial potential in the near- to medium-term time frame of this inventory.

Methane is emitted from a diverse set of human-related activities that currently represent about 70% of global emissions. Importantly, methane emissions from these activities represent the waste of a valuable fuel; the methane often can be recovered under conditions where the saved fuel justifies the investment. Sixteen currently available technologies and practices are identified and characterized in the inventory. These technologies

and practices have been demonstrated to use otherwise wasted methane profitably, have been implemented to some extent already, and could be implemented on a much more widespread basis. They are economically viable under a range of conditions, represent different levels of technical complexity and capital needs, and should be adaptable to a wide variety of country conditions. Furthermore, these technologies and practices are generally attractive options because of the many other benefits that they provide—benefits that are consistent with the development goals of many countries.

The inventory contains characterizations for a range of major methane sources that spans energy and agricultural activities covering about 70% of anthropogenic emissions: natural gas systems, coal mining, waste disposal, wastewater treatment, and domesticated livestock. Efforts still are required to develop and demonstrate options for reducing methane emissions from rice cultivation and biomass burning, and therefore these methane sources are not reflected in the inventory at present. The latest research efforts in these areas have been documented by the U.S./Japan Working Group on Methane (1992).

28.2.1. Example 1: Energy Supply—Fossil Fuel Technologies

Pressurized Fluidized-Bed Combustion

Pressurized fluidized-bed combustion (PFBC) is an advanced technology for burning coal that offers high thermal efficiency and low environmental emissions. The system operates at pressures of 6–16 atmospheres and typically utilizes smaller combustion chambers than a conventional furnace because of its more efficient steam production. Due to its high thermal efficiency, PFBC can reduce the quantity of carbon dioxide emitted per unit of energy produced. Therefore, it is a potentially useful technology for mitigating emissions generated in the production of electricity. The inventory identifies the anticipated size of commercial PFBC units (200–400 MW$_e$), their application (electric power generation), and the fuels that can be used. Performance measures of the technology are provided in terms of the operating thermal efficiency of current demonstration plants (33–42%) and of projected second-generation plants (45–50%).

The capital cost of current demonstration plants ($1900–$3200/kW) is compared with the expected costs of a mature, commercial unit (about $1500/kW) and a second-generation plant (about $1000/kW). Nonfuel operating and maintenance costs range between 2.0 and 2.5¢/kWh. Fuel costs can range anywhere between 2.2 and 34¢/kWh, depending on the type of fuel chosen. The environmental performance of PFBC is very good; it generates relatively small quantities of solid waste, which can be safely landfilled or sold as a byproduct, and it produces low emissions of sulfur dioxide and nitrogen oxides. Most importantly for global climate change, emissions of carbon dioxide are estimated to be in the range of 930–1060 g CO_2/kWh, lower than conventional pulverized coal plants. Labor requirements to operate a PFBC plant (25–89, depending on size) and to maintain it (40–60) are presented, together with relevant

information on infrastructure requirements, such as the need for connection to an electricity transmission grid.

28.2.2.   Example 2: Energy End-Use Technologies

Compact Fluorescent Lights

Compact fluorescent lights are three to four times more energy efficient than incandescent bulbs and last ten times as long. They can therefore reduce the amount of electricity required to deliver a given amount of lighting. The reduction in carbon dioxide emissions will depend on the fuel used to generate the electricity. Compact fluorescent units are available with screw-in adaptors for use in incandescent lamp fixtures or as dedicated fixtures. Compact fluorescents also are available as integrated lamp/ballast/adapter units; however, since the ballasts typically outlive the lamps, integration of ballast and lamp results in the ballast being discarded before the end of its useful life. Lower wattage twin tubes cost about $5 per lamp. The more luminous quad tubes cost about $9 per lamp. Integrated units cost about $15–25 per lamp. Utility rebates in the range of $4–15 per lamp typically are available in the U.S.

Compact fluorescent lights are slightly bigger and heavier than incandescent bulbs. Thus, they may not be a suitable replacement in every application. Performance suffers in tight fixtures, and under-lit spaces may result if thermal effects are not considered in system planning. Preheat lamps have a 1- to 2-second delay before lighting, although rapid-start systems are becoming available.

28.2.3.   Example 3: Energy Supply—Renewable Energy Technologies

Landfills: Gas Recovery and Utilization Techniques

Recovering gas from landfills reduces methane emissions and allows the energy value of the recovered methane to be used profitably. The recovery technologies are relatively straightforward: Gas wells are drilled into an area of disposed waste, and collection systems are installed. These systems typically recover 50–85% of the gas generated. The recovered gas is about 50% methane, a medium-Btu fuel. It typically requires some processing to remove particulate matter, water, and corrosive compounds. The costs of the technology depend on the costs for recovery systems, labor, and utilization systems. Landfill gas recovery provides additional benefits in the form of reduced explosion hazard and protection of local air and water quality. The best opportunities are for large waste-disposal sites that have a nearby demand for medium-quality fuel.

28.3.   Other Technology Inventories

Several other initiatives are under way aimed at gathering and disseminating information on technologies for limiting greenhouse gas emissions or increasing greenhouse gas uptake. Efforts will be made to coordinate this inventory with these other systems.

The Environmentally Compatible Energy Strategies (ECS) Project at the International Institute for Applied Systems Analysis in Laxenburg, Austria, has developed a comprehensive inventory of technological options for mitigating and adapting to possible global warming (Schafer *et al*., 1992). The supporting data base, CO2DB, contains detailed descriptions of the technical, economic, and environmental performance of approximately four hundred technologies. Efficiency improvements, conservation, enhanced use of low-carbon fuels, carbon-free sources of energy, afforestation, and enhancement of carbon sinks are included.

At the Forschungszentrum Julich GmbH in Germany, the IKARUS Project has been involved in the development of computer models and a database for comparing strategies for reducing the energy-related emissions of greenhouse gases, particularly carbon dioxide (Katscher, 1993). The technology database in the IKARUS system contains basic technical, economic, and environmental data on individual technologies that can be used to construct technology chains and feed to sector-specific simulation models. The goal is to be able to assess mitigation possibilities for the German energy system in 1989, 2005, and 2020.

The International Energy Agency (IEA) has two related activities. The IEA established the Centre for the Analysis and Dissemination of Demonstrated Energy Technologies (CADDET), an Implementing Agreement that offers an international network to exchange information on demonstrations of energy-saving end-use technologies for all energy consumers (IEA, 1991). CADDET maintains *The CADDET Register*, a computerized database providing information on international energy demonstration projects. Also, the IEA has implemented the Energy Technology Systems Analysis Programme (ETSAP), an Implementing Agreement that also distributes technology information to IEA member countries (IEA, 1992).

An interagency joint project on databases and methodologies for comparative assessment of different energy sources for electricity generation (DECADES) has been established by the International Atomic Energy Agency (IAEA), in collaboration with several other international organizations, with the objective of enhancing capabilities for incorporating health and environmental issues in the comparative assessment of different electricity generation chains and strategies (IAEA, 1995). The DECADES project includes a technology inventory that characterizes energy chains for electricity generation from fuel extraction to waste management, as well as an information system that provides user-oriented access to electronic databases.

28.4.   Obtaining a Copy of the Inventory

Copies of the inventory may be obtained by contacting the Convening Lead Author or through the U.S. Country Studies

Program. The Convening Lead Author may be contacted at the following address:

Appendix B

GLOSSARY OF TERMS

acclimatization
physiological adaptation to climatic variations

active layer
the top layer of soil in permafrost that is subjected to seasonal freezing and thawing

adaptability
the degree to which adjustments are possible in practices, processes, or structures of systems to projected or actual changes of climate; adaptation can be spontaneous or planned, and can be carried out in response to or in anticipation of changes in conditions

afforestation
forest stands established artificially on lands that previously have not supported forests for more than 50 years

agroclimatic
climatic conditions as they relate to agricultural production; discrete set of zones each of which identifies areas capable of like types and levels of agricultural production

airshed
the mass of air associated with a usually enclosed or otherwise bounded area, like a cove or valley

albedo
the surface reflectivity of the globe

algal blooms
a reproductive explosion of algae in a lake, river, or ocean

alpine
the biogeographic zone made up of slopes above timberline and characterized by the presence of rosette-forming herbaceous plants and low shrubby slow-growing woody plants

anaerobic
living, active, or occurring in the absence of free oxygen

anaerobic digestion
fermentation processes conducted in the absence of oxygen

anthropogenic
caused or produced by humans

anticyclone system
a system of winds that rotates about a center of high atmospheric pressure (clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere)

aquifer
a stratum of permeable rock that bears water

arbovirus
any of various viruses transmitted by arthropods and including the causative agents of dengue fever, yellow fever, and some encephalitis

arid lands
ecosystems with <250 mm precipitation per year

autonomous adaptation
adaptation that occurs without specific human intervention

bagasse
the dry, fibrous residue remaining after the extraction of juice from the crushed stalks of sugar cane; used as a source of cellulose for some paper products and as a source of energy

ballast
a device that takes electricity from the line and transforms that electricity to the proper current and voltage for starting and operating a fluorescent lamp

baseline scenario
the set of predicted levels of economic growth, energy production and consumption, and greenhouse gas emissions assumed as the starting point for an analysis of mitigation options

baseload
that part of total energy demand that does not vary over a given period

biodiversity
the number of different species or functional groups of flora and fauna found in an area or ecosystem

biofuels
fuels obtained as a product of biomass conversion (e.g., alcohol or gasohol)

biogas
a gas composed principally of a mixture of methane and carbon dioxide produced by anaerobic digestion of biomass

biogeography
the study of the geographical distribution of living organisms

biomass
the total quantity of living matter in a particular habitat; plant and organic waste materials used as fuel and feedstock in place of fossil fuels

biome
a grouping of similar plant and animal communities into broad landscape units that occur under similar environmental conditions

bottom-up modeling
a modeling approach that arrives at economic conclusions from an analysis of the effect of changes in specific parameters on narrow parts of the total system

breeder reactor
a reactor that produces from a non-fissile material a fissile material (e.g., plutonium) identical to the one it consumes and in greater quantity (i.e., the ratio of fissile material by material consumed is greater than unity)

building stock
the residential and/or commercial structures extant in a society or a geographic area

busbar
conductor for collecting and distributing electric current; frequently used to denote electricity generation output, capacity, or generating costs of power plants at output or capacity rates of electricity delivered to the busbar

C_3 plants
plants that produce a three-carbon compound during photosynthesis, including most trees and agricultural crops such as rice, wheat, soybeans, potatoes, and vegetables

C_4 plants
plants that produce a four-carbon compound during photosynthesis; mainly of tropical origin, including grasses and the agriculturally important crops maize, sugar cane, millet, and sorghum

calcining
the heating of calcium carbonate to high temperatures to thermally decompose it into carbon dioxide and calcium oxide

calving
the breaking away of a mass of ice from a floating glacier, ice front, or iceberg

CAM
variant of the C_4 photosynthetic pathway in which most gas exchange occurs at night; occurs primarily in succulents (e.g., cacti)

carbon intensity
CO_2 emissions per unit of energy or economic output

carbon sequestration
the biochemical process through which carbon in the atmosphere is absorbed by biomass such as trees, soils, and crops

carbon sinks
chemical processes that absorb carbon dioxide

carbon stocks
the amount of carbon that is stored in carbon sinks

carbon tax
a levy exacted by a government on the use of carbon-containing fuels for the purpose of influencing human behavior (specifically economic behavior) to use less fossil fuels

carrying capacity
the number of individuals in a population that the resources of a habitat can support

catchment
area having a common outlet for its surface runoff

catotelm
the layers of peat generally not subjected to oxic conditions; also called peat proper

Chagas' disease
a parasitic disease caused by the *Trypanosoma cruzi* and transmitted by triatomine bugs in the Americas, with two clinical periods: Acute (fever, swelling of the spleen, edemas) and chronic (heart disorder that may produce high fatality, or digestive syndrome)

CO_2 fertilization
the enhancement of plant growth as a result of elevated atmospheric CO_2 concentration

coefficient of performance
the ratio of useful thermal energy output per unit of energy input; a measure of the thermal efficiency of an energy-conversion device

cogeneration
production of electricity and heat, both as main output, by a combined process (combined heat and power) from energy sources (e.g., from coal, oil, gas, or nuclear power) in an installation such as a thermal plant or block heating station

combined cycle
electricity generation using one or more gas-turbine generator units whose exhaust gases are fed to a waste-heat boiler, which may or may not have a supplementary burner; the steam raised by the boiler is used to drive one or more steam-turbine generator units

communicable disease
infectious disease caused by transmission of an infective biological agent (virus, bacterium, protozoan, or multicellular macroparasite)

consumer surplus
a measure of the value of consumption beyond the price paid for the goods

converter reactor
a device in which a self-sustaining nuclear fission chain reaction can be maintained and controlled (fission reactor)

cryosphere
all global snow, ice, and permafrost

decarbonization
reduction of carbon intensity of an energy process or a system

demand-side management
any activity designed to alter the customer's timing or use of electricity, natural gas, or other energy form; such actions are designed to control the demand upon that utility by manipulating the consumers' use of electricity to limit electricity usage during peak periods, shift usage from demand peaks to demand valleys, build load, conserve overall energy usage, and/or otherwise change the demand placed upon the utility

dematerialization
decreasing the amount of a material employed in a product by employing a design that exercises economy in material usage or by substituting a lighter material for the original

Dengue fever
an infectious viral disease spread by mosquitoes, the first infection of which is often called breakbone fever and is characterized by severe pain in joints and back, fever, and rash; a subsequent infection is usually characterized by fever, bleeding from bodily orifices, and sometimes death

desert
an ecosystem with <100 mm precipitation per year

diapause
period of suspended growth or development and reduced metabolism in the life cycle of many insects, when organism is more resistant to unfavorable environmental conditions than in other periods

digestor
a tank designed for the anaerobic fermentation of biomass; a vessel in which substances are softened or decomposed, usually for further processing

disposable income
the amount of income available for consumers to spend on discretionary items

dissolved load
the amount of particles in a stream or other water source that arises as a result of erosion

district heat
thermal energy transmitted through pipelines in the form of heated water or steam to point of consumption

diurnal climate
a climate with uniform amplitudes of temperature throughout the year

econometric
an approach to studying a problem through use of mathematical and statistical methods in the field of economics to develop and verify theories

economies in transition
national economies that are moving from a period of heavy government control toward lessened intervention, increased privatization, and greater use of competition

ecotax
a levy exacted by a government for the purpose of influencing human behavior (specifically economic behavior) to follow an ecologically benign path

ecotone
transition area between adjacent ecological communities (e.g., between forests and grasslands), usually involving competition between organisms common to both

ecotopic
tendency or involving adjustment to specific habitat conditions

edaphic
of or relating to the soil; factors inherent in the soil

El Niño
an irregular variation of ocean current that, from January to February, flows off the west coast of South America, carrying warm, low-salinity, nutrient-poor water to the south; does not usually extend farther than a few degrees south of the Equator, but occasionally it does penetrate beyond 12°S, displacing the relatively cold Peruvian current; usually short-lived effects, but sometimes last more than a year, raising sea-surface temperatures along the coast of Peru and in the equatorial eastern Pacific Ocean, having disastrous effects on marine life and fishing

embodied energy
the energy (natural gas, oil, coal, etc.) that is required to produce a manufactured good and that is thereby included in the finished product or service

emission factor
a coefficient that relates actual emissions to activity data as a standard rate of emission per unit of activity

endemic infection
a sustained, relatively stable, pattern of infection within a specified population

energy conversion
energy transformation with a change in the form of energy

energy efficiency
ratio of energy output of a conversion process or of a system to its energy input; also known as first-law efficiency

energy intensity
ratio between the consumption of energy to a given quantity; usually refers to the amount of primary or final energy consumed per unit of gross domestic or national product

energy service
the application of useful energy to tasks desired by the consumer such as transportation, a warm room, or light

energy transformation
production of energy involving no change in the physical state of the form of energy

engineering cost
the direct materials and labor costs associated with projects; these estimates are used in assessments of the economic feasibility of mitigation projects

enhanced oil recovery
advanced methods for recovering oil from reservoirs in addition to that recoverable by conventional primary and secondary recovery methods; enables larger proportion of oil *in situ* to be exploited from a reservoir

enthalpy
energy content per unit mass

epidemic
appearance of an abnormally high number of cases of infection in a given population; can also refer to noninfectious diseases (e.g., heart disease) or to acute events such as chemical toxicity

eutrophication
the process by which a body of water (often shallow) becomes (either naturally or by pollution) rich in dissolved nutrients with a seasonal deficiency in dissolved oxygen

evapotranspiration
loss of water from the soil both by evaporation from the surface and transpiration from the plants growing thereon

exergy
the maximum amount of energy that under given (ambient) thermodynamic conditions can be converted into any other form or energy; also known as availability or work potential

exergy efficiency
the ratio of (theoretical) minimum exergy input to actual input of a process or a system; also known as second-law efficiency

fallow
land left unseeded after plowing; uncultivated

fast ice
sea or lake ice that remains tied to the coast (usually less than 2 m above sea level)

feedback
when one variable in a system triggers changes in a second variable that in turn ultimately affects the original; a positive feedback intensifies the effect, and a negative reduces the effect

feedstock
raw material (e.g., oil products or natural gas) used as input into industrial processes for manufacturing of materials or consumer goods (e.g., plastics, fertilizer, etc.); energy feedstocks are often included in total energy consumption even though they represent so-called non-energy consumption

final energy
the energy supplied to the consumer to be converted to useful energy (e.g., electricity at the socket, gasoline at the service station, or fuelwood in the barn); sometimes also called available energy, but the term should be avoided due to possible confusion with availability or exergy

first-law efficiency
see energy efficiency

fluidized bed
a bed of fuel and non-combustible particles set in vigorous, turbulent motion by the combustion air blowing upward throughout the bed; the non-combustible particles are generally coal ash or a sulfur-absorbent (acceptor) such as limestone

fluidized bed combustion
a method of burning a fuel with non-combustible particles in a state of suspension by the upward flow of the combustion air through the fluidized bed

fly-ash
the mineral content of coal released as particulate matter upon its combustion

food calorie
1000 (technical) calories

forest
an ecosystem in which the dominant plants are trees; woodlands are distinguished from forests by their lower density of trees

forestation
generic term for establishing forest stands by reforestation and afforestation

forest decline
premature, progressive loss of tree and stand vigor and health

frazil ice
fine spicules or plates of ice in suspension in water

fuel cells
devices for the conversion of chemical energy to electrical energy

general equilibrium analysis
an approach that considers simultaneously all the markets in an economy, allowing for feedback effects between individual markets

geomorphic
of or related to the form of the Earth or its surfaces

germ plasm
the reproductive cells of an organism, in particular the portion of the cells involved in heredity

greenhouse gas
any gas that absorbs infrared radiation in the atmosphere

gross primary production
the amount of carbon fixed in photosynthesis by plants

ground ice
ice present within rock, sediments, or soil

groundwater recharge
process by which external water is added to the zone of saturation of an aquifer, either directly into a formation or indirectly by way of another formation

halocarbons
chemicals containing carbon and members of the halogen family

heat cascading
process integration aimed at effectively utilizing thermal energy at all temperature levels by successively using waste heat from higher temperature processes as heat sources for lower temperature ones; also applicable to cold sources at below-ambient temperatures, if reversed

heat content
the amount of heat per unit mass released upon complete combustion

heath
any of the various low-growing shrubby plants of open wastelands, usually growing on acidic, poorly drained soils

heat island
an area within an urban area characterized by ambient temperatures higher than those of the surrounding area because of the absorption of solar energy by materials like asphalt

heat pump
a device capable of extracting heat from a lower temperature source (e.g., the external environment) and releasing thermal energy to a higher temperature heat sink (e.g., an installation requiring heating); this temperature lift is achieved by using an internal fluid loop that undergoes changes in phase (evaporation and condensation) and operating pressure (expansion and compression)

herbaceous
flowering, non-woody plants

herbivore
an animal that feeds on plants

higher heating value
quantity of heat liberated by the complete combustion of a unit volume or weight of a fuel assuming that the produced water vapor is completely condensed and the heat is recovered; also known as gross calorific value

hydroperiod
the depth, frequency, duration, and season of wetland flooding

ice cap
a dome-shaped glacier covering a highland area (considerably smaller in extent than ice sheets)

ice jam
an accumulation of broken river or sea ice caught in a narrow channel

ice sheet
a mass of snow and ice of considerable thickness and large area greater than 50,000 km^2

ice shelf
a floating ice sheet of considerable thickness attached to a coast (usually of great horizontal extent with a level or gently undulating surface); often a seaward extension of ice sheets

icing
a sheet-like mass of layered ice formed by the freezing of water as it emerges from the ground or through fractures in river or lake ice

immunosuppression
reduced functioning of an individual's immune system

incidence
the number of cases of a disease commencing, or of persons falling ill, during a given period of time within a specified population

incinerator
a furnace or container for burning waste materials

income elasticity
the expected percentage change in the quantity demand for a good given a 1% change in income

industrial ecology
the set of relationships of a particular industry with its environment; often refers to the conscious planning of industrial processes so as to minimize their negative interference with the surrounding environment (e.g., by heat and materials cascading)

industrialization
the conversion of a society from one based on manual labor to one based on the application of mechanical devices

infiltration
flow of water through the soil surface into a porous medium

infrastructure
the basic installations and facilities upon which the operation and growth of a community depend, such as roads; schools; electric, gas, and water utilities; transportation and communications systems; and so on

inoculation
the introduction of a pathogen or antigen into a living organism to stimulate the production of antibodies

integrated resource planning
a system in which a utility considers all means of meeting the energy-service needs of its customers (on both the supply and demand sides) and to select the mix of actions that meets those needs at the least cost to the consumers, possibly including external costs like environmental degradation

isohyet
a line on a map or chart indicating equal rainfall

joule
unit of energy; 1 joule (J) is the work done when the point of application of a force of 1 newton ($1 N = 1 kg m/s^2$) is displaced through a distance of 1 m in the direction of the force

land use
the purpose an area of the Earth is put to (e.g., agriculture, forestry, urban dwellings, or transportation corridors) or its character (e.g., swamp, grassland, or desert)

lapse rate
the rate of temperature decrease with increase in altitude

leaching
the removal of soil elements or applied chemicals through percolation

legume
plants that through a symbiotic relationship with soil bacteria are able to fix nitrogen from the air (e.g., peas, beans, alfalfa, clovers)

lichen
symbiotic organisms consisting of an alga and fungus important to the weathering and breakdown of rocks

life-cycle cost
the cost of a good or service over its entire lifetime

lignite
brown coal; a low-grade coal having a heat content slightly higher than peat

low emissivity
a property of materials that hinders or blocks the transmission of a particular band of radiation (e.g., that in the infrared)

lower heating value
quantity of heat liberated by the complete combustion of a unit volume or weight of a fuel assuming that the produced water remains as a vapor and the heat of the vapor is not recovered; also known as net calorific value

macroeconomic
pertaining to a study of economics in terms of whole systems, especially with reference to general levels of output and income and to the interrelations among sectors of the economy

maglev
a mode of transport that uses magnetic force to suspend a vehicle above its supporting structure, thereby limiting or eliminating friction between the vehicle and the ground

malaria
endemic or epidemic parasitic disease caused by species of the genus *Plasmodium* (protozoa) and transmitted by mosquitoes of the genus *Auopheles*; produces high fever attacks and systemic disorders, and kills ~2 million people every year

market equilibrium
the point at which demand for goods and services equals the supply; often described in terms of the level of prices, determined in a competitive market, that "clears" the market

market penetration
the percentage of all its potential purchasers to which a good or service is sold per unit time

materials cascading
successive downgrading of a material's use into applications requiring lower quality

methanogenesis
the creation of methane from its constituent molecules

mitigation
an anthropogenic intervention to reduce the emissions or enhance the sinks of greenhouse gases

monsoon
the season of the southwest wind in India and adjacent areas that is characterized by very heavy rainfall

montane
the biogeographic zone made up of relatively moist, cool upland slopes below timberline and characterized by the presence of large evergreen trees as a dominant life form

moraine
an accumulation of Earth and stones carried and finally deposited by a glacier

morbidity
the rate of occurrence of disease or other health disorder within a population, taking account of the age-specific morbidity rates; health outcomes include, for example, chronic disease incidence or prevalence, rates of hospitalization, primary care consultations, disability-days (e.g., of lost work), and prevalence of symptoms

mortality
the rate of occurrence of death within a population within a specified time period; calculation of mortality takes account of age-specific death rates, and can thus yield measures of life expectancy and the extent of premature death

net ecosystem production
the net gain or loss of carbon from an ecosystem or region

net primary production
the increase in plant biomass or carbon of a unit of a landscape; gross primary production (all carbon fixed through photosynthesis) minus plant respiration equals net primary production

newton
the unit of force required to accelerate 1 kg of mass 1 m/s^2

nitrification
the oxidation of ammonium salts to nitrites and the further oxidation of nitrites to nitrates

NO$_x$
any of several oxides of nitrogen

non-tidal wetlands
areas of land not subject to tidal influences where the water table is at or near the surface for some defined period of time, leading to unique physiochemical and biological processes and conditions characteristic of water-logged systems

northern wetlands
wetlands in the boreal, subarctic, and arctic regions of the northern hemisphere

orography
the branch of physical geography that deals with mountains and mountain systems

pack ice
any area of sea, river, or lake ice other than fast ice

paleoecology
the branch of ecology concerned with identifying and interpreting the relationships of ancient plants and animals to their environment

pancake ice
new ice about 0.3 to 3-m in diameter, with raised rims about the circumference from striking other pieces

peat
unconsolidated soil material consisting largely of partially decomposed organic matter accumulated under conditions of excess moisture or other conditions that decrease decomposition rates

perfluorocarbons
organic chemicals containing only carbon and fluorine (e.g., carbon tetrafluoride and hexafluoroethylene)

permafrost
perennially frozen ground that occurs wherever the temperature remains below 0°C for several years

phenology
the study of natural phenomena that recur periodically (e.g., blooming, migrating) and their relation to climate and seasonal changes

photochemical smog
a mix of photochemical oxidant air pollutants produced by the reaction of sunlight with primary air pollutants, especially hydrocarbons

photoperiodic response
response to the lengths of alternating periods of light and dark as they affect the timing of development

photosynthate
the product of photosynthesis

photovoltaic
capable of producing a voltage when exposed to radiant energy, especially light

physiographic
of, relating to, or employing a description of nature or natural phenomena

phytophagous insects
insects that feed on plants

potential evapotranspiration
maximum quantity of water capable of being evaporated in a given climate from a continuous stretch of vegetation (i.e., includes evaporation from the soil and transpiration from the vegetation of a specified region in a given time interval, expressed as depth)

potential production
estimated production of a crop under conditions when nutrients and water are available at optimum levels for plant growth and development; other conditions such as daylength, temperature, soil characteristics, etc., determined by site characteristics

prevalence
the proportion of persons within a population who are currently affected by a particular disease

price elasticity
the responsiveness of demand to the cost for a good or service; specifically, the percentage change in the quantity consumed of a good or service for a 1% change in the price for that good or service

primary energy
the energy that is embodied in resources as they exist in nature (e.g., coal, crude oil, natural gas, uranium, or sunlight); the energy that has not undergone any sort of conversion

producer surplus
returns beyond the cost of production that provide compensation for owners of skills or assets that are scarce (e.g., agriculturally productive land)

radiative forcing
a change in average net radiation at the top of the troposphere resulting from a change in either solar or infrared radiation due to a change in atmospheric greenhouse gases concentrations; perturbance in the balance between incoming solar radiation and outgoing infrared radiation

rangeland
unimproved grasslands, shrublands, savannas, and tundra

redox potential
the relative capacity of an atom or compound to donate or accept electrons, expressed in volts; higher numbers denote more powerful oxidizers

reference scenario
the set of predicted levels of economic growth, energy production and consumption, and greenhouse gas emissions (and underlying assumptions) with which other scenarios examining various policy options are compared

reforestation
forest stands established artificially on lands that have supported forests within the last 50 years

regenerative braking
a process wherein the motion of a vehicle is slowed or stopped, and the energy of motion is captured and stored for future reuse

reserves
those occurrences of energy sources or minerals that are identified and measured as economically and technically recoverable with current technologies and prices

resources
those occurrences of energy sources or minerals with less certain geological and/or economic/technical recoverability characteristics, but that are considered to become potentially recoverable with foreseeable technological and economic development

respiration
the metabolic process by which organisms meet their internal energy needs and release CO_2

rotary kiln
a rotating cylinder heated to dry or chemically transform its contents

runoff
water (from precipitation or irrigation) that does not evaporate or seep into the soil but flows into rivers, streams, or lakes, and may carry sediment

ruderal
pertaining to or inhabiting highly disturbed sites; weedy

salinization
the accumulation of salts in soils

saltation
the transportation of particles by currents of water or wind in such a manner that they move along in a series of short intermittent leaps

seasonal climate
a climate characterized by both warm and cold periods through the year

second-law efficiency
see exergy efficiency

semi-arid lands
ecosystems that have >250 mm precipitation per year, but are not highly productive; usually classified as rangelands

sensitivity
the degree to which a system will respond to a change in climatic conditions (e.g., the extent of change in ecosystem composition, structure and functioning, including net primary productivity, resulting from a given change in temperature or precipitation)

sequestration
to separate, isolate or withdraw; usually refers to removal of CO_2 from atmosphere by plants or by technological measures

set-aside program
a generic term covering a variety of government programs—primarily in the U.S., Canada, and Europe that require farmers to remove a portion of their acreage from production for purposes of controlling yield, soil conservation, etc.

shelterbelt
a natural or artificial forest maintained for protection against wind or snow

silt
unconsolidated or loose sedimentary material whose constituent rock particles are finer than grains of sand and larger than clay particles

slip faces
the lee side of a dune where the slope approximates the angle of rest of loose sand (usually ~33°)

snowpacks
a seasonal accumulation of slow-melting snow

soil erosion
the process of removal and transport of the soil by water and/or wind

southern oscillation
a large-scale atmospheric and hydrospheric fluctuation centered in the equatorial Pacific Ocean; exhibits a nearly annual pressure anomaly, alternatively high over the Indian Ocean and high over the South Pacific; its period is slightly variable, averaging 2.33 years; the variation in pressure is accompanied by variations in wind strengths, ocean currents, sea- surface temperatures, and precipitation in the surrounding areas

sphagnum moss
a genus of moss that covers large areas of wetlands in the northern hemisphere; sphagnum debris is usually a major constituent of the peat in these areas

stakeholders
the entities that will be affected by a particular action or policy

stomata
the minute openings in the epidermis of leaves through which gases interchange between the atmosphere and the intercellular spaces within leaves

succession
transition in the composition of plant communities following disturbance

superconduction
the flow of electric current without resistance in certain metals, alloys, and ceramics at temperatures near absolute zero degrees Kelvin, and in some cases at temperatures hundreds of degrees above absolute zero (high-temperature superconduction)

susceptibility
probability for an individual or population of being affected by an external factor

sustainable
a term used to characterize human action that can be undertaken in such a manner as to not adversely affect environmental conditions (e.g., soil, water quality, climate) that are necessary to support those same activities in the future

symbionts
organisms that live together to mutual benefit [e.g., nitrogen-fixing bacteria that live with a plant (legume)]

synoptic
relating to or displaying atmospheric and weather conditions as they exist simultaneously over a broad area

taiga
coniferous forests of northern North America and Eurasia

talik
a layer of unfrozen ground occurring between permafrost and the active layer

technological calorie
the amount of heat needed to raise the temperature of 1 g of water 1°C at 15°C

thermodynamic free-energy limit
the minimum possible amount of energy required for producing a substance from its components, corresponding to the energy required to break down and/or create chemical bonds between molecules; the stronger the bond, the more energy is required to synthesize or break down a substance, which limits the possibility of lowering energy consumption by industrial process energy-efficiency improvements

thermohaline circulation
circulation driven by density gradients, which are controlled by temperature and salinity

thermokarst
irregular, hummocky topography in frozen ground caused by melting of ice

timberline
the upper limit of tree growth in mountains or high latitudes

transpiration
the emission of water vapor from the surfaces of leaves or other plant parts

tsunami
a large tidal wave produced by a submarine earthquake, landslide, or volcanic eruption

unexploited energy
energy (usually thermal, at near-environmental temperature) that is discarded in spite of its potential for use; often existing in large amounts, but with a low heat value/work potential

upwelling
transport of deeper water to the surface, usually caused by horizontal movements of surface water

urbanization
the conversion of land from a natural state or managed natural state (such as agriculture) to cities

useful energy
the energy drawn by consumers such as heat from their own appliances after conversion of final energy (e.g., mechanical energy at the crankshaft of an automobile engine or an industrial electric motor; the heat of a household radiator or an industrial boiler, or the luminosity of a light bulb)

usufruct
the legal right of using and enjoying the fruits or profits of something belonging to another

vector
an organism, such as an insect, that transmits a pathogen from one host to another

vulnerability
the extent to which climate change may damage or harm a system; it depends not only on a system's sensitivity, but also on its ability to adapt to new climatic conditions

wadi
a water course that is dry except during the rainy season; the stream or flush that runs through it

waste heat
excess heat from industrial or other processes that is either discarded or used in other processes requiring lower temperature heat sources

water use efficiency
carbon gain in photosynthesis per unit water lost in evapotranspiration; can be expressed on a short-term basis as the ratio of photosynthetic carbon gain per unit transpirational water loss, or on a seasonal basis as the ratio of net primary production or agricultural yield to the amount of available water

winter dormancy
period without biochemical activity in plant tissues

SCW	"Slowly Changing World" Scenario
SDSIDS	Global Conference on the Sustainable Development of Small Island Developing States
SERI	Solar Energy Research Institute
SFWMD	South Florida Water Management District
SI	International System of Units
SMR	Small- and Medium-Size Reactors
SNL	Sandia National Laboratories
SO	Southern Oscillation
SOC	Soil Organic Carbon
SOFC	Solid Oxide Fuel Cell
SPEFC	Solid Polymer Electrolyte Fuel Cell
SPFC	Solid Polymer Fuel Cell
SRWC	Short Rotation Woody Crops
SST	Sea-Surface Temperature
STIG	Steam Injected Gas Turbine
TERI	Tata Energy Research Institute
TES	Terrestrial Environment System
TRW	Thompson, Ramo, and Wooldridge
TSU	Technical Support Unit
TVM	Terrestrial Vegetation Model
UBC	University of British Columbia
UCAR	Universtiy Corporation for Atmospheric Research
UKMO	United Kingdom Meteorological Office
UKMOH	High-Resolution UKMO Model
UN	United Nations
UNCED	UN Conference on Environment and Development
UNCHS	UN Center for Human Settlements
UNCNRSEED	UN Committee on New and Renewable Sources of Energy and on Energy for Development
UNCTAD	UN Conference on Trade and Development

UNDP	UN Development Programme
UNEP	UN Environment Programme
UNESCO	UN Educational, Scientific and Cultural Organization
UNIDO	UN Industrial Development Organization
UNFPA	UN Population Fund
UNSCEAR	UN Scientific Committee on the Effects of Atomic Radiation
UNSEGED	UN Solar Energy Group on Environment and Development
USDA	U.S. Department of Agriculture
USDC	U.S. Department of Commerce
USEPA	U.S. Environmental Protection Agency
USGCRP	U.S. Global Change Research Program
USGS	U.S. Geological Survey
USLE	Universal Soil Loss Equation
UVR	Ultraviolet Radiation
VAV	Variable Air Volume
VBD	Vector-Borne Disease
VOC	Volatile Organic Compound
WCC	World Coast Conference
WCRP	World Climate Research Programme
WEC	World Energy Council
WEC	Weigel Engineering Company
WEE	Wind Erosion Equation
WGI	Working Group I
WGMS	World Glacier Monitoring Service
WHO	World Health Organization
WMO	World Meteorological Organization
WRI	World Resources Institute
WRR	Wetenschappelijke Raad voor het Regeringsbeleid (The Netherlands Scientific Council for Government Policy)
WUE	Water-Use Efficiency
WWF	World Wide Fund for Nature

CHEMICAL SYMBOLS USED IN THE WORKING GROUP II VOLUME

a-Si	Amorphous Silicon
C	Carbon
CF_4	Tetrafluoromethane, CFC-14
C_2F_6	Hexafluoroethane, CFC-116
CFC	Chlorofluorocarbon
CH_4	Methane
CH_3OH	Methanol
CO	Carbon Monoxide
CO_2	Carbon Dioxide
CaO	Calcium Oxide
$CaCO_3$	Calcium Carbonate
CdTe	Cadmium Telluride
$CuInSe_2$	Copper Indium Selenide
EthOH	Ethanol
H	Atomic Hydrogen
H_2	Molecular Hydrogen
HCFC	Hydrochlorofluorocarbon

HCO_3	Bicarbonate Ion
HFC	Hydrofluorocarbon
K	Potassium
MeOH	Methanol
N	Atomic Nitrogen
N_2	Molecular Nitrogen
NH_3	Ammonia
N_2O	Nitrous Oxide
NO	Nitric Oxide
NO_X	Nitrogen Oxide
O	Atomic Oxygen
O_2	Molecular Oxygen
O_3	Ozone
Pu	Plutonium
SO_X	Sulfur Oxide
SO_2	Sulfur Dioxide

Appendix D

UNITS USED THROUGHOUT THE WORKING GROUP II VOLUME

SI (Systéme Internationale) Units

Physical Quantity	Name of Unit	Symbol
length	meter	m
mass	kilogram	kg
time	second	s
thermodynamic temperature	kelvin	K
amount of substance	mole	mol

Fraction	Prefix	Symbol	Multiple	Prefix	Symbol
10^{-1}	deci	d	10	deca	da
10^{-2}	centi	c	10^2	hecto	h
10^{-3}	milli	m	10^3	kilo	k
10^{-6}	micro	μ	10^6	mega	M
10^{-9}	nano	n	10^9	giga	G
10^{-12}	pico	p	10^{12}	tera	T
10^{-15}	femto	f	10^{15}	peta	P
10^{-18}	atto	a	10^{18}	exa	E

Special Names and Symbols for Certain SI-Derived Units

Physical Quantity	Name of SI Unit	Symbol for SI Unit	Definition of Unit
force	newton	N	$kg\ m\ s^{-2}$
pressure	pascal	Pa	$kg\ m^{-1}\ s^{-2}\ (= Nm^{-2})$
energy	joule	J	$kg\ m^2\ s^{-2}$
power	watt	W	$kg\ m^2\ s^{-3}\ (= Js^{-1})$
frequency	hertz	Hz	s^{-1} (cycle per second)

Decimal Fractions and Multiples of SI Units Having Special Names

Physical Quantity	Name of Unit	Symbol for Unit	Definition of Unit
length	ångstrom	Å	$10^{-10}\ m = 10^{-8}cm$
length	micrometer	μm	$10^{-6}m = \mu m$
area	hectare	ha	$10^4\ m^2$
force	dyne	dyn	$10^{-5}\ N$
pressure	bar	bar	$10^5\ N\ m^{-2}$
pressure	millibar	mb	$1hPa$
weight	ton	t	$10^3\ kg$

Non-SI Units

°C	degrees Celsius (0°C = ~273K); Temperature differences are also given in °C rather than the more correct form of "Celsius degrees"
Btu	British Thermal Unit
kWh	kilowatt-hour
MW$_e$	megawatts of electricity
ppmv	parts per million (10^6) by volume
ppbv	parts per billion (10^9) by volume
pptv	parts per trillion (10^{12}) by volume
tce	tons of coal equivalent
toe	tons of oil equivalent
tWh	terawatt-hour

Appendix E

LIST OF MAJOR IPCC REPORTS (IN ENGLISH UNLESS OTHERWISE STATED)

Climate Change—The IPCC Scientific Assessment
The 1990 Report of the IPCC Scientific Assessment Working Group (*also in Chinese, French, Russian, and Spanish*)

Climate Change—The IPCC Impacts Assessment
The 1990 Report of the IPCC Impacts Assessment Working Group (*also in Chinese, French, Russian, and Spanish*)

Climate Change—The IPCC Response Strategies
The 1990 Report of the IPCC Response Strategies Working Group (*also in Chinese, French, Russian, and Spanish*)

Emissions Scenarios
Prepared for the IPCC Response Strategies Working Group, 1990

Assessment of the Vulnerability of Coastal Areas to Sea Level Rise–A Common Methodology
1991 (*also in Arabic and French*)

Climate Change 1992—The Supplementary Report to the IPCC Scientific Assessment
The 1992 Report of the IPCC Scientific Assessment Working Group

Climate Change 1992—The Supplementary Report to the IPCC Impacts Assessment
The 1992 Report of the IPCC Impacts Assessment Working Group

Climate Change: The IPCC 1990 and 1992 Assessments
IPCC First Assessment Report Overview and Policymaker Summaries, and 1992 IPCC Supplement

Global Climate Change and the Rising Challenge of the Sea
Coastal Zone Management Subgroup of the IPCC Response Strategies Working Group, 1992

Report of the IPCC Country Studies Workshop
1992

Preliminary Guidelines for Assessing Impacts of Climate Change
1992

IPCC Guidelines for National Greenhouse Gas Inventories
Three volumes, 1994 (*also in French, Russian, and Spanish*)

IPCC Technical Guidelines for Assessing Climate Change Impacts and Adaptations
1995 (*also in Arabic, Chinese, French, Russian, and Spanish*)

Climate Change 1994—Radiative Forcing of Climate Change and an Evaluation of the IPCC IS92 Emission Scenarios
1995

ENQUIRIES: IPCC Secretariat, c/o World Meteorological Organization, P.O. Box 2300, CH1211, Geneva 2, Switzerland.
